Hypervitaminosis A has seldom been observed in man. It has been reported in patients treated with large doses of this vitamin and in persons who had eaten great quantities of polar-bear liver. Animals fed on concentrated liver oils have anorexia, loss of hair, weakness or paralysis, multiple fractures, hemorrhages, emaciation, and fatty degeneration of the liver (Takahashi, Collazo, *et al.*).

Sources of Vitamin A

Vitamin A is produced in the organism by the conversion of provitamins found in vegetables. These precursors are plant pigments called "carotenoids," which are found in green plants or in animals that have eaten these plants. In the green or yellow parts of plants that are vitamin precursors, over ten carotenoids have so far been found. The most significant of these are α, β, and γ (especially β) carotene. These pigments are absorbed in the intestine and are converted into vitamin A. They are stored mainly in the liver together with carotenes. Vitamin A is excreted into milk. Milk and butter are important sources of this vitamin in the human diet; therefore when butter is replaced by margarine, the latter should be reinforced by the addition of vitamin A. Cod-liver oil contains 600 IU/gm.; other fish-liver oils have even larger quantities, *e.g.*, shark 30,000 and halibut 60,000. There is no vitamin or provitamin A in vegetable oils, except in coconut oil and in corn oil. Cereals, with the exception of yellow corn, have little or no vitamin A. There is none in potatoes, but it is found in sweet potatoes. Green and yellow vegetables, such as lettuce, water cress, runner beans, peas, and carrots; fruits such as melons and bananas; and alfalfa contain carotenes that are vitamin A precursors. The vitamin A content of certain foods is given in Table 69.

* Parentheses, imputed values.

Animals cannot synthesize the precursors of vitamin A, but they can convert part of some of the carotenes into vitamin A. Thus avitaminosis A can be prevented in the rat by daily administration of either 0.05 to 0.1 mg. of vitamin A or 3 to 5 mg. of carotene.

Absorption of vitamin A in the intestine is deficient when there is no bile (*e.g.*, cases of obstruction of the common bile duct); in certain intestinal infections that damage the intestinal mucosa; and when mineral oil is taken.

In certain cases of myxedema, carotenoids increase in the blood plasma and skin, which take on a yellow tinge. Conversion of carotenoids into vitamin A proceeds at a slow rate in these patients.

Assay. The concentration of vitamin A in foods can be determined by physical, chemical, and biological methods. The latter consist in measuring the amounts of food needed to prevent or cure avitaminosis A in the white rat. The international unit (IU), as defined in 1949, is the activity of 0.344 μg of crystallized vitamin A acetate, equivalent to 0.3 μg of pure vitamin A (alcohol). The unit of provitamin A is the activity of 0.6 μg of carotene. The two units are equivalent.

Requirement. The National Research Council recommends a daily allowance of 5,000 IU (75 IU per kg.) for an adult man or woman. Pregnant and nursing mothers and adolescents should be given a supplementary amount.

Physical and Chemical Properties

Vitamin A was first obtained in pure form by Karrer in 1931 and synthesized by Kuhn and Morris in 1937.

Vitamin A

Vitamin A is soluble in fat and in organic solvents. It is easily oxidized, but it is resistant to heat and can be distilled in the absence of oxygen. It is liquid at 8°C. It shows an absorption band between 325 and 328 mμ. It gives a vivid blue color with antimony trichloride, with an absorption band between 572 and 606 mμ.

THIAMINE (VITAMIN B_1)

Thiamine, also known as the antineuritic or antiberiberi vitamin, or aneurin, is found in and produced by many yeasts, bacteria, and plants. It is an indispensable dietary factor for man and other mammals, with the exception of ruminants, and for birds. In the ruminants it is synthesized by bacteria in the digestive tract. Thiamine is essential for the growth of certain fungi and bacteria.

Avitaminosis and Hypovitaminosis

Thiamine deficiency causes many disturbances.

Nervous symptoms. There are multiple degenerative lesions in the nerves (neuritis, polyneuritis). At first there is muscular weakness, especially of the quadriceps, so that the subject has difficulty in standing up. There are also sensory disturbances, such as loss of vibratory sensation when a tuning fork is placed over the skin near a bone (tibia, malleolus, etc.). The calf muscles are sensitive to pressure and there is hyperesthesia in the feet. The ankle and knee reflexes first diminish and then disappear completely. If the deficiency is prolonged, these disturbances become permanent and the patient becomes paralyzed (Fig. 222). In acute cases there are degenerative lesions not only in peripheral nerves but also in the nerve cells and centers, *e.g.*, in pigeons there are violent convulsions and the head is thrown back (opisthotonos) or twisted; all the disorders disappear rapidly after the injection of thiamine (Fig. 223).

Thiamine plays an important part in the chemical processes of the nerve (von Muralt). It is set free when the nerve is stimulated, and it sensitizes the nerve to the effects of acetylcholine.

Cardiac symptoms. There are cardiac insufficiency with dilatation of the heart, tachycardia in man and dogs and bradycardia in rats and pigeons, and arterial hypotension with venous hypertension. The deflections of the electrocardiogram are of small amplitude and frequently the T wave is inverted (Fig. 224). There is accumulation of fluid between the cardiac fibers (edema) and vacuolization of the cardiac fibers and nerve cells in the myocardium. There are also degenerative focal lesions.[1] Intracellular and extracellular edema causes the weight of the heart to increase.
FIG. 222. Polyneuritis due to deficiency of vitamin B_1 (thiamine). Nervous form of beriberi. Muscular atrophy and impotence.

These cardiac disturbances do not respond, or respond feebly, to cardiotonic drugs if thiamine is not given simultaneously.

Digestive symptoms. Intense anorexia (loss of appetite) is usually observed. The patients do not eat enough, and inanition may occur. There is gastric achylia, and the tone of the stomach diminishes. Spasms or loss of tone are observed in the intestine.

Edema. In man there is frequently accumulation of tissue fluid in the legs, and serous effusion. The blood volume is usually decreased.

Blood and urine. The blood concentration of thiamine is low, and its excretion in the urine diminishes.

Other disturbances. Growth ceases in animals, there is considerable loss of weight owing to the lack of appetite, and the animals die emaciated after having suffered from convulsions and paralysis. Carbohydrate metabolism is disturbed; there is a characteristic increase in pyruvic and lactic acid, especially after the administration of glucose. In advanced stages, hyperglycemia and a decrease in liver glycogen may be observed, and injected glucose is not completely oxidized.

[1] SOLDATI, L. DE, "Trastornos Circulatorios de la Avitaminosis B_1," El Ateneo, Buenos Aires, 1940.

Incidence of avitaminosis B_1. Thiamine deficiency is widespread and there are millions of cases in the tropics, especially in Japan, the Philippines, India, and tropical America. The disease is called "beriberi" or "shoshin" in the East. It presents several clinical forms: (*a*) the "dry" type, with emaciation, polyneuritis, and nervous disturbances predominating; (*b*) the "wet" type, with edemas and serous effusions; (*c*) the acute type, with severe cardiac symptoms, which is rapidly fatal; (*d*) the mixed type, in which complex symptoms are observed; (*e*) the encephalopathic type.
FIG. 223. Pigeons with avian polyneuritis due to deficiency of vitamin B_1 (thiamine). Opisthotonus, paralysis, and convulsions (above) disappear when thiamine is injected, and the animal has completely recovered (below) 3 hr. after the injection.

Recent experiments in man have contributed important knowledge on the initial signs and symptoms[1] of hypovitaminosis B_1 and on its

[1] WILLIAMS, R. D., *et al.*, *Arch. Int. Med.*, **66**, 785, 1940; **69**, 721, 1942; **71**, 38, 1943.

hidden forms. When only 0.10 mg. thiamine is given daily for every 1000 kg.-cal. in the diet, there are loss of appetite or nausea, weakness, tiredness, irritability, neurasthenia, precordial pain or oppression, cutaneous or muscular hyperesthesia, or hyperacousia (auditory hypersensitiveness), muscular cramps, dyspnea on exercise, insomnia, palpitations, constipation, mental torpor, loss of manual ability, and finally polyneuritis. When 0.22 mg. per 1000 kg.-cal. is allowed, in some cases there are mental and physical disturbances, but not polyneuritis. It is advisable that the diet should contain twice this amount of thiamine.

Secondary hypovitaminosis. Polyneuritis may occur in alcoholics because of deficient absorption of thiamine by the intestine. In certain gastrointestinal disorders and sometimes in pregnancy, polyneuritis is provoked by this mechanism.

SOURCES OF VITAMIN B_1

Thiamine is found in the germ and pericarp (bran) of cereals. Beriberi became prevalent in the East when the consumption of polished rice, deprived of its pericarp by milling, became general. Brewer's yeast contains large quantities of thiamine, but when it is fresh it does not always give it up easily; therefore it should be hydrolyzed or dried. Thiamine is also found in peas, beans, the leaves of green vegetables, and the following animal tissues: liver, kidney, heart, muscle, brain, and egg yolk. Milk does not contain much thiamine, and the concentration varies with the diet of the lactating female. Certain bacteria in the rumen of ruminants and the large intestine of rats and infants synthesize thiamine, which is excreted in the feces. This fact explains how coprophagia (ingestion of feces) can improve the condition or cure avitaminotic rats. Only small amounts of thiamine are stored in the body. Most of it is obtained from food or bacterial synthesis in the intestine.

FIG. 224. Cardiac dilatation due to deficiency of vitamin B_1 (thiamine). Inversion of T wave in lead IV of the electrocardiogram (left). Decrease in cardiac area and normalization of the ECG after 1 month's treatment with thiamine (right).

Assay. Thiamine can be assayed by physical, chemical, and biological methods. The most commonly used chemical method is based on the oxidation of thiamine to thiochrome; this substance gives a blue

fluorescence which can be estimated in ultraviolet light. There are several biological methods: (*a*) bacterial growth is observed in species that require thiamine for their development; (*b*) avitaminosis is provoked in rats, and the effect of the substance assayed on convulsions and paralysis or on bradycardia is observed; (*c*) the unknown substance is used for treatment of avitaminosis in pigeons.

The international unit (IU) is equivalent to the activity of 3 μg crystallized thiamine.

Requirement. The National Research Council advises an allowance of 1.5 to 2.3 mg. of thiamine daily for every adult. During the second half of pregnancy and during lactation, the maximum amount should be given. The quantity of thiamine needed varies with the diet. The optimum lies between 0.5 and 1 mg. per 1,000 kg.-cal. (not less than 0.33 mg., according to Williams). High-carbohydrate diets require more than low-carbohydrate diets of the same caloric value. The requirement increases when the metabolic rate rises, as in fever and hyperthyroidism and in pregnancy and lactation. In cases of avitaminosis B_1, 25 to 50 mg. daily should be given. These large doses are not harmful because of the low toxicity of thiamine; doses of even 500 mg. have been given without ill effects. When there is a disturbance in the intestinal absorption of vitamin B_1 (alcoholic neuritis) or it is urgent to remedy the deficiency (delirium tremens), thiamine should be injected intravenously. During the Second World War 2 mg. per lb. was added to white wheat flour, in order to compensate for possible deficiencies due to wartime dietary restrictions.

Physical and Chemical Properties

Takaki eliminated beriberi from the Japanese navy by changing the diet in 1884. A few years later Eijkman (1893–1897) observed that birds fed on polished rice suffered from polyneuritis, which could be cured by feeding them rice polishings. A crystalline substance of high antineuritic potency was obtained from rice polishings by Funk (1911). Thiamine was crystallized by Jansen and Donath in 1926, and Williams prepared it by synthesis in 1936. It is now available in large quantities at low cost.

It is formed by the union of a pyrimidine nucleus and a thiazole nucleus; it also has an amine. The name "thiamine" was suggested by its structural formula.

Diphosphothiamine
(Co-carboxylase)

Oxidation of α-Keto acids (pyruvic and α-ketoglutaric) in animal tissues requires a coenzyme, lipothiamide pyrophosphate, which is a combination of diphosphothiamine and lipoic acid.

Thiamine is soluble in water, in 70 per cent alcohol, and in acetic acid; it is insoluble in organic solvents. It resists dry heat but is destroyed by heat in the presence of water. It is only partially destroyed by boiling for a short time, but at 120°C. it disintegrates rapidly, especially in an alkaline solution, and more slowly in an acid medium. It is easily adsorbed by fuller's earth.

Mechanism of its Effect

Thiamine is an important factor in carbohydrate metabolism. Diphosphothiamine acts as a coenzyme of carboxylase in the decarboxylation of pyruvic acid in yeast.

$$\underset{\text{Pyruvic acid}}{CH_3{\cdot}CO{\cdot}COOH} \rightarrow \underset{\text{Acetaldehyde}}{CH_3{\cdot}CHO} + CO_2$$
When the diet is deficient in thiamine, pyruvic acid accumulates in the blood, and this accumulation inhibits the breakdown of lactic acid. Surviving brain slices taken from pigeons in avitaminosis B_1 have a low oxygen consumption, and pyruvic and lactic acids accumulate. The addition of thiamine increases oxygen consumption and formation of CO_2 and the utilization of pyruvic acid. Thiamine pyrophosphate (diphosphothiamine) acts as a coenzyme in the oxidation of pyruvic acid.

Pyruvic acid is carboxylated by animal and plant tissues, CO_2 is bound, and C_4 dicarboxylic acids are formed, which are metabolized following the tricarboxylic cycle (see Chap. 34).

Thiamine is apparently a necessary factor in the synthesis of fat from carbohydrate (McHenry). It is also a factor in water metabolism, since its deficiency causes edema: probably this effect is due to disturbances in carbohydrate metabolism.

Antivitamins. Thiaminase, an enzyme that destroys thiamine, has been found in the flesh of certain fishes. Certain substances with a chemical structure similar to thiamine (*e.g.*, pyrithiamine) interfere with he utilization of thiamine by replacing it in the enzyme systems of which it forms part. As these substances do not have the same effect as thiamine, the coenzyme is inactive and symptoms of thiamine deficiency are observed.

RIBOFLAVIN (VITAMIN B_2)

Riboflavin is synonymous with vitamin B_2 and lactoflavin.[1]

Avitaminosis and hypovitaminosis. Riboflavin deficiency in the rat causes cessation of growth, alopecia, and vascularization of the cornea. In the monkey, growth ceases and there are dermatitis and anemia. In man, ariboflavinosis is usually associated with deficiency of other vitamins in group B, especially with beriberi and pellagra; there are disturbances in the mouth, eyes, and skin.

Oral lesions. There is inflammation of the lips, which are of a bright red color and sometimes everted, especially the lower lip; frequently there is also reddening, or fissures, in the angles of the mouth (angular stomatitis). This condition is known as cheilosis (Greek χειλος, lip). There is also glossitis, *i.e.*, inflammation of the tongue, which is bright red or magenta, with flattened papillae.

Eye lesions. The eyes itch and smart. There are photophobia, pericorneal vasodilatation, and sometimes invasion of the cornea by blood vessels. In the more severe cases there is infiltration and opacity of the cornea (interstitial keratitis).

Cutaneous lesions. On an erythematous background there are scaling of the skin and accumulation of sebaceous secretion, especially in the nasolabial sulcus, in the alae nasi, around the eyelids, extending sometimes to the cheeks and forehead, and on the ears.

Sources and requirement. Riboflavin is one of the lyochromes, a division of the flavines, commonly found in the yellow parts of plant and animal tissues. It is also produced by certain bacteria and by brewer's yeast. It is found in milk, liver, kidney, heart, retina, and egg yolk, and in small quantities in muscles. Riboflavin exists in spinach, carrots, lettuce, peas, pears, bananas, peanuts, etc.

An adult man or woman needs from 2.2 to 3.3 mg. per day (0.6 to 0.7 mg. per 1000 kg.-cal.). The daily intake should not fall below 2 mg., and in pregnant women and adolescents it is advisable to increase it to 4 mg. In cases of ariboflavinosis, doses of 5 mg. should be administered three times per day over a long period. The elimination of riboflavin is sometimes greater than the amount ingested. This is apparently due to the production of riboflavin by intestinal bacteria.[1]

Physical and chemical properties. Kuhn *et al.* discovered the chemical nature of vitamin B_2 in 1933. It is a flavine, which can be free or bound to other substances; it has a yellow color (whence the name "flavine") and gives a green fluorescence in ultraviolet light. It has ribitol in its molecule (6-7-dimethyl-9 [*d-l'*-ribityl] isoalloxazine) and is therefore usually known as riboflavin.

[1] The term "vitamin B_2" was first used for concentrates containing several vitamins in the B group; later it was applied to riboflavin.

Riboflavin

Combined to phosphoric acid, it forms nucleotides: (*a*) a mononucleotide, riboflavin-5′-phosphoric acid; (*b*) a dinucleotide of riboflavin and adenosine. These nucleotides act as prosthetic groups of several oxidizing enzymes which form part of the mechanism of cell respiration. They are thus of considerable importance in carbohydrate and amino-acid metabolism, oxidation of xanthine, and other chemical processes of the tissue (see Chap. 34).

NICOTINIC ACID (NIACIN) AND NICOTINIC ACID AMIDE

Certain dietary deficiencies cause a disease known as pellagra in man and black tongue in dogs. These disturbances are cured by foods that contain the so-called pellagra-preventing (P-P) factor or antipellagra vitamin or by the administration of nicotinic acid (niacin) or nicotinic acid amide (niacinamide).

COOH, N — Nicotinic acid

$CO \cdot NH_2$, N — Nicotinamide
Pellagra is widespread in badly nourished communities of northern Italy, Rumania, parts of the southern United States, Africa, and South America, where the main, almost exclusive,

Source: Elvehjem, C. A., *J. A. M. A.*, **120,** 1388, 1942.

foodstuff consumed is corn. The incidence increases in the spring and summer. Pellagra was first described by Casal in 1735 and was the object of a careful study by Goldberger. The curative effect of nicotinic acid and nicotinic amide was demonstrated in dogs with black tongue by Elvehjem in 1937 and later applied to cases of pellagra in man by Spies and Fours.

Avitaminosis and hypovitaminosis. Deficiency of this vitamin is characterized by dermatitis, diarrhea, and dementia, severe forms leading to death. The most outstanding disturbances are

1. *Glossitis.* The sides and tip of the tongue are swollen and imprinted by the teeth. The tongue is scarlet, with congested and hypertrophied papillae in the first stages and later atrophy of the papillae. Sometimes there is ulceration of the tongue. Similar lesions are observed on the lips, the gums, and the buccopharyngeal mucosa.
2. *Digestive disturbances.* There are burning sensations in the mouth, esophagus, and stomach. There are also gastric achylia, nausea, vomiting, and severe diarrhea.
3. *Dermatitis.* There is itch, and the skin reddens. Later it becomes swollen and rough, and blisters and ulcers are formed. Eventually the skin becomes thick, scaly, and pigmented. These lesions are especially marked in the face, neck, back of the hands and feet, knees, elbows, axillae, and perineum.
4. *Mental and nervous disturbances.* There are mental confusion, loss of memory, depression, and sometimes violent outbursts, with hallucinations and ideas of persecution. Many of the patients become inmates of mental hospitals. There are also peripheral nerve disturbances, and in advanced cases rigidity and other abnormalities of movement.

Sources and requirement. Pellagra in man and black tongue in dogs can be prevented or cured by the ingestion of sufficient amounts of milk, meat, and brewer's yeast. Injection of nicotinic acid or nicotinic amide is followed by rapid and sometimes spectacular results; in 24 to 72 hr. most of the disturbances completely disappear. Tryptophane has a favorable effect, as it gives rise to a certain amount of niacin, but it cannot cure the disease.

Diets that produce black tongue are deficient in several factors (protein, vitamins A, B_1, B_2, calcium), and human pellagra is usually accompanied by deficiency in thiamine (polyneuritis) and ariboflavinosis (cheilosis). Therefore in the treatment of these cases not only must nicotinic acid be given, but also other dietary deficiencies should be corrected.

Pellagra is frequently due to a deficiency of nicotinic amide, but an antivitamin has been found in corn, which competes with nicotinic amide and increases the deficiency (Wooley).

There are cases of secondary pellagra in conditions in which there is a deficient diet or disturbances in absorption. This is frequently observed in alcoholism and sometimes in malaria and tuberculosis.

A normal adult needs from 15 to 25 mg. of nicotinic acid per day (Table 74). During the Second World War, to prevent deficiencies due to dietary restrictions, 30 to 50 mg. of nicotinic acid was added to every kilogram of white flour. Patients suffering from deficiency should be given 200 to 500 mg. per day.

Mechanism of action. Nicotinic amide forms part of the pyridine-nucleotides which act as dehydrogenases in the oxidation of carbohydrate, protein, etc. (see Chap. 34). These nucleotides are (*a*) diphosphopyridine-nucleotide (DPN), also known as coenzyme I or cozymase I, formed by adenine, two molecules of phosphoric acid, two molecules of ribose, and nicotinamide; (*b*) triphosphopyridine-nucleotide (TPN), also known as coenzyme II or cozymase II, which differs from DPN in having three instead of two molecules of phosphoric acid (see Chap. 34).

FOLIC ACID

This vitamin, also known as folacin, was first called "*Lactobacillus casei* factor" or "*Streptococcus lactis* factor" because it is necessary for growth of these and other bacteria. Its deficiency, if sufficiently marked and prolonged, is fatal in several species (guinea pig); growth ceases in chicks (vitamin B_c), and paralysis develops in turkeys. Anemia is provoked by folic-acid deficiency in several animals, and certain forms of anemia in the chick, rat, and monkey and in man (pellagra, sprue, pregnancy, etc.) are improved by folic acid. Some cases refractory to treatment with vitamin B_{12} respond to folic acid. In some cases of pernicious and other macrocytic anemias in man, folic-acid treatment causes the anemia to disappear, but nervous

disturbances due to degenerative lesions in the spinal cord are not modified (see Chap. 5).

Folic acid is found in the liver and kidneys, in eggs and milk, and in many seeds and leaves (hence its name).

Folic acid has been prepared by synthesis. It is also known as pteroylglutamic acid, and its component parts are pteridin, paraminobenzoic acid, and glutamic acid. It is similar to the yellow pigment in the wings of butterflies.

Folic acid is converted by the liver into folinic acid or citrovorum factor, or leucovorin, so called because it is necessary for growth of *Leuconostoc citrovorum*. This factor forms part of a coenzyme essential to formate (HCOOH) transfer. This process is an important step in the synthesis of purines and thymine, and therefore in that of nucleic acids. Formate carbon also appears in serine, choline, and methionine.

Certain substances chemically related to pteroylglutamic acid, *e.g.*, 4-aminopteroylglutamic acid (aminopterin) act as folic-acid antagonists, *i.e.*, they provoke symptoms of folic-acid deficiency which are reversed by large doses of folic acid, and more efficiently by folinic acid.

VITAMIN B_{12}

This vitamin is found in several foods, but it is not absorbed in the absence of Castle's intrinsic gastric factor. It is Castle's extrinsic factor (see Chap. 5). It was first obtained in 1948 from liver extracts, but is now prepared on a large scale from cultures of a mold, *Streptomyces griseus*. It forms red crystals which contain cobalt. Three of these vitamins have been separated: B_{12}a, which contains a cyanide group (cyanocobalamine); B_{12}b, which does not have this group (hydroxycobalamine); and B_{12}c (nitrocobalamine).

It not only has a potent antianemic activity (see Chap. 5) but also is a growth factor for the chick, rat, pig, etc., and for several bacteria, *e.g.*, *Lactobacillus lactis*. It has antithyroid and lipotropic effects. Vitamin B_{12} plays a part in protein anabolism, in the synthesis of purines and thymidine, and in transmethylation. Its activity is in some way related to that of folic acid.

OTHER VITAMINS IN GROUP B

At first it was thought that yeast contained a single vitamin, which was called "vitamin B," but gradually several different factors necessary for growth and normal metabolism in different animal species, yeasts, and bacteria were separated from the "B complex." The factor necessary for the growth of yeast was called "bios," but later this was found to be made up of inositol and biotin. The factors essential for bacterial growth can be inhibited by several other substances known as antibiotics (such as the sulfanilamides), which thus suppress the development and pathogenic effects of many bacteria. The following is a short list of vitamins that are active in different animals.

Vitamins B_3 to B_8. These are vitamins necessary for normal nutrition in different species. B_3 is mostly pantothenic acid, essential in pigeons. B_4 is necessary to rats and B_5 to pigeons. B_8 is adenylic acid.

Pyridoxine. Vitamin B_6 has been crystallized and identified as 2-methyl-3-hydroxy-4,5-dihydroxymethylpyridine. The aldehyde (pyridoxal) and amine (pyridoxamine) are also active. This vitamin is a growth factor for rats and for many bacteria. Pyridoxine deficiency in rats causes acrodynia (painful extremities) and dermatitis, which are cured by the administration of pyridoxine or one of its derivatives. In dogs and pigs there is also anemia. At one time it was mistakenly believed that vitamin B_6 was the antipellagra factor for man. It does not cure pellagra or beriberi, but improves the condition of the patients by rapidly diminishing the severity of certain symptoms, such as irritability, insomnia, abdominal pains, disturbances in movements, and ulcerations resistant to nicotinic amide, thiamine, and riboflavin. Pyridoxine has been found in human milk and urine, but deficiency is not easily provoked in man.[1] It is thought an adult needs 1.5 to 2 mg. daily.[2] Pyridoxal phosphate acts as a coenzyme of some amino-acid decarboxylases and transaminases, and is indispensable for the metabolism of tryptophan.

Biotin. Du Vigneaud crystallized and synthesized biotin in 1940.[3] It is necessary for the growth of certain bacteria, and it acts in several carboxylation and decarboxylation reactions. Rats fed on egg white have dermatitis and eventually die, unless they are given large doses of biotin, because a substance known as avidin, found in egg white, combines with biotin and suppresses its activity. In the dog and rat, biotin deficiency causes paralysis and death. Biotin has an antilipotropic effect; it produces fatty infiltration of the liver. It has been found in human

[1] Mueller, J. E., and R. W. Vilter, *J. Clin. Investigation*, **29**, 139, 1950.
[2] Williams, R. J., *J. A. M. A.*, **119**, 1, 1942.
[3] Du Vigneaud, V., *Science*, **96**, 454, 1942.

tissues and in blood, but its importance in human nutrition is not yet well understood. Biotin deficiency in man[1] causes paleness of the skin and mucosae (due to slight anemia), cutaneous desquamation, loss of appetite, tiredness, and muscular pains. An adult requires 0.15 mg. of biotin daily.

Inositol. Deficiency of this substance causes retardation in growth and loss of hair in rats. Sometimes only the hair around the eyes is lost, and the animals appear to be wearing spectacles. It is a lipotropic factor and prevents or cures the fatty liver provoked by biotin. Its importance in human nutrition is unknown; nevertheless Williams believes the diet of an adult should contain 1 gm. per day.

Para-aminobenzoic acid (PABA). This substance is necessary for the growth of several bacteria, probably because it is needed for the formation of folic acid and related substances. Sulfanilamides apparently compete with PABA, thus checking bacterial development. It has a preventive effect on certain rickettsias. PABA deficiency causes graying of the coat in black rats (achromotrichia), and the normal color is restored by treatment with PABA, but it does not restore it in human graying hair, as was believed at one time.

Pantothenic acid. This substance is found in nearly all animal tissues; hence its name. It has been obtained in pure form and was synthesized by Williams and his associates in 1940. It is a growth factor in certain bacteria, yeasts, and plants. Together with adenosine, thioethanol amine, and three phosphate groups it forms coenzyme A which acts in transacetylation processes in the formation of citric acid, acetylcholine, etc. Its deficiency causes dermatitis and loss of color in the plumage of chicks, and graying of the coat in mice. In the rat there are retardation of growth, anemia, necrosis of the adrenals and other organs, and several other disturbances. Pantothenic acid has been found in the blood of man; it diminishes in thiamine and riboflavin deficiencies and in pellagra. Its importance in human nutrition is not yet well known, but Williams advises that 11 mg. per day for an adult man or woman should be allowed in a normal diet.

VITAMIN C (ASCORBIC ACID)

Vitamin C is also known as ascorbic acid or cevitamic acid; formerly it was called the antiscorbutic vitamin. It was found in the adrenal cortex by Szent-Györgyi (1928), who demonstrated its antiscorbutic activity in 1932. King and Waugh obtained it from lemon juice.

Avitaminosis and hypovitaminosis. Scurvy is due to ascorbic-acid deficiency; man and the guinea pig are the most sensitive species. Experimental scurvy can be easily provoked in guinea pigs fed on a scorbutic diet. After 3 weeks there are loss of weight, subperiosteal hemorrhages, lesions in bones and teeth, and digestive disturbances; the teeth can be extracted almost without effort. Eventually the animals die. In man scurvy has been observed in small children fed exclusively on milk sterilized by heating, and in adults fed for a long time on a restricted diet without fresh food. Scurvy was observed in sailors on long voyages in the time of sailing ships, in members of polar expeditions, and in the inhabitants of besieged towns. The most recent occurrences of scurvy on a wide scale were observed in the besieged city of Kut-el-Amara in Mesopotamia, during the First World War, and in the war in the Chaco between Paraguay and Bolivia. In the eighteenth century the English naval surgeon Jones demonstrated that lemon juice and fresh vegetables prevent or cure scurvy. The severity and duration of scurvy depend on the degree of the deficiency of ascorbic acid. In man the following are the main signs and symptoms of the disease:

Hemorrhage frequently occurs in the skin, under the periosteum, in the mucosae of the mouth, in the digestive tract, in the serous cavities including the joint spaces (painful joints), and in the muscles.

The gums are red, swollen, sensitive, and bleed easily. In chronic cases of scurvy they are thickened and retracted, leaving bare the roots of the teeth or forming a cleft between the tooth and the gum which, on becoming infected, gives rise to pyorrhea.

The teeth soon suffer severe damage. Periodontal tissues are softened and teeth fall out spontaneously (expulsive gingivitis) or when the slightest force is exerted on them. Dentine is porous and poorly calcified. The pulp is congested; the odontoblasts are irregularly distributed and show degenerative lesions. In chronic scurvy, osteodentine is formed in the pulp cavity.

The bones show varied lesions. In children the lower limbs are painful, there are subperiosteal hemorrhages, and endochondral ossification

[1] SYDENSTRICKER, V. P., *et al.*, *J. A. M. A.*, **118**, 1199, 1942.

ceases, because the organic matrix is not formed. After a time there is osteoporosis, and in chronic cases there are marked lesions in the bone and in the neighborhood of the joints. Fractures are not easily consolidated.

Anemia, general weakness, and digestive disturbances are observed in scurvy. Diarrhea and sometimes pneumonia precede death in severe cases.

The concentration of ascorbic acid in blood falls from the normal of 1.2 mg. per cent to 0.5 mg. per cent or less. Urinary excretion of ascorbic acid is also considerably below the normal of 30 to 50 mg. daily. If 300 mg. of ascorbic acid is given to a normal subject, 50 mg. or more is excreted in the urine in the course of the next day. Patients suffering from scurvy retain ascorbic acid, and the dose must be repeated for several days (saturation period) before urinary elimination of ascorbic acid takes place as in normal subjects. The examination of blood ascorbic acid, or its elimination, and testing of capillary resistance, are the methods usually employed to detect slight degrees of ascorbic-acid deficiency.

Sources and requirement. Ascorbic acid is found in large quantities in (*a*) citrus fruits, such as lemons, limes, oranges, and grapefruits (50 to 100 mg. per 100 gm.), and strawberries (50 to 70 mg. per 100 gm.); (*b*) fresh vegetables, such as cabbages (30 to 120 mg. per cent), green and red peppers (100 to 200 mg. per cent), tomatoes (10 to 40 mg. per cent), spinach (8 to 33 mg. per cent), fresh peas (40 to 50 mg. per cent), potatoes (8 to 25 mg. per cent); (*c*) seeds, after the onset of germination (not before). Cow's milk has little vitamin C; there is more in human milk. In boiled milk most of it is destroyed.

The optimum amount for an adult is 70 to 100 mg. per day (Table 74). It should never fall below 10 mg. per day, and it is better to allow more than 30 mg. for adults. Small children should be given 3 to 8 mg. per kg. of body weight per day, adolescents 6 to 7.5 mg. per kg., and adults 0.7 to 1.6 mg. per kg. In cases of scurvy, doses between 250 mg. and 1,000 mg. per day have been given without observing toxic symptoms.

Physical and chemical properties. In animal tissues L-ascorbic acid is found in equilibrium with dehydroascorbic acid. It has six carbon atoms, and its structural formula is as follows:

```
  OC——┐             OC——┐
  |   |             |   |
 HOC  |             OC  |
  ||  O             |   O
 HOC  |             OC  |
  |   |             |   |
  HC——┘             HC——┘
  |                 |
 HOCH              HOCH
  |                 |
 H2COH             H2COH
L-Ascorbic acid    Dehydroascorbic acid
```
Ascorbic acid is destroyed by prolonged boiling, owing to progressive oxidation. Copper catalyzes this oxidation. Drying destroys most of the ascorbic acid in foods, unless it is performed by special rapid processes that prevent oxidation. Ascorbic acid is preserved better in citrus fruits than in other natural foods.

Assay. Biological assay of ascorbic acid is performed by measuring the preventive or curative effect of the substance tested on experimental scurvy in the guinea pig, or by histological demonstration of the protective effect on the teeth (Höjer). Chemical methods are based on the reducing power of ascorbic acid, measured by the decoloration of methylene blue (Martini and Bonsignore), or more usually by Tillman's method, which measures the decoloration of 2-6-dichlorophenolindophenol. The latter method gives erroneously high results for leaves that contain tannin (tea, maté, etc.).

The international unit is the activity of 0.05 mg. L-ascorbic acid.

Mechanism of action. Ascorbic acid acts as a reducing agent *in vitro*. This fact led to the belief that it played a part in oxidation-reduction processes in the body, as a hydrogen carrier, but there is not yet sufficient proof of this. On the other hand there is satisfactory evidence that in ascorbic-acid deficiency intercellular substances are not normally formed. Collagen fibrils and the organic matrix of bone are not formed, and the capillary endothelium becomes fragile. Ascorbic acid exerts some protective effect against intoxication by lead, arsenic, benzene compounds, and certain bacterial toxins.

Antivitamin. Glucoascorbic acid inhibits the effect of ascorbic acid and produces scurvy not only in guinea pigs but also in the rat, an animal that does not require ascorbic acid in the diet because it can produce it by synthesis in its body.

Vitamin P and rutin. Vitamin P, or citrin, is found together with ascorbic acid in the juice of citrus fruits and other vegetable foods. Deficiency of this vitamin, according to Szent-Györgyi, is in part responsible for hemorrhages observed in scurvy, because it controls capillary permeability. The physiologic importance of this vitamin is still the subject of discussion. Substances with vitamin P activity are flavone derivates; the most active one used in therapeutics is rutin, obtained from rue (*Ruta graveolens*). Treatment with these substances diminishes capillary fragility.

FIG. 225. Radiograph of the wrist of a 14-month-old child suffering from rickets (left). After treatment with vitamin D the radiograph (right) showed normal calcification. (*Courtesy of Professor Garrahan.*)

THE D VITAMINS

The D vitamins are sterols which regulate certain processes of calcium and phosphorus metabolism, especially the formation of bone and teeth, and which prevent or cure rickets. There is not only one vitamin D; up to the present, 10 provitamins D are known, and four vitamins D have been obtained in pure form. The provitamin most frequently found in higher animals and man is 7-dehydrocholesterol, which is converted into vitamin D_3 by irradiation with ultraviolet rays. The predominant provitamin in yeasts and lower organisms is ergosterol, which is converted by ultraviolet irradiation into vitamin D_2 and is generally called calciferol, viosterol, or vigantol.[1] It is the one most frequently used in the treatment of rickets.

AVITAMINOSIS AND HYPOVITAMINOSIS

Deficiency of vitamins D causes rickets. Children from four months to two years of age are more susceptible than older children. It is a disease that involves the whole body; the most outstanding signs and symptoms are seen in the bones and teeth and in phosphorus metabolism. It is produced only during the period of growth. Slight forms do not disturb the general health of the child; the common idea of a rickety child, emaciated and with grossly deformed bones, is true only of severe rickets.

Bone lesions. There are marked disturbances in endochondral ossification, but the whole bone is involved. The epiphyseal cartilages are enlarged, especially those of the wrists, ankles, knee, elbow, and chondrocostal joints ("beading of the ribs" or "rachitic rosary") (Fig. 225). The fontanels remain open up to an advanced age. The bones of the head are soft and can be easily depressed (craniotabes); bosses are developed in

[1] Vitamin D_1 is not a chemical entity; it is a combination of vitamin D_2 and lumisterol. Vitamin D_4 is obtained by irradiation of 22-dehydroergosterol. Vitamin D_5 is prepared by irradiating 7-dehydrositosterol.

the frontal and parietal bones. The bones are poorly calcified, soft, and pliable. The natural curvatures of the long bones are exaggerated (knock-knees, bowlegs, curvature of the spine, etc.). In severe rickets, the thorax and pelvis are deformed.

Microscopic examination shows a disturbed and retarded endochondral and periosteal ossification. The epiphyseal cartilage grows to ten times or more its normal width. The cartilage cells are irregularly distributed, not in orderly columns as in normal bone. Osteoid, poorly calcified tissue is formed, and the bony trabeculae are weak and irregular. In severe rickets, calcium and phosphorus are reabsorbed from the bone, which is thus softened and becomes deformed by the stress and strain exerted by the body weight and muscles.

Dental lesions. In severe rickets, dentition is delayed, and there is defective implantation and malformation of the teeth. Calcification of enamel and dentine is deficient. The enamel surface is not smooth and bright, but irregular and pigmented, and in places the enamel is missing (hypoplasia). The pulp cavity is enlarged owing to poor development of dentine, which is not compact and homogeneous; it is incompletely calcified. Calcium is deposited in the organic matrix forming spheres (calcospherites), which do not coalesce as in normal teeth but leave spaces filled with organic substance between them (globular dentine) (Fig. 226).
Fig. 226. Bone and dental lesions in rickets. Above: normal dog, bones, jaw, and section of tooth showing homogeneous dentine. Below: dog with experimental rickets, bowlegs, poorly calcified bones, hypoplasia in teeth, globular dentine, and defective enamel. (*Mellanby, M., "Diet and the Teeth," Med. Res. Council. Spec. Report No. 191, London, 1934.*)

General symptoms. Muscular weakness and hypotonia are observed in cases of severe rickets. Frequently there is a certain degree of anemia.

Metabolic disturbances. There are significant changes in phosphorus metabolism. Inorganic phosphate in plasma falls from between 4 and 6 mg. per cent (the normal level in children) to 2 mg. per cent or less. Phosphorus is mobilized from the bones and its excretion is abnormally high.

Plasma calcium is usually normal (9.5 to 11 mg. per cent). In some cases it decreases slightly; if it falls below 7 mg. per cent tetany may be produced. Chemical analysis of rachitic bone shows that it contains less Ca and P than normal bone, and has a higher percentage of water and organic substances.

Incidence. Rickets occurs frequently in communities deficiently nourished and not much exposed to sunlight; it is especially prevalent in children kept indoors in dark rooms. Rickets is increased by the inclusion in the diet of substances such as beryllium, iron, aluminum, strontium, or an excess of calcium, which insolubilize phosphorus and decrease its absorption, or substances that insolubilize calcium, such as phytin and cereals that contain phytin.

Mild rickets is frequently ignored. It can be detected only by taking x-ray pictures of the wrist and by the determination of phosphate and phosphatase in plasma. A complete study of experimental rickets requires also a study of the calcium and phosphorus balance, chemical analysis of the bone, and histologic examination of the epiphyseal cartilages.

Sources and Requirement

The D vitamins are sterols found in the unsaponifiable fraction of many fats. There are considerable amounts in several fish-liver oils, in butterfat, in egg yolk, and in irradiated yeast. The most commonly used source is cod-liver oil, but other fish-liver oils have 100 to 400 times the concentration of vitamin D of cod-liver oil. The D vitamins in fish-liver oils are mixtures of vitamins D_2, D_3, and others less well known. Milk, cream, and butter are also sources of these vitamins. Egg yolk contains vitamin D, and the concentration increases if the eggs have been laid by hens fed with ergosterol or irradiated with ultraviolet rays.

Ultraviolet rays activate provitamins in the body or in foods and convert them into one of the D vitamins. Rachitic children have been treated successfully with ultraviolet irradiation (Huldschinsky), which converts a provitamin in the skin into vitamin D_3. Ultraviolet irradiation of milk, yeast, and other foodstuffs has been used to increase their antirachitic effect by converting the provitamins they contain into the corresponding D vitamin.

Sunlight is of great importance in the prevention of rickets, but it is much less efficacious than ultraviolet rays in the treatment of this disease.

The amount of vitamin D in a substance can be determined by spectrophotometric analysis, because D vitamins have characteristic absorption spectra. Biological methods consist in estimating the curative effect on rats with rickets provoked by feeding a diet lacking vitamin D. In this case the effect should be compared with that of a standard preparation, because of variations in the response of the animals.

The international unit is the activity of 0.025 μg of crystallized calciferol (1 gm. is the equivalent of 40,000,000 units).

Requirement. Children, women in the second half of pregnancy, and nursing mothers should be given 800 IU daily, and the amount should never fall below 400 IU. The requirement of adults is not well known. Artificially fed infants should always be given cod-liver oil or some other vitamin D preparation, and their milk should be reinforced by the addition of 400 IU irradiated ergosterol per quart or by irradiation with ultraviolet rays. Vitamin D has sometimes been added to flour (not less than 250 nor more than 1,000 IU per kilogram of flour).

Treatment of rickets. The administration of vitamin D in patients suffering from rickets diminishes the excretion of calcium and phosphorus, and increases blood phosphate. It causes the deposition of Ca and P in bone, and normal ossification is restored. In some cases with low blood calcium, the sudden increase in blood phosphorus may provoke tetany because the P: Ca ratio is altered.

Physical and Chemical Properties

The D vitamins are sterols with a cyclopentene-phenanthrene nucleus; the B ring is opened by ultraviolet irradiation. Vitamin D_2 or calciferol is derived from ergosterol, and vitamin D_3 is obtained by irradiation of 7-dehydrocholesterol.

Commercial preparations of vitamin D are usually solutions of calciferol. Irradiation of ergosterol with ultraviolet rays provokes the formation of a series of substances in the following order: ergosterol → lumisterol → tachysterol → calciferol (vitamin D_2) → toxiferol and other derivatives.[1] The D vitamins crystallize; they are colorless, are soluble in fats, and can be distilled in a vacuum. They have typical ultraviolet-light absorption spectra.

[1] Dihydrotachysterol (commercially known as AT 10) has little antirachitic activity, but it is useful in the treatment of tetany because it raises the blood calcium, an effect which is obtained by treatment with vitamin D only when very large doses are given (150,000 to 400,000 IU per day, according to Severinghaus).

Mechanism of action. Vitamins D have the following effects: (*a*) they increase Ca and P absorption in the intestine; (*b*) they control deposition of P and Ca in the bone, and so regulate normal ossification; (*c*) they decrease elimination of Ca and P by the intestine, especially in patients with rickets; (*d*) they control the blood phosphate level. Their action differs considerably from that of parathyroid hormone (see Chap. 55) which raises blood Ca, lowers blood phosphate, and mobilizes Ca in the bone, causing an increase in calcium excretion, a negative calcium balance, and decalcification of bone. Vitamin D in moderate (physiologic) amounts, on the contrary, increases absorption and retention of calcium; only very large doses cause a rise in blood calcium. Parathyroidectomy does not suppress the effects of vitamin D. On the other hand the parathyroids are hypertrophied in rickets.

Common formula of provitamins D
Common formula of vitamins D

Vitamin D_3

Toxicity. Pure vitamin D_2 has little toxicity. Cases of intoxication observed a few years ago were due to toxic impurities in vitamin D preparations. More recently toxic symptoms have been observed only after prolonged treatment with high doses (20,000 IU per day). Single doses of 600,000 and even 1,000,000 IU have been given to patients with rickets with excellent therapeutic effects and without provoking toxic symptoms. In tetany due to parathyroidectomy, an initial dose of 10 to 40 mg. (400,000 to 1,600,000 IU) and subsequent daily doses of 3 to 5 mg. (120,000 to 200,000 IU) have been administered without producing toxic effects, hypercalcemia, or renal disturbances. These doses maintain a normal blood-calcium level and cure tetany.

Experimental or clinical vitamin D intoxication, owing to prolonged administration of high doses, is accompanied by the following signs and symptoms: (*a*) loss of appetite, vomiting, and diarrhea; (*b*) hypercalcemia, in which plasma calcium may reach a level of 17 mg. per cent; (*c*) in the first stages, retention of Ca, which goes on to decalcification and excess elimination of Ca and P; (*d*) abnormal deposition of calcium in the kidney, stomach, arteries, etc. Severe cases have ended in death.

THE E VITAMINS

Vitamin E has also been called the antisterility vitamin. It is indispensable in several animal species, but there is no evidence that it is needed by man, and so far no human cases of vitamin E deficiency

have been reported. Evans and Bishop discovered it in 1922, and Evans and the Emersons obtained it in pure form in 1938. It has been prepared synthetically by Karrer and his associates (1938). Three substances are known to have vitamin E activity: α-tocopherol, β-tocopherol, and γ-tocopherol. The first of these is the most active of the three.

```
α-Tocopherol

Vitamin E deficiency causes sterility in the rat. In the male there is testicular atrophy with irreversible degeneration of the germinal epithelium. In the female the sexual cycle, ovulation, copulation, and fertilization are normal, but between the eighth and twentieth day of pregnancy the blood vessels of the placenta are occluded by proliferation of mesodermal cells, causing death and reabsorption of the fetuses. In prolonged deficiencies paralysis has been observed in young rats, muscular dystrophia in several species, and softening of the brain in chicks. All these disturbances are prevented or cured by the administration of vitamin E, which also prevents liver necrosis provoked by dietary deficiencies. Tocopherols act as antioxygens in the oxidation of body fats, and they protect vitamin A from oxidation. In man, treatment with vitamin E has been given in cases of repeated abortion and in muscular dystrophia. Remarkable results have been reported, but they have not been confirmed; more evidence is needed before arriving at definite conclusions. Vitamin E is found in wheat-germ oil, egg yolk, alfalfa, lettuce, and other foodstuffs. The international unit is the activity of 1 mg. of synthetic α-tocopherol acetate in oil.

VITAMIN K

Vitamin K deficiency causes a tendency to hemorrhage, which is due to a decrease in the formation of prothrombin. Dicumarol, salicylate, and some of the naphthoquinones prepared by synthesis inhibit the effect of vitamin K. This vitamin was considered in Chap. 8, when dealing with the coagulation of the blood.

CHOLINE

Choline is not strictly a vitamin, but its importance in nutrition is now well understood.[1] Deficiency in choline causes a series of disturbances: (*a*) fatty infiltration of the liver, which is followed by cirrhosis if the condition lasts for some time; (*b*) degenerative lesions and hemorrhagic necrosis in the cortex of the kidney (if the animal is young and recovers, later hypertension may develop); (*c*) delayed growth; (*d*) papillomatous epithelial hyperplasia of the stomach in the rat; (*e*) atrophy of the thymus; (*f*) diminished egg laying in hens; (*g*) in chicks and turkeys, a disturbance known as the slipped-tendon syndrome, or perosis; (*h*) diminished milk secretion. If the deficiency is sufficiently prolonged, the animals die.

All these disturbances are prevented or cured by the administration of choline or other substances which are methyl donors, *i.e.*, easily release methyl groups, such as betaine, methionine, etc. (see Chap. 42, Fat Metabolism). These substances have lipotrophic activity; they prevent or cure fatty infiltration of the liver. Choline increases the production of phosphatides in the liver and enters into the constitution of lecithin. Moreover, choline is the parent substance of acetylcholine, which is of great importance in the transmission of the nerve impulse (see Chap. 84). Several substances give up methyl groups to each other in a process known as transmethylation (see "Transmethylation," Chap. 42).

Fatty infiltration of the liver and cirrhosis of the liver have been treated with some success

[1] Best, C. H., and C. C. Lucas, Choline, *Vitamins & Hormones*, 1, 1, 1943.

by the administration of protein, choline, or methionine.

CHAPTER 50

The Normal Diet of Man

THE FEEDING OF human beings has improved considerably in the last few decades, but it is still far from satisfactory in many parts of the world. An adequate diet is of primary importance in the maintenance of the health and efficiency of a people. If the diet is not up to rational nutritional standards, there is an unfavorable effect on growth, vigor, and health; there is high infantile mortality, resistance to disease is lowered at all ages, and the life span is shortened.

Even in prosperous communities part of the population is inadequately fed, and in less prosperous areas there is frequently widespread and even serious malnutrition. The principles of nutrition are universally valid, but limitation of resources in some cases, and habit and taste everywhere, are major factors in the establishment of the diet in different countries.

The problems of nutrition are often extremely complicated because they involve a knowledge not only of chemistry, biology, medicine, and public health, but also of international economics and finance, agriculture, industry, commerce, and transport. They frequently require the aid of the psychologist, not to mention the basic importance of the culinary art. Bad cooking spoils not only the taste of food but also its nutritive value. This is not the place to discuss all these problems; here only the requirements of man in calories, protein, fat, carbohydrate, mineral substances, and vitamins in different circumstances will be considered. The diet should contain a sufficient amount of the substances needed to fulfill the requirement of energy and to permit optimum growth, maintenance of body temperature, regulation of nutrition, and good health.

Food supplies the organism with (*a*) energy for the fulfillment of normal functions; (*b*) substances for growth, maintenance, and repair of body tissues; (*c*) regulatory substances, which in minimal amounts are indispensable for normal nutrition. Food therefore has three functions: energetic, plastic, and regulatory. In practice the most frequently encountered deficiencies are those of vitamins, mineral substances, and protein (indispensable amino acids).

Foodstuffs have been divided into protective and energetic. Protective foods are those which contain relatively large amounts of vitamins, minerals, or proteins that are otherwise scarce or absent in the food most commonly consumed. Thus in the United States the diet consists in great part of white bread, meat, and sugar; protective foods, therefore, are milk and green vegetables. In certain districts of Asia the main constituents of the diet are rice, soya beans, and a few green vegetables; meat has great protective value. The most important protective foods are milk and milk products (butter, cream, cheese, etc.), eggs, glandular tissues (liver, kidney, etc.), green vegetables and fruit, fish, and meat (muscle).

Energy-providing foods yield a large quantity of calories, but they are usually deficient in vitamins, mineral substances, or proteins. Thus cereals provide calories and have some protective action, but this protective action is lost by milling, and the more highly milled flours have no protective effect. Sugar and starch provide only energy; they contain neither minerals nor vitamins. If nonprotective foods form a large part of the diet, the amount of protective foods may not be enough to provide the indispensable amino acids, vitamins, and minerals. Potatoes are among the best of energy-providing foods, because they contain protein, vitamins C and B, calcium, phosphorus, and iron.

THE DIETARY REQUIREMENT OF MAN

The human diet should fulfill the following conditions:

1. It should be digestible, agreeable, and well prepared. A diet that is excellent for a herbivorous animal may not be digested by man. The aspect and taste of food should awaken appetite, thus stimulating secretion and motor activity in the digestive tract. Good cooking not only increases the agreeableness of food but also facilitates digestive processes by softening or partial hydrolysis; it also destroys some parasites that may have contaminated the food. Cooking must not destroy vitamins or wash out mineral substances from the food.
2. It should provide a sufficient amount of energy to cover the caloric needs of the organism.
3. It should contain protein, fat, and carbohydrate; in particular, a sufficient quantity of the indispensable amino acids.
4. It should contain minerals in sufficient amounts, particularly calcium, phosphorus, iron, iodine, chloride, sodium, and potassium.
5. Vitamins should be included in sufficient quantities.
6. There should be an adequate balance between the different kinds of food to assure optimum nutrition.
7. The final object of nutrition is to fulfill all the needs of the organism so it may function harmoniously as an integrated unit.

Special needs created by climatic, geographic, or individual conditions should be taken into account. Age, sex, height, weight, pregnancy, lactation, nature of work performed, environmental temperature, and level of the BMR are some of the factors that modify dietary requirements. Moreover, a diet must be balanced; the relative need of some foodstuffs varies with the quality and quantity of other components.

The diet must contain a minimum amount of each one of the indispensable principles; otherwise disturbances are observed. This amount can be increased to an optimum, but an excess may cause serious damage to the organism. For example, water is one of the simplest and most indispensable of foods, and man cannot live for long if totally deprived of it, yet excessive amounts of water will produce the syndrome of

water intoxication in certain conditions. An insufficient diet causes weakness and eventually death, but overeating leads to obesity and other disturbances in nutrition. There is an optimum for the total amount of food and for each one of the indispensable factors in the diet.

The dietary level of a population can be considered satisfactory when there are normal growth and development, high natality, low infantile and general mortality, a long average life span, high working efficiency, good teeth, and resistance to infection.

Caloric requirement. A technical committee of the United Nations[1] has advised the following daily caloric rations for persons living in a temperate climate:

	Kg.-cal.
Man, twenty-five years old and 65 kg. weight	3200
Woman, twenty-five years old and 55 kg. weight	2300
Woman after third month of pregnancy	Add 450
Woman during lactation	Add 1000

[1] *Ann. de la Nutrit. et de l'Aliment.*, 4, 183, 1950.

To adjust these amounts to the body weight, the following formulas are used: for men, $152 \times W^{0.73}$, and for women, $123 \times W^{0.73}$.

Sedentary men require only 2400 kg.-cal. and sedentary women 1700 kg.-cal. Hard physical labor requires an increase to 4000 kg.-cal. in man and 2800 kg.-cal. in women.

The caloric requirement of children of different ages is given in Table 72. Adolescent girls

Table 72. Caloric Need of Children

Age, years	*Kg.-cal.*	*Age, years*	*Kg.-cal.*
0.5–1	110*	10–12	2500
1–3	1200	13–15	2600†
4–6	1600	13–15	3200‡
7–9	2000		

* Per kilogram of body weight.
† Girls.
‡ Boys.

sixteen to twenty years old require 2400 kg.-cal. and boys 3800 kg.-cal., *i.e.*, 105 per cent and 120 per cent respectively of the amounts required by adult women and men.

Another estimate[1] assesses the daily caloric requirement of an adult man as 3000 kg.-cal. net, *i.e.*, the caloric value of food absorbed. Approximately 10 per cent of the caloric value is lost in preparing or cooking food or is not absorbed by the digestive tract; therefore to obtain 3000 kg.-cal. net, from 3300 to 3400 kg.-cal. gross should be allowed. An adult woman needs 2500 kg.-cal. net; *i.e.*, 2800 kg.-cal. gross. The female coefficient with respect to the caloric requirements of man is 0.83.

These figures are only averages for the total adult male population. Men leading sedentary lives need only 2400 kg.-cal. per day, while those doing heavy manual labor need 4000 to 5000 kg.-cal. Workmen in Canadian or Swedish lumber camps, who do very heavy work in a cold climate, require from 8000 to 9000 kg.-cal.

The following examples show how the caloric requirement of an individual is calculated:

An adult man 1.72 m. in height and 70 kg. in body weight has a body surface of 1.8 sq. m. His BMR is 72 kg.-cal. per hr. (using as the average standard figure 40 kg.-cal. per sq. m. per hr.). This amount covers all the caloric requirements during the 8 hr. of sleep, but during the rest of the day there is activity for which energy must be provided. Eight of the waking hours are employed in work and 8 hr. in ordinary current activities such as moving from one place to another and eating, which leads to the specific dynamic activity of food, keeping up the body temperature, etc. These activities increase the metabolic rate by approximately 30 per cent. Work requires a variable amount of energy, according to its nature; let us suppose it is covered by 1000 kg.-cal. Thus the total caloric requirement of this man is as follows:

[1] FOOD AND NUTRITION BOARD, NATIONAL RESEARCH COUNCIL, Washington, D.C., *J. A. M. A.*, **116**, 2601, 1941.

	Kg.-cal.
8 hr. of sleep at 72 kg.-cal. per hr. (BMR)	576
8 hr. awake at 94 kg.-cal. per hr. (BMR + 30 per cent)	752
8 hr. working (BMR + 1,000 kg.-cal.)	1576
Total	2904
Advisable average	3000

A woman 1.58 m. in height, weighing 56 kg., has a body surface of 1.6 sq. m. and a BMR of 37 kg.-cal. per sq. m. per hr. Energy needed for manual work can be considered as two-thirds that of a man, *i.e.*, 660 kg.-cal. Therefore the total caloric requirement is as follows:

	Kg.-cal.
8 hr. sleep at 59 kg.-cal. per hr. (BMR)	472
8 hr. awake at 77 kg.-cal. per hr. (BMR + 30 per cent)	616
8 hr. work (BMR + 660 kg.-cal.)	1132
Total	2220
Advisable average	2500

Mental activity does not increase the caloric requirement. In a cold climate the basic ration should be increased.

Children need relatively more food per kilogram of body weight than adults because (*a*) they have a higher BMR per kilogram; (*b*) part of the food is used to build up tissue; (*c*) they are in continuous activity. A pregnant woman or a nursing mother uses part of the food ingested in building up the tissues of the fetus or in producing milk for her child.

ORGANIC CONSTITUENTS OF THE DIET

The average composition of a good diet for an industrial population is given in Table 73. This diet exceeds the requirement of a man with sedentary habits and is not sufficient for one

who does hard manual labor; it is an average adequate for persons doing moderately intense manual work.

Protein. The diet of an adult should contain 1 gm. of protein per kilogram per day, which is more than the minimum protein requirement discussed in Chap. 43. Amounts varying from 20 to 130 gm. daily have been considered adequate. Undoubtedly 30 to 40 gm. of first-class protein can fulfill the minimum need of protein, but it is advisable to allow 100 or 105 gm.[1] for a diet containing 3400 kg.-cal. There should be 50 gm. of first-class protein[2] such as that in milk and milk products, eggs, meat, and glandular tissue (liver and kidney); the rest can be second-class protein, such as that of vegetables. Potato protein is one of the best of vegetable proteins. A relatively high-protein diet (1.3 to 1.5 gm. per kg.) is preferred in the United States, Western Europe, and Argentina. Countries with a low standard of living have a low-protein diet.

Table 73. Composition of Average Normal Diet

	Gm.	*Kg.-cal.*	*% of total calories*
Proteins	100	410	12
Fats	100	930	27
Carbohydrate	500	2050	61

The amount of protein in the diet should be increased during growth, pregnancy, and lactation. A pregnant woman should be given 1.5 to 2 gm. of protein per kilogram daily. The protein requirement of children varies with their age, as follows: one to three years, 3.5 gm. per kg.; three to five years, 3 gm. per kg.; five to twelve years, 2.5 gm. per kg.; fifteen to seventeen years, 2 gm. per kg.; seventeen to twenty-one years, 1.5 gm. per kg. A large proportion of the protein intake during growth, pregnancy, and lactation should be in the form of first-class protein. Muscular effort does not increase the protein requirement.

[1] A survey made in the city of Buenos Aires showed that 54 per cent of the families consumed less than 105 gm. of protein, 20 per cent consumed more; in 20 per cent of the cases the amount of protein was definitely below a safety level (ESCUDERO, P., and B. ROTHMAN, *Trab. & publ. inst. nac. nutr., Buenos Aires*, **4**, 7, 1939).

[2] These are more easily digested and absorbed and contain the essential amino acids, therefore they are more efficient in the maintenance of growth and protein equilibrium.

A greater proportion of animal protein is absorbed (90 to 95 per cent) than of vegetable protein (80 per cent). Vegetables, brown bread, cellulose, or bran in the diet decrease the absorption of animal protein.

Usually protein makes up only 12 to 15 per cent of the total caloric value of the diet, but in certain cases there is a much larger proportion, *e.g.*, the Eskimos studied by Krogh consumed 300 gm. of protein daily, their diet being almost exclusively protein and fat.

Carbohydrate. Usually more than half the calories in the diet (50 to 70 per cent) are in the form of carbohydrate. This is due to the fact that carbohydrate is cheap, agreeable, digestible, and easily absorbed. Excess carbohydrate causes flatulence owing to fermentation in the digestive tract. Carbohydrate foods are frequently refined to excess, *e.g.*, flours and sugar, and thus lose important constituents such as vitamins and protein. It is therefore advisable to replace part of the white flour and sugar in the diet by potatoes, which contain a fairly good supply of protein, thiamine, ascorbic acid, and salts.

Fat. A diet of 3000 kg.-cal. should contain from 80 to 125 gm. of fat. Usually 20 to 30 per cent of the caloric value of the diet is in the form of fat. Small children should receive approximately 4 gm. of fat per kg. The figure for adults varies considerably in different circumstances; thus Canadian lumbermen have a diet of 6000 to 8000 kg.-cal. with 300 gm. of fat (35 to 40 per cent of the total calories). It is not possible to say what amount is the indispensable minimum of fat, because rats (Mendel) and men (Pirquet, Hinhede) have been kept in good condition fed on diets with very little fat; moreover, the Japanese consume a diet which has only 20 or 30 gm. of fat daily. Nevertheless fat in adequate proportions has many advantages as a food, and a minimum is necessary to provide the indispensable linoleic, linolenic, and arachidonic acids. Also fat-soluble vitamins (A, D, E) are contained in certain fats: butter, cod- and other fish-liver oils, wheat-germ oil, etc.[1] Fats give some foods their characteristic and appetizing odor and taste. They are more satisfying than other foods and give a sensation of satiety. They are absorbed slowly, sometimes taking 5 to 6 hr. to be absorbed, so they have a prolonged nutritive effect. They contain a large

[1] Vitamin requirements are given in Table 74.

amount of calories (9.3 kg.-cal. per gm.) in a small bulk and therefore are of special value in preparing high-caloric rations.

An excess of fat, not adequately compensated by carbohydrate or protein, provokes ketosis and acidosis. Excess of fat, even when it forms part of a well-balanced diet, leads to obesity. Animal fats with high vitamin content, such as butter and fish-liver oils, are protective foods. Vegetable oils have the same caloric value as animal fats, and many have a pleasant taste, but most of them do not carry vitamins.

MINERAL CONSTITUENTS OF THE DIET

The amount of water taken per day varies according to the diet, the nature and amount of work done, and the environmental temperature. In basal conditions it is 2,500 to 3,000 cc. per day (see Chap. 44, Water Metabolism). The importance of minerals in diet has only recently been understood. Optimum quantities of Ca and Fe are given in Table 74; the subject has been discussed in Chap. 45, Mineral Metabolism. The requirements of growing children, pregnant women, and nursing mothers are particularly important, because mineral deficiencies in the period of growth may produce effects, especially in the bones and teeth, that last throughout life.

The adult's diet should contain 0.8 gm. of calcium per day, that of women in the second half of pregnancy 1.5 gm., and that of nursing mothers 2 gm. The daily amount of phosphorus for adults should be 1.3 to 1.4 gm., and 2.5 to 3 gm. for pregnant women. A normal diet contains 3 to 6 gm. of sodium, 2 to 4 gm. of potassium, and 5 to 15 gm. of sodium chloride per day.

It is advisable that the iron content should not be less than 12 mg. per day for an adult and 15 mg. for a pregnant or adolescent woman, although 3 mg. daily suffices the needs of an adult man. The iodine content should be from 100 to 200 μg daily (0.002 to 0.004 mg. per kg. of body weight daily).

SPECIAL NUTRITIONAL NEEDS

When a diet is prescribed, age, sex, work, environmental temperature, and special conditions such as pregnancy, lactation, or disease should be taken into account.

The diet of pregnant women should be carefully controlled, because deficiencies may cause permanent injury to the fetus. Not only should extra calories be allowed, but also an adequate amount and quality of protein should be given; deficiencies in calcium, phosphorus, iron, and (in goiter districts) iodine should be carefully avoided. The following vitamins are of special importance in pregnancy: thiamine, riboflavin, niacin, ascorbic acid, and antirachitic vitamin. All these factors can be given in protective foods.

Small children especially require high-quality protein, calcium, phosphorus, and vitamins. Before 6 months, iron should be added to the diet in the form of egg yolk, strained green vegetables, or strained carrots. Potatoes are preferable to white flours.

Pregnant and nursing women should be given adequate amounts of vitamin D, especially if the exposure to the sun is restricted, either because of weather conditions or because of customs. Cod- and other fish-liver oils or vitamin D_2 concentrates are the usual forms of administering the antirachitic vitamin.

Physical exercise or manual labor does not imply an increase in protein requirement; the extra energy is obtained from carbohydrate and fat. In high-caloric diets up to 45 per cent of the caloric value may be obtained from fat.

It is preferable to use natural foods of good quality instead of covering deficiencies by adding synthetic vitamins to the diet. In certain cases, nevertheless, it is advisable to enrich foods by restoring or increasing the normal vitamin concentration of some foods. Thus up to 400 IU of vitamin D_2 can be added to 1 quart of milk with the object of controlling mild rickets. During the Second World War protective substances were added to white flours to supplement deficiencies; *e.g.*, the following quantities of vitamins and minerals were added to 1 lb. of white flour:[1] thiamine, 2.0 to 2.5 mg.; riboflavin, 1.2 to 1.5 mg.; niacin, 16 to 20 mg.; iron, 13 to 16.5 mg.; and optionally 500 to 625 mg. Ca and 250 to 1,000 IU of vitamin D. Calcium is added to counteract the effect of phytic acid in cereals, which precipitates Ca in the intestine and makes its absorption difficult. Oleomargarine should be reinforced by at least 9,000 IU of vitamin D_2 per pound.

In districts where the drinking water does not contain enough iodine to prevent endemic goiter, iodine should be added to table salt. The amount of iodine advised has varied from 5 to 200 mg. of KI per kilogram, but usually 100 mg. per kg. is considered an adequate quantity[2] (a chemical stabilizer should also be added). Each person consumes approximately 6.2 gm. of table salt daily, *i.e.*, 0.62 mg. of iodide, or 0.47 mg. of iodine; this is twice the amount usually considered as the optimum (100 to 200 mg., or 2 to 4 μg per kg., daily). In England[3] 10 mg. of KI per kilogram of salt is advised, supposing that each person consumes 10 gm. daily, *i.e.*, 100 μg of iodide or 76 μg iodine.

REMARKS ON CERTAIN FOODS

Milk. Communities where there is a high milk consumption are vigorous and have a long average life span, a high longevity rate, and a low death rate. Milk protein is of the highest biologic value, with the advantage of a low cost. It has easily digestible fat (because it is emulsified), large quantities of readily absorbable calcium and phosphorus, thiamine, riboflavin, and other vitamins. It is deficient only in vitamin D and iron. Children and pregnant women should drink 1 quart of milk daily. Where the consumption of milk is low, there are usually a low standard of living, high infant mortality, and subnormal growth and development in children. Dried, powdered milk can be used to replace ordinary fluid milk in cases where it must be transported for long distances.

Meat. Meat contains 15 to 20 per cent protein of high biologic value and 15 to 30 per cent fat, but no carbohydrate. Communities living on an almost exclusively meat diet, *e.g.*, the Eskimos and Argentine "gauchos," do not

have any nutritional disorders that might be attributed to the diet such as gout, arthritis, renal disease, rickets, or scurvy.[1] A meat diet can prevent or cure scurvy or pellagra. Nevertheless from the nutritional point of view a mixed diet has many advantages over an exclusively meat diet. In a cold climate a high meat content is spontaneously chosen, possibly because its specific dynamic action contributes to maintain body heat and gives a sensation of well-being. In a hot climate, or in people who lead a sedentary life, a high meat diet is not so advantageous. The consumption of meat usually increases with the income.

Eggs. Eggs have excellent protein and a high content of iron and other minerals, vitamins A and D, thiamine, and riboflavin.

Vegetables. Green vegetables contain vitamins A, C, and B, iron, and minerals. If vegetables are boiled most of these substances are extracted and, if the water is thrown away, they are lost; for this reason steaming is preferable to boiling. Fruit contains much vitamin C, cellulose, and pectin.

Alcohol. Alcohol is oxidized in the organism, setting free 7 kg.-cal. per gm. The respiratory quotient is 0.67. As an energy-yielding food it has many disadvantages. It cannot be stored; it does not contribute to the formation of constituent substances of the body; it is toxic and habit-forming; it is expensive; it can be used as a substitute for other energy-yielding substances only for the maintenance of body temperature.

Alcohol is absorbed partly in the stomach but mainly in the small intestine. Absorption is delayed if other drink and food is ingested at the same time. The concentration of alcohol in the blood reaches a maximum approximately 1½ hr. after it has been ingested. It is oxidized in the liver (Lundsgaard; Leloir and Muñoz[2]). The concentration of alcohol in the blood falls at a steady rate related to the blood alcohol level.[3] According to Mellanby the decrease is 0.012 per cent per hour. The curve of alcohol concentration in blood is not modified by exercise.

When the concentration of alcohol in blood is 0.1 to 0.15 per 100 cc. the subject is slightly intoxicated, and definitely so when the concentration reaches 0.2 per cent except in subjects habituated to alcohol. A concentration of 0.25 per cent is usually accompanied by severe drunkenness. Little alcohol is eliminated by the kidney. The concentration of alcohol in urine is approximately 1.35 that in blood; therefore when there is 0.36 per cent alcohol in urine the subject is completely intoxicated. Alcohol is eliminated twice as rapidly by the lung as by the kidney. Thus in 8 liters of expired air there may be 3 to 4 mg. of alcohol. The condition of an alcoholized person can be estimated for purposes of medical jurisprudence by measuring the rate of alcohol elimination in the expired air.

Weak solutions of alcohol stimulate gastric secretion, but 5 to 10 per cent alcohol retards digestion, and higher concentrations have an irritating effect on the gastric mucosa, causing hypersecretion of mucus. Alcohol diminishes the absorption of vitamins in the B complex and so may lead to the production of deficiency diseases such as beriberi, polyneuritis pellagra, etc.

Alcohol increases the heart rate, causes vasodilatation in the skin, and gives a sensation of warmth. It thus favors heat loss and may have harmful results in subjects exposed to cold. It has the same effects as anoxia on the central nervous system. Persons at high altitudes (mountain climbers, aviators) should not take alcohol because the effects of alcohol are summated to those of low oxygen tension.

Kraepelin, Mott, and others have given good descriptions of the progressive effects of alcohol on the central nervous system. At first there is inhibition of the higher centers, with release of the lower centers. Critical control is diminished, pain and worry are forgotten, and there is a sensation of well-being. There are loquacity and exaggerated motility, and the subject is amenable to suggestion. During the second stage, critical control is lost, behavior is no longer normal, and emotivity is increased and uncontrolled. In a third stage, speech is slurred, vision is not clear (frequently there is diplopia), and there is incoordination of movement (alcoholic ataxia) with disturbances in posture and walking. There may be visual and auditory hallucinations. The subject is immoderately hilarious, maudlin, or quarrelsome, and in some cases immoral tendencies are no longer inhibited. The subject in this stage may become dangerous, and he is always a disgusting spectacle. In the last stages there are stupor, incontinence of sphincters, sometimes coma, and even death.

Small doses produce effects in relation to the con-

centration of alcohol in the blood and previous habituation. The usual effects are those of a narcotic that produces paralysis. The knee jerk decreases, sometimes after a transitory phase of exaggeration. The reaction time is lengthened, although Kraepelin found in some cases a brief period during which it was shortened. Errors increase, especially in tests requiring concentration and memory, and the subject is easily fatigued. In summary, alcohol produces an illusion of stimulation, covering disturbances in neuromotor functions and in critical control of movement and behavior; it usually diminishes efficiency in the performance of physical and intellectual tasks.

Alcohol produces an agreeable sensation of well-being and causes forgetfulness of pain and worry; hence its consumption. Taken in moderate amounts it may not be harmful, but the border line of moderation is difficult to establish and maintain. The abuse of alcohol causes many social evils apart from the harm it does to the persons indulging in it. Control of alcoholism is a major subject in social security, requiring legislation for the protection of the community and education of the people on the dangers of the abuse of alcohol.

SECTION SIX

Internal Secretions

CHAPTER 51

Introduction to Endocrinology

The glands of external secretion discharge the products of their activity on the external surface of the body, the skin, the digestive or respiratory mucosae, etc. The glands of internal secretion, also called "ductless glands" or "endocrines," pour their secretions into the blood. Certain glands are made up of two kinds of cells, some of which are exocrine and others endocrine; *e.g.*, the pancreas, the zymogenous cells of which secrete the pancreatic juice into the duodenum and the islet cells of which secrete insulin into the blood.

The glands of internal secretion produce specific chemical substances, called "hormones," which regulate important functions and are the active principles of humoral correlation between the different parts of the body. Hormonal activity was first demonstrated in 1849 by Berthold, who showed that the crest of a capon could be made to develop by grafting a testicle into the bird. The term "internal secretion" was first used by Claude Bernard (1855) when he discovered the secretion of glucose by the liver into the blood. The modern concept of internal secretion was formulated by Brown-Séquard (1869–1889) and demonstrated in 1902 by Bayliss and Starling, who showed that when acids stimulate the duodenal mucosa, a substance, secretin, is poured into the blood and is carried by the blood stream to the pancreas, where it provokes the secretion of pancreatic juice. Substances such as these, which are produced by one organ, pass into the blood, and stimulate activity in another organ, act as "chemical messengers." Bayliss and Starling called them hormones, a name suggested to them by Hardy.[1] Thus the knowledge of humoral correlation between the different parts of the organism was established. Humoral correlation appears in the embryo and in the phylogenetic scale before nervous correlation. The integration of the organism of invertebrates without a nervous system is carried out exclusively by humoral correlation; in higher animals there are mechanisms of humoral and nervous correlation, which in many cases supplement each other.

Hormones. Hormones have the following characteristics: (*a*) they are chemical entities produced specifically by a certain type of cell; (*b*) they are secreted into the *milieu intérieur* and conveyed to all parts of the body; (*c*) they provoke a specific activity in distant organs which are susceptible to their effect; (*d*) they are active in minute quantities and do not contribute energy or matter in significant amounts.

These properties distinguish hormones from other substances that are also poured into the circulating fluids, such as (*a*) nutritive substances, which provide the tissues with matter and energy, *e.g.*, glucose, amino acids, lipids, etc.; (*b*) vitamins, which are chemical regulators obtained from food; (*c*) parahormones (Gley), which are waste products of metabolism produced by all the cells of the body but which have a regulatory effect on certain functions, *e.g.*, CO_2, which regulates respiration; (*d*) chemical mediators of nerve stimulation, set free at the nerve endings on nerve cells, muscle fibers, and glandular cells, on which they have a local effect; (*e*) organizers, *i.e.*, substances in the

[1] The word "hormone" is used also for substances that do not excite activity but rather inhibit it. According to Sharpey-Schäfer, the term "autacoid" would be appropriate for all chemical messengers; "hormone" for chemical messengers that stimulate activity; and "chalone" for those which inhibit it. This terminology has not been generally adopted, chiefly because certain substances stimulate at certain doses and inhibit at others, or have an excitatory effect on some organs and an inhibitory effect on others.

embryo that exert local activity in the differentiation of tissues, even when they are transplanted to other parts of the embryo or cultivated *in vitro*.

Hormones do not initiate or suppress functions or reactions of the body; they only modify those which already exist.

According to their chemical structure hormones can be classified into three main groups: (*a*) phenol derivatives, *e.g.*, adrenaline, noradrenaline, thyroxine; (*b*) proteins, *e.g.*, the hormones of the hypophysis, pancreas, and parathyroid glands; (*c*) steroids, *e.g.*, the sexual and corticoadrenal hormones.

Active substances, known as "natural hormones," have been extracted from the ductless glands. Some of the hormones have been prepared by synthesis. Certain chemical products exert effects on the organism similar to those of hormones; they are sometimes mistakenly called "artificial hormones."

Hormones are effective in very small quantities; the minimal dose of many of them is measured in micrograms. Some of the hormones are rapidly removed from the blood, others more slowly, but in all cases hormones are being destroyed continuously, so excessive amounts are not accumulated.

Antihormones. Hormones secreted by the organism do not provoke the formation of antibodies; there is no immunity against the individual's own hormones, but extracts of ductless glands with hormonal activity, especially protein extracts of glands from other animal species, provoke the formation of antihormones which neutralize the effects of the hormone injected and may also inhibit the effect of the animal's own secretion. Hormonal substances of simple chemical structure, such as phenols (adrenaline) and steroids (ovarian, testicular, and corticoadrenal hormones), do not provoke the formation of antibodies, but protein hormones, such as the anterior hypophyseal hormones, easily provoke their formation. Insulin is a protein, but it produces antihormones in very few cases—fortunately, because insulin treatment frequently has to be kept up for many years. Prolonged treatment with parathyroid extract does not provoke the formation of an antihormone; nevertheless after a certain time the organism ceases to respond to this extract (see Functions of the pars distalis, Antihormones, in Chap. 52).

Functions of the endocrine glands. The ductless glands are of great physiologic importance, and they fulfill many functions, which may be classified as follows:

1. Metabolic, such as the increase in the rate of oxidation produced by the secretion of the thyroid, or the more specific effect of insulin on carbohydrate metabolism, or of the parathyroid hormone on calcium metabolism.
2. Morphogenetic, *i.e.*, the regulation of growth of the whole body or of certain tissues and organs, thus contributing to establish the constitution of the individual.
3. Endocrine interrelation and equilibrium, *e.g.*, the anterior hypophysis is a factor in the maintenance and development of the thyroid, adrenal cortex, and sexual glands, and reciprocally these glands regulate the activity of the anterior hypophysis.
4. Sexual and reproductive, *i.e.*, stimulation or inhibition of morphologic, functional, and psychic sexual characters and the libido.
5. Nervous and mental; hormones have considerable influence on higher nervous activity and on personality and character.
6. Resistance and adaptation, *i.e.*, they modify processes which condition the resistance, immunity, and adaptation of the body.
7. Vital; some of the ductless glands are of vital importance, so that if they are destroyed the subject dies.

At one time the ductless glands were supposed to have an antitoxic function, and endocrine insufficiencies were thought to be due to the accumulation of toxic substances that were not destroyed. These hypothetical toxic substances have never been found. On the other hand, ample proof has been given that extirpation, or destruction by disease, of an endocrine gland suppresses the secretion of a hormone that takes part in the regulation of a nutritive process; symptoms of endocrine insufficiency are due to nutritional disturbances caused by hormonal deficiency. For example, diabetes is a disturbance in carbohydrate metabolism due to insulin insufficiency, parathyroid insufficiency causes hypocalcemia, and corticoadrenal insufficiency brings about disturbances in the metabolism of salts and water. Death is caused, not by the accumulation of a toxic substance, but by these nutritive disturbances. Thus a parathyroidectomized animal can be kept alive by

the administration of calcium, and adrenalectomized animals can be treated successfully with sodium chloride. The antitoxic theory of endocrine function was definitely abandoned when the secretion of specific hormones that regulate nutritive processes was demonstrated.

Some of the hormones have a direct action on peripheral tissues; others act indirectly. Thus the pars distalis of the hypophysis secretes certain hormones which modify growth by direct action on the tissues, and others which stimulate the gonads. The sex glands thus stimulated secrete hormones which act directly on the tissues. The effect of the hypophyseal hormones on secondary sex characters is therefore exerted indirectly through the sex glands and does not take place in castrates.

The effect of one hormone can be strengthened or weakened by another hormone. Thus progesterone has a marked effect on the endometrium or on the mammary gland if these tissues have been previously developed by estrogens. In certain proportions these hormones inhibit each other.

Methods of study. The following methods are used to study the functions of the endocrine glands: (*a*) the anatomical or anatomophysiological method, which consists in the study of the macroscopic (size, weight, etc.) and microscopic (cellular changes) aspects of the gland in different physiologic and pathologic conditions; (*b*) chemical methods, which are used to extract and identify the active principles in the secretion and to study the chemical changes caused by deficiency or excess of hormone; (*c*) physiological methods, which serve to study the effects of insufficient or excessive secretion or of the injection of hormones; (*d*) the anatomoclinical method,[1] which consists in the correlation of functional disturbances observed in patients with the morphologic changes observed in the endocrine glands by means of biopsies or at autopsy.

[1] In many cases anatomoclinical observations have been the starting point of the study of problems of internal secretions, especially in the beginnings of endocrinology. Later rapid and important advances were made by the application of the experimental method, causing insufficiency by extirpation of the gland, and treating the deficiency thus created by the administration of gland extracts or (at a later stage) of purified hormones. In some cases it has not been possible to reproduce in animals the effects of the disease as observed in man.

The physiological method consists in (*a*) functional suppression of the gland and observation of the effects thus produced; (*b*) compensation of this insufficiency by glandular graft or the injection of extracts or hormones of the gland that has been removed; (*c*) the administration of excessive amounts of extracts or hormones with the object of provoking the effects of hypersecretion. The activity of a glandular extract is due in part to the specific hormone or hormones it contains, and in part to nonspecific impurities. The functions of a gland cannot therefore be deduced exclusively from the effects of its extracts. The method is nevertheless valuable when it is used simultaneously with others and gives results in agreement with them. A permanent glandular insufficiency is produced simply by removing the gland, but a permanent condition of hyperfunction is not easily maintained, because the organism tends to restore a normal functional level.

Specificity. In most cases hormonal effects are similar in different species, and a hormone obtained from one species is active in others.[1] There is, on the other hand, specificity of origin and of action, *i.e.*, a hormone is produced exclusively by one type of cell and it always has the same effect; *e.g.*, insulin is produced only by the islet cells of the pancreas and provokes hypoglycemia in all the vertebrates. Each hormone acts predominantly on one tissue or physiologic process, but it may have some effects on others. Thus testosterone exerts its principal effect on the male sexual characters, but it also has a general metabolic activity and produces some effects on the female sexual organs (endometrium, mammary gland, etc.).

Hormonal assay. Only a few hormones (*e.g.*, adrenaline) can be assayed by chemical methods. In many cases only biological methods are available. The general procedure is as follows: The different doses of the substance to be assayed are injected into a series of animals, and a definite dose of a standard preparation is injected into a second series. Certain effects, *e.g.*, the blood-sugar level, or convulsions in the case of insulin, are then observed and compared in both series. A standard preparation must be used

[1] Some of the protein hormones have a certain degree of zoological specificity. Thus sexual hypophyseal hormones (gonadotrophins) of mammals are active on the ovary of the toad only if given in large doses. Reciprocally, toad gonadotrophins have very little activity on the mammalian ovary.

because of individual variations in response, due to feeding and other causes.

The rate of secretion of a hormone can be determined in two different ways:

1. The venous blood coming from the gland is collected over a known time, and the hormone it contains is determined by chemical or biological methods. The results are usually expressed in terms of 1 gm. of glandular tissue, or 1 kg. of body weight, and 1 min. This method has given good results in estimating adrenaline secreted by the adrenal medulla, but it is not easy or even possible to apply it to other glands.
2. The dose of hormone, given in continuous or frequently repeated injections, necessary to maintain a normal functional level after removal of the gland in question, is determined. This is known as the substitution or replacement method.

An approximate idea of the rate of secretion may be obtained by measuring the hormonal concentration in the blood or the urinary elimination of the hormone, or of substances derived from the hormone. For example, the urinary elimination of 17-ketosteroids is an index of corticoadrenal and testicular activity. Similarly, pregnandiol, a derivative of progesterone, indicates the activity of the corpus luteum.

Regulation of internal secretions. Some of the ductless glands secrete continuously at a basal rate, *e.g.*, the islets of the pancreas and the adrenal medulla.[1] The rate increases or diminishes in different circumstances; *e.g.*, insulin secretion increases when there is hyperglycemia and diminishes when there is hypoglycemia.

The basal rate of secretion is maintained even after a large part of the gland has been removed; thus the blood sugar is kept at a normal level in spite of the extirpation of five-sixths to seven-eighths of the pancreatic tissue. The insufficiency of the remaining glandular tissue is made evident only in cases of emergency, *i.e.*, when there is a demand for an increase in secretion. The basal rate of secretion is not raised when the mass of glandular tissue is artificially increased. For example, three pancreases can be grafted into a dog by vascular anastomoses, thus increasing the islet tissue in the circulation to four times the normal, without provoking hypoglycemia. The total amount of insulin secreted is regulated not by the mass of pancreatic islet tissue but by the blood-sugar level. Tissue mass is important only when it is in insufficient amount.

Not only is the rate of secretion of each hormone controlled, there is also an equilibrium between the rates of secretion of the different glands on which the functional equilibrium of the whole organism is dependent.

Most of the endocrine glands continue to function normally after they have been completely denervated, because they are mainly controlled by humoral mechanisms. The adrenal medulla is an exception to this rule; after it has been completely denervated adrenaline secretion is reduced to a minimum.

Disturbances in endocrine regulation may cause (*a*) insufficiency, when the secretion is inhibited or the gland is partially destroyed and there is an insufficient mass of functioning tissue; (*b*) hypersecretion, when the nerves are stimulated (*e.g.*, sympathetic stimulation increases the rate of adrenaline secretion) or the gland is stimulated by another hormone (*e.g.*, thyroid stimulation by anterior hypophyseal thyrotrophin). Permanent hyperfunction is observed in cases of hyperplasia or adenoma of the endocrine gland. Adenomatous tissue does not respond normally to the regulatory mechanisms, but secretes an excess of hormone.

[1] Cannon has maintained there is no basal secretion of adrenaline, which is secreted only in cases of emergency.

CHAPTER 52

The Hypophysis

THE HYPOPHYSIS IS an endocrine organ that fulfills very important functions in all vertebrates. In man it is placed in the sella turcica and measures approximately 1 cm. in its anteroposterior, 1 to 1.5 cm. in its transverse, and 0.5 cm. in its vertical diameter. It weighs from 0.5 to 0.7 gm. in man, varying with the height of the individual. It is larger in women than in men and increases in size at each pregnancy, weighing 0.8 to 0.9 gm. or even more (Comte, Erdheim, and Stumme).

The hypophysis owes its name to its situation below the brain. It was formerly called the "pituitary body," because it was mistakenly thought to secrete mucus through the cribriform plate of the ethmoid into the nasal cavities. The hypophysis is joined to the floor of the third ventricle by a thin stalk. The optic chiasma is just above the anterior part of the hypophysis, from which it is separated by the dura. The chiasma is often compressed in cases of tumor of the hypophysis.

The hypophysis is made up of two parts: (*a*) the adenohypophysis, epithelial in nature, derived from Rathke's pouch, which is a prolongation of the buccopharyngeal epithelium; (*b*) the neurohypophysis, which has its origin in an outgrowth of the floor of the third ventricle, *i.e.*, the hypothalamus. An anterior and a posterior lobe can be distinguished macroscopically, but the microscopic and embryological study of the gland has shown that it is more complex and can be divided as follows:

Adenohypophysis	Lobus glandularis	Pars distalis	Anterior lobe
		Pars tuberalis	
		Pars intermedia	Posterior lobe
Neurohypophysis	Lobus nervosus	Processus infundibularis	
	Infundibulum	Pediculus infundibularis	Hypophyseal stalk (formed by nerve fibers covered by cells of the pars tuberalis)
		Bulbus infundibularis	
		Labrum infundibularis	

The pars distalis forms the anterior lobe in mammals.[1] It is made up of nests and rows of epithelial cells separated from each other by sinusoids. There are chromophobe cells, which do not have granules, and the chromophil cells with specific granules. The granules of some of the latter stain with acid dyes; they are called acidophil, or α, cells. In others the granules stain with basic dyes; they are called basophil, or β, cells. In man 52 per cent (34 to 66 per cent) of the cells are chromophobe, 37 per cent (23 to 60 per cent) are acidophil, and 11 per cent (4 to 27 per cent) are basophil (Rasmussen). All these cells are derived from a single type of cell in the embryo, which gives rise to the different types of the adult. Chromophil cells sometimes lose their granules. There has been much discussion as to whether there is a single type of cell, which passes through different stages, or two

[1] In amphibians the pars distalis is posterior to the neurointermediate lobe.

separate types of chromophil cells. The second of these opinions is based on the following facts: (*a*) the Golgi apparatus is different in each type of cell; (*b*) hypophyseal adenomas can be made up exclusively of one type of cell, acidophil (in acromegaly) or basophil (in hypophyseal basophilism); (*c*) in different physiologic or pathologic circumstances only one type of cell may respond.

There is a cleft (the hypophyseal cleft) between the anterior and posterior lobes in nearly all mammals. Frequently a thick colloid or solid substance accumulates in this cleft. In man the cleft is found in the fetus, but not in the adult.

The pars intermedia is formed by cells of slightly basophil protoplasm, but without granules. Colloid cysts are sometimes found. The pars intermedia arises from the posterior wall of Rathke's pouch, and it does not exist in some species (fowls, whales). It is not clearly differentiated in adult man, but next to the pars nervosa there is an area in which there are colloid vesicles and basophil cells; these cells sometimes form columns which invade the pars nervosa.

The pars tuberalis surrounds the hypophyseal stalk and forms a thin layer of cells on the ventral aspect of the infundibulum. Hypophysectomy in mammals usually does not remove this part of the pars tuberalis. Atwell was the first to differentiate this part of the hypophysis in the fetus and adult. It is formed by small chromophobe cells.

The third ventricle is prolonged downward into the infundibulum; in the cat this recess extends into the pars nervosa of the hypophysis (Fig. 227). The neurohypophysis does not consist only of the processus infundibularis; it is made up of four parts: (*a*) the processus infundibularis; (*b*) the neural stalk (pediculus infundibularis); (*c*) the infundibulum (bulbus infundibularis); and (*d*) the median eminence of the tuber cinereum (labrum infundibularis). Hypophysectomy usually does not remove all the neurohypophysis; the infundibulum and the median eminence of the tuber remain.
Fig. 227. Hypophysis: *a*, in the cat; *b*, in the monkey. *Ch*, optic chiasma; III*V*, third ventricle; *em.m.*, median eminence of the tuber cinereum; *P.tub.*, pars tuberalis; *B.I.*, bulbus infundibularis; *H.s.*, hypophyseal stalk; *N.stalk*, neural stalk; *P.int.*, pars intermedia; *P.dist.*, pars distalis; *Pr.i.*, processus infundibuli (pars nervosa); *H.c.*, hypophyseal cleft. (*Rioch, D., G. B. Wislocki, and J. L. O'Leary, "The Hypothalamus," Research Pub. No. XX, Association for Research in Nervous and Mental Disease, Williams & Wilkins, Baltimore, 1940.*)

The nervous lobe (processus infundibularis) is formed by neuroglia cells and by other cells with granules, known as pituicytes. There are also numerous nerve fibers.

Numerous nerve fibers from the hypothalamic nuclei, especially the supraoptic nuclei, pass through the stalk to the hypophysis (Fig. 228). Fibers from the supraoptic nuclei end in the median eminence of the tuber and in the nervous lobe of the hypophysis; a few pass into the pars intermedia and the anterior lobe. The supraoptic hypophyseal tract conducts impulses which govern the secretion of the neurohypophysis.

According to Scharrer the nerve cells of the supraoptic and paraventricular nuclei produce the posterior lobe hormones which pass along the fibers of the supraopticohypophyseal tract down to the neurohypophysis. This neurosecretion is stored there in the nerve endings from which it is released into the blood vessels. Nerve cells in these nuclei have the appearance of secretory cells (Scharrer). Gomori hematoxylin stains the neurosecretion (Bargmann). Nervous control of the anterior hypophysis through the hypophyseal stalk has been well demonstrated, but the origin and path of the impulses are not known. According to Harris this action is mediated by the blood vessels.

The hypophysis is nourished by a network of capillaries and sinusoids deriving from the carotid arteries. Popa and Fielding (1930) described a portal circulation in which blood flowed from the hypophysis to the hypothalamus. Later it was seen that blood flows from the hypothalamus to the ventral aspect of the pars distalis.[1] Damage to the vessels on the surface of the infundibulum in toads causes anemic necrotic infarcts in the pars distalis.

There is no satisfactory proof that the secretion of the hypophysis passes into the cerebrospinal fluid. The secretions of the pars distalis, the pars intermedia, and the neurohypophysis are poured into the blood stream and carried by the circulation throughout the body.

Functions of the hypophysis. The different parts of the hypophysis have the following functions:

1. *The neurohypophysis* (*a*) regulates renal excretion of water; (*b*) controls the tone of capillaries and arterioles in amphibians; (*c*) stimulates the uterus (oxytocic effect); (*d*) provokes excretion of milk.
2. *The pars intermedia* controls the dispersion of chromatosomes (pigment granules) in the pigment cells of fishes, amphibians, and reptiles.
3. *The pars distalis* regulates (*a*) growth and development; (*b*) metabolism; (*c*) endocrine functions; (*d*) sexual functions.
Fig. 228. Sagittal section of human hypophysis. Above, the hypophyseal stalk; to the left (dark), the pars distalis; to the right (light), the processus infundibuli.

To facilitate study, the functions of the neurohypophysis will be considered first, then those of the pars intermedia, and finally those of the pars distalis.

FUNCTIONS OF THE NEUROHYPOPHYSIS

Methods of study. Knowledge of the functions of the neurohypophysis has been obtained by (*a*) studying the effects of neurohypophyseal extracts or hormones; (*b*) partial hypophysectomy; (*c*) stimulation of the nerve centers and paths which innervate the neurohypophysis and control its function.

Hormones of the Neurohypophysis. Extracts of the neurohypophysis or the posterior lobe[1] have the following effects: (*a*) antidiuretic effect; (*b*) circulatory effect; (*c*) stimulation of contraction of the uterus (oxytocic

[1] Lascano-González, J. M., *Rev. Soc. argent. de biol.*, **11**, 309 and 318, 1935; *Compt. rend. Soc. de biol.*, **120**, 725 and 723, 1935; Green, J. D., *Anat. Rec.*, **97**, 338, 1947; **99**, 21, 1947; **100**, 273, 1948; *Am. J. Anat.*, **88**, 225, 1951.

[1] Posterior lobe extracts contain the hormones of its two parts, *i.e.*, the processus infundibularis, neural lobe, or *pars nervosa*, and the *pars intermedia* of epithelial origin.

effect) and other smooth muscles; (*d*) stimulation of excretion of milk; (*e*) other effects.

Neurohypophyseal extracts contain specific active principles, inert substances, and in some cases histamine. Kamm and his associates[1] have separated two active principles: (*a*) a pressor substance, which increases the blood pressure, has an antidiuretic effect, and causes contraction of the intestine; (*b*) an oxytocic substance, which stimulates the uterus.

Du Vigneaud and his associates have separated and purified both hormones; they have also prepared them by synthesis.[2] These hormones are polypeptides formed by nine amino acids. They differ from each other only by two of the amino acids. Two vasopressins have been found, one (in the pig) with lysine and the other (in the cow) with arginine.

The activity of posterior hypophyseal extracts is expressed in units. The international unit is the activity of 0.5 mg. of bovine posterior hypophyseal lobe extracted with acetone, dried in vacuum over P_2O_5, and kept in sealed tubes in a nitrogen atmosphere.[3] Extracts are prepared by boiling the powder for a few minutes in 0.2 per cent acetic acid solution; they usually contain 10 IU per cc.

Site of production of the active principles. The active principles are found in all parts of the neurohypophysis. At present there is no definite proof whether they are produced by the pituicytes or the nerve cells of the supraoptic nuclei. After the supraoptic hypophyseal tract has been severed in the cat, the neurohypophysis atrophies (Fig. 230); an extract of the atrophied posterior lobe does not have oxytocic, pressor, or antidiuretic effects, but still disperses the melanosomes in the pigment cells, because the pars intermedia is not atrophied.[1]
Fig. 229. Sagittal section of the hypothalamus and hypophysis in the cat, showing the hypothalamic hypophyseal and tuberohypophyseal connections. (*Fisher, C., W. R. Ingram, and S. W. Ranson, "Diabetes Insipidus and Neurohumoral Control of Water Balance," Edwards Bros., Inc., Ann Arbor, Mich., 1938.*)

Control of Renal Elimination of Water

The neurohypophysis secretes an antidiuretic hormone which stimulates reabsorption of water by the renal tubes, thus diminishing the amount of urine excreted. It is an important factor in the regulation of water metabolism.

The normal daily filtration of fluid through the glomeruli is approximately 170 liters in man. Only 1.5 liters is excreted in the urine; therefore 168.5 liters is reabsorbed by the tubes. Of the total amount reabsorbed, only one-eighth

to one-sixth is controlled by the antidiuretic hormone (facultative reabsorption); the neurohypophysis plays no part in the reabsorption of the remainder (obligatory reabsorption).

Polyuria insipida. The neurohypophysis is innervated by fibers which arise in all the neurons in the supraoptic nuclei and the rostral part of the paraventricular nuclei (Fig. 229). The normal structure of the neurohypophysis and the secretion of the antidiuretic hormone are dependent on this innervation. Secretion of the antidiuretic hormone can be suppressed by (*a*) destruction of the supraoptic nuclei; (*b*) section of the supraopticohypophyseal tracts:[1] (*c*) extirpation of the neurohypophysis. In all these cases the operation is followed by the excretion of large amounts of dilute urine of low specific gravity. This condition is known as polyuria insipida or diabetes insipidus.[2]

There are three types of experimental diabetes insipidus:

1. When hypophyseal denervation is not complete, polyuria lasts only 3 to 5 days.
2. When denervation is complete, polyuria is established permanently.
3. In some cases there are three different stages (Fig. 231): (*a*) during an initial stage of approximately five days there is polyuria; (*b*) diuresis then returns to normal during a few days; (*c*) 14 to 15 days after the operation, polyuria is again observed and becomes permanent.

Hypothalamic lesions do not act directly on the kidneys through the renal nerves because they provoke polyuria in animals with denervated kidneys.[1]

During polyuria the animals show signs of intense thirst and drink continuously (polydipsia). Polyuria precedes polydipsia. Polyuria is increased by the administration of sodium chloride.

Diabetes insipidus has been observed in men and women. These patients excrete from 4 to 10 liters of dilute urine (sp. gr. 1.002 to 1.006) daily; in one case up to 43 liters was excreted. They are continuously thirsty and drink large quantities of water not only in the daytime but also during the night. If they are deprived of water, they suffer intense discomfort and their blood becomes slightly concentrated.

The pars distalis is not necessary for the production of permanent polyuria if the neurohypophysis has been completely denervated, but the excretion of urine is not so great if the pars distalis has also been removed. If part of the neurohypophysis continues to function (*e.g.*, in cases of incomplete denervation) and the pars distalis is intact, there may be polyuria, but it ceases after extirpation of the pars distalis.[2]

[1] Ranson, S. W., C. Fisher, and W. R. Ingram, The Pituitary Gland, *Research Publ., A. Nerv. & Ment. Dis.*, **17**, 410, 1938; Heinbecker, P., H. L. White, and D. Rolf, *Endocrinology*, **40**, 104, 1947; O'Connor, W. J., *Quart. J. Exper. Physiol.*, **34**, 29, 1947.

[2] The term "diabetes insipidus" was first used to distinguish this condition from the diabetes in which there is polyuria and glycosuria and the urine has a sweet taste.

[2] Heinbecker, P., H. L. White, and D. Rolf, *Endocrinology*, **40**, 104, 1947.

The augmentatory effect of the pars distalis on polyuria in patients with diabetes insipidus had already been reported many years ago.[1]

The pars distalis exerts its effect on diuresis through three of its hormones: the growth hormone (somatotrophin), thyrotrophin, and adrenocorticotrophin. After removal of the pars distalis, water is eliminated slowly and several renal functions are impaired.[2] Treatment with hypophyseal growth hormone compensates for these deficiencies and provokes an increase in diuresis not only in hypophysectomized animals but also in normal ones.

The effect of thyrotrophin on water excretion is mediated by the thyroid, which is stimulated by this hormone. Thyroidectomy suppresses moderate polyuria provoked by incomplete denervation of the neurohypophysis and diminishes polyuria in cases of total denervation. Thyroid treatment with doses that have no effect on normal diuresis cause an increase in polyuria insipida and provoke its appearance in latent cases.

The adrenal cortex apparently has an effect on renal excretion of water that is antagonistic to that of the antidiuretic hormone.[1] Corticoadrenal hormones control the excretion of salt and water (see Chap. 54).

There is clinical and experimental evidence that in polyuria insipida there may be a primary disturbance in the neural mechanism of thirst associated with the hormonal antidiuretic mechanism of the neurohypophysis.[2]

Neurohypophyseal extracts. Posterior hypophyseal lobe extracts and extracts of the neurohypophysis have antidiuretic activity.[3] This effect is best seen in animals which have been given water by stomach tube before injecting

[3] Schaefer and Magnus (1901) and Hering (1906) first described a slight diuretic effect. Later, Farini and van der Velden (1913) discovered the antidiuretic effect.

the antidiuretic extract; the usual increase in urinary excretion is not observed, and in some cases a short period of anuria may be observed (Fig. 231). Diuresis begins again a few hours later, after the effect of the extract has passed. The antidiuretic principle acts directly on the kidney; its effects can be observed after complete renal denervation or in a perfused kidney. In patients with diabetes insipidus, subcutaneous injections of posterior lobe extracts must be repeated every few hours to maintain a normal diuresis. To avoid the discomfort of frequent injections, posterior lobe powder can be administered by aspiration through the nose, because the active principle is absorbed through the mucosa. The effect of the extract can be prolonged by combining its active principle with a substance that releases it gradually (*e.g.*, vasopressin tannate); a single injection of this preparation produces effects that last for several days.

The antidiuretic principle increases reabsorption of water from the glomerular filtrate in the renal tubes. Large doses inhibit reabsorption of NaCl. The administration of NaCl diminishes or suppresses the antidiuretic effect of posterior lobe extract. The antidiuretic principle is apparently the same substance as the pressor principle, but smaller doses are needed to obtain a decrease in the excretion of urine than to provoke a rise in blood pressure.[1]

Secretion of the antidiuretic hormone. Electrodes have been placed in the hypothalamus, and after the effects of anesthesia and trauma had passed, the nerve centers were stimulated; a decrease in urinary excretion was observed.[2] The existence of this hormone in the circulating blood is demonstrated by the following experiment: a kidney in a heart-lung preparation secretes a large amount of dilute urine; if the blood is then shunted through the head of the animal with the hypophysis intact before it passes through the kidney, the urine becomes concentrated and its volume decreases.[3]

The decrease in diuresis observed in emotional states, or provoked by reflexes or by certain drugs, has been attributed to an increase in the

[1] According to Shannon (*J. Exper. Med.*, **76**, 387, 1942) the amount secreted normally is the equivalent of 0.001 to 0.005 pressor units per hour in a 10- to 15-kg. dog (1 unit = 0.5 mg. standard posterior lobe powder).

[3] Verney, E. B., *Proc. Roy. Soc., London, s.B.*, **99**, 487, 1926; *Lancet*, **1**, 539, 1929.

secretion of the antidiuretic principle. This decrease is observed in animals with denervated kidneys, but not after suppression of the functions of the neurohypophysis.[1]

Secretion of the antidiuretic principle apparently is diminished when there is diuresis caused by ingestion of water and is increased by the injection of hypertonic salt solution. Probably in the head there are special receptors (osmoreceptors) sensitive to an increase in the concentration of the blood or tissue fluids, because injection of small amounts of hypertonic solutions of NaCl into the carotid causes a decrease in diuresis but not if the neurohypophysis has been removed or denervated.[2] Apparently the osmoreceptors are situated in the hypothalamus because local injection of hypertonic solution in anesthetized goats provokes copious drinking of water (Andersson).

An antidiuretic principle has been found in the urine of animals in anhydremia (Gilman and Goodman), which has been supposed to be the neurohypophyseal antidiuretic principle.

In amphibians, injection of the antidiuretic principle has the same effect on the kidney as in mammals. In larger doses it also increases reabsorption of water through the skin, and the animals increase in weight (Brunn).

Toxic effects. Large doses of posterior lobe extract provoke gastric ulcers and anemia (Dodds) due to hydremia and hypotonicity of the plasma. In epileptics they cause retention of water and provoke convulsions.

Action on the Uterus and in Labor

Posterior lobe extracts (or extracts of the neurohypophysis) provoke contraction of the uterus *in situ* or isolated from the body and submerged in an appropriate saline solution (Dale, 1909). The pregnant uterus is much more sensitive than the virgin uterus. The oxytocic effect is utilized in obstetrics to stimulate an inert uterus, and after birth to provoke the expulsion of the placenta or to stop uterine hemorrhage (Fig. 232). Small doses increase the tonus and rhythmic contractions of the uterus. Large doses may provoke sustained contractions. Occasionally rupture of the uterus has been observed, owing to a relatively large dose having been given to a patient with a hyperkinetic

uterus. Purified vasopressin contains 5 to 13 per cent of the excito-uterine activity of purified oxytocin. Vasopressin is active on the human uterus.[1] Oxytocin has no pressor activity in mammals; it produces a characteristic fall in blood pressure in fowls.

Electric stimulation of the hypothalamus increases peristalsis in the rabbit (Harris). Posterior lobe extract provokes contraction of the bladder, ureter, and gall bladder, but the effect is less marked than in the uterus and intestine (Houssay, 1911). These extracts sometimes pro-
FIG. 232 Oxytocic effect of hypophyseal posterior lobe extract on the human uterus (external hysterography). 1, uterine inertia; 2, injection of posterior lobe extract; 3, expulsive contractions; 4, delivery; 5, expulsion of the placenta.

Stimulation of the hypophyseal stalk in female cats and rabbits provokes contraction of the uterus, even when the head and trunk are connected only by blood vessels.[2] Stimulation of the hypothalamus at some distance from the hypophysis provokes uterine contraction and a decrease in diuresis similar to the effects produced by injection of oxytocic posterior lobe extract.[3]

There is no definite proof that the neurohypophysis plays a part in normal labor, but the following facts are of interest in this respect: (*a*) early in pregnancy a pitocinase appears in the blood which destroys the oxytocic principle; (*b*) toward the end of pregnancy the uterus becomes sensitized toward the principle; (*c*) there is no satisfactory proof of an increase in oxytocic activity of the blood or the cerebrospinal fluid in pregnancy, or that oxytocic substances in the blood are of hypophyseal origin; (*d*) extirpation of the posterior lobe of the hypophysis (the anterior lobe remaining intact) does not prevent pregnancy and labor; (*e*) in female cats in which the neurohypophysis has been denervated (Fisher *et al.*, 1938) and in female guinea pigs with lesions in the hypothalamus behind the hypophyseal stalk (Dey *et al.*, 1941), abortion, difficult labor, or even impossibility of delivery is frequently observed.

Action on other plain muscles. Posterior-lobe extracts provoke contraction of the small and large intestine, and defecation in most subjects.

voke bronchial constriction, but this effect is due to histamine in the extracts, not to a hypophyseal principle.

Evacuation of Milk

Extracts of the neurohypophysis or the posterior hypophyseal lobes provoke evacuation of the lactating mammary gland. The oxytocic is more potent than the vasopressor principle. Suction of the nipple produces reflex release of this hormone. Stimulation of the supraoptic nuclei or the supraopticohypophyseal tract has the same effect (see Chap. 62).

Action on the Circulation

Oliver and Schaefer discovered in 1895 that hypophyseal extracts provoke hypertension. Shortly afterward Howell (1898) showed that this effect was due to a substance in the posterior lobe.

The most characteristic effect of posterior lobe extracts, when injected intravenously, is a prolonged rise in blood pressure, which is preceded by a brief fall in blood pressure when large doses are given (Fig. 231). The rise in blood pressure lasts 10 to 20 min.; it is accompanied by bradycardia with ample beats. The change in the heart rate is considerably reduced after vagotomy and is not observed if the heart has been completely denervated before injecting the extract. The rise in blood pressure is caused by constriction of the arterioles, due to direct stimulation of the vascular muscle fibers. Constriction is also observed in isolated arterioles submerged in Ringer's fluid, when the extract is added. Coronary and

pulmonary arteries are constricted to a lesser degree and for a shorter time than arteries of other territories. Cerebral and renal arteries are not constricted; they are dilated passively by the rise in blood pressure in the intact animal injected with posterior lobe extract. A second injection does not increase the blood pressure, except after a long interval; it may even provoke a fall in blood pressure. The initial fall in blood pressure is due to a weakening of the heartbeat, which reduces the systolic volume; hypotension following a second injection of extract is caused by the same mechanism. Posterior lobe extracts are not used in therapeutics with the object of raising the blood pressure, because of their effect on the heartbeat; doses of 0.5 to 2 cc. injected subcutaneously usually provoke hypotension (a fall of 10 to 30 mm. Hg) lasting approximately 30 min. These doses cause bradycardia, preceded in some cases by transitory tachycardia, marked paleness, and a sensation of precordial constriction, sometimes extending to the limbs.

FIG. 233. Effect of hypophyseal posterior lobe extract on the blood pressure. *a*, intravenous injection of saline extract of 0.25 gm. human hypophysis into a 3.9-kg. dog anesthetized with chloralose (carotid blood pressure); *b*, intravenous injection of 0.2 gm. fresh bovine posterior lobe extract into a 17-kg. dog anesthetized with chloralose (upper tracing, arterial blood pressure; lower tracing, respiration).

The neurohypophysis is of much more importance in the maintenance of vascular tone in amphibians than in mammals. In the former, hypophysectomy causes the following disturbances: (*a*) marked capillary and arteriolar dilatation (Krogh and Rehberg, 1922; Aubrun, 1935); (*b*) an increase in capillary permeability to saline solutions, with the rapid formation of edema (Senderey); (*c*) in the toad, 40 per cent fall in blood pressure, which is not observed after removal of the pars distalis alone, or lesions in the tuber. The blood-pressure level is restored by the injection of posterior lobe extract.[1] These facts are satisfactory evidence that the neurohypophysis is an important factor in the maintenance of capillary and arteriolar tone in amphibians. Removal of the pars distalis is not followed by a fall in blood pressure until some time after the operation. Hypotension and asthenia coincide with metabolic disturbances caused by pars distalis insufficiency.

In mammals lesions of the neurohypophysis do not have such severe consequences. Section of the supraopticohypophyseal tract does not cause changes in blood pressure. Hypophysectomy produces a slight fall (20 mm. Hg) in the blood pressure of the dog[2] and rat,[3] which is apparently due to corticoadrenal insufficiency, because it is controlled by treatment with

[1] ORÍAS, O., *Rev. Soc. argent. de biol.*, **10**, 91, 1934; *Compt. rend. Soc. de biol.*, **116**, 894, 1934.

corticoadrenal hormone or adrenocorticotrophin (Fig. 235).

Vasopressor response is subnormal in hypophysectomized animals, which are especially sensitive to hemorrhage and to drugs, such as histamine, which produce hypotension. Recovery of the blood pressure level after a relatively small hemorrhage (1.5 per cent of body weight) takes much longer than in normal animals.[1]

No satisfactory evidence of the existence in the blood of hypophyseal pressor or vasoconstrictor substances has been given. Pressor substances are found in shed blood obtained under various conditions, but they have not been proved to be produced by the hypophysis.

[1] Braun Menéndez, E., *Rev. Soc. argent. de biol.*, **10**, 204, 1934; *Compt. rend. Soc. de biol.*, **117**, 453, 1934.

Centripetal stimulation of the vagus causes a rise in blood pressure, and the oxytocic, antidiuretic, and melanosome-dispersing activities of the blood increase. These effects are not observed if the hypophysis has been removed; therefore a reflex discharge of hypophyseal secretion has been postulated.[1]

FUNCTIONS OF THE PARS INTERMEDIA

Regulation of chromatophores. The pars intermedia secretes a substance that disperses the melanosomes (pigmentary granules) in the melanocytes (pigment cells), thus conditioning to a certain extent the color of the skin in fishes, amphibians, and reptiles. This function is controlled by the nervous system. There are four

a

b c

Fig. 236. Effect of hypophysectomy on the melanocytes of *Bufo arenarum* (Hensel). *a*, left, normal toad; right, toad 10 days after hypophysectomy. *b*, section of skin of normal toad; melanosomes dispersed throughout the protoplasm and cell processes of the melanocytes. *c*, section of skin of toad 10 days after hypophysectomy; melanosomes concentrated around the nuclei of the melanocytes; the epidermal cuticle is not shed, but remains attached to the skin.

principal types of pigment cell in the skin of these animals: (*a*) melanophores, with melanin granules; (*b*) guanophores, with guanin granules; (*c*) xanthophores, with yellow granules; (*d*) erythrophores, with red granules. After total hypophysectomy, or removal of only the pars intermedia, the granules of the melanophores and erythrophores in fishes, and those of the melanophores in amphibians, are found concentrated around the nucleus; the rest of the cell, including the cellular processes, remains colorless (Fig. 236). The animals become pale, a fact which has been observed in tadpoles,[1] adult frogs,[2] and several species of fishes and reptiles.

[1] Abel, 1914; Allen, 1916; and Smith, 1916.

[2] Hogben and Winton, 1922; Giusti and Houssay, 1924.

Injection of hypophyseal extract causes intense darkening of the skin in normal and hypophysectomized amphibians.[1] This is due to dispersion of the pigment granules all over the protoplasm and cell processes, with the formation of a dark network. The cell does not expand, as was suggested by the term "melanophore-expanding substance," given to this principle. The substance should be called "melanodispersing principle," and the effects observed, "melanodispersion" and "melanoconcentration."

The pars intermedia secretes a substance that maintains a certain degree of dispersion of the melanosomes within the pigment cells. Zondek (1932) gave the name of "intermedin" to the hormone that disperses the erythrosomes in fishes, but it seems to be the same one that acts on the melanosomes of amphibians. The melanodispersing hormone exerts a continuous effect, as is shown by the rapidity with which the animals become pale after hypophysectomy. The following evidence proves that the hormone is secreted by the pars intermedia: (*a*) extracts of pars intermedia contain a higher concentration of the substance than other parts of the gland;[2] (*b*) destruction of the pars intermedia by parasites (Bayer) or by surgical removal (Atwell) in the embryo causes the development of pale animals with the pigment concentrated around the nucleus of the pigment cell, although the other parts of the hypophysis are intact; (*c*) pure cultures of cells of the pars intermedia produce the melanodispersing substance; (*d*) grafting pars intermedia into hypophysectomized tadpoles restores their normal skin color (Swingle).

The skin color of amphibians is controlled by several factors which act on the granules of the pigment cells: (*a*) the secretion of the pars intermedia; (*b*) adrenaline secreted by the adrenals; (*c*) nerves acting on the pigment cells. The hypophysis is the predominant factor in amphibians, and hypophysectomy reduces to a minimum pigmentary responses to light and darkness, and suppresses the effects of many drugs. The skin of amphibians deprived of light or blinded by removal of the eyes becomes dark[3] owing to an increase in hypophyseal secretion. When the animals are placed in a strong light they become pale because hypophyseal secretion diminishes, and the secretion of adrenaline, which has a melanoconcentrating effect, increases. Light exerts its effects on the hypophysis through the hypothalamus; section of the nerve paths from the hypothalamus to the hypophysis suppresses these effects (Stoppani).

Extracts of mammalian hypophysis also have a melanodispersing effect, but its physiologic significance is unknown. Substances that darken the skin of amphibians have been found in human urine, but it is not known whether they are produced by the hypophysis. Purified preparations of the melanodispersing hormone have been obtained by Stehle and later by Geiling.[1]

Hypophysectomy diminishes the dispersing effect of light on the melanic pigment of the retina. Injection of posterior lobe extracts restores the response to light.

FUNCTIONS OF THE PARS DISTALIS

The pars distalis, commonly called the "anterior lobe," fulfills the following functions: (*a*) stimulation of growth and development; (*b*) stimulation and control of other endocrine glands; (*c*) stimulation and control of sexual functions; (*d*) control of metabolic processes. Functions (*a*), (*b*), and (*d*) are necessary for the development and maintenance of the individual; function (*c*) is necessary for the maintenance of the species. The anterior hypophysis is the central organ of the endocrine system because it is an important factor in the development and maintenance of the structure and activity of other endocrine glands. Extirpation of the anterior hypophysis is followed by the atrophy of most of the endocrine glands. A hypophysectomized animal suffers from multiple endocrine insufficiencies and metabolic disturbances.

Methods of study. To demonstrate an anterior hypophyseal function, the following evidence must be obtained: (*a*) the removal of the anterior lobe must cause a definite and specific disturbance; (*b*) the disturbance must be controlled by restoring the anterior lobe (injection

[1] Hogben and Huxley, 1921; Houssay and Ungar, 1924–1925.

[2] In fowls, whales, and other animals without a differentiated pars intermedia, the melanodispersing substance is found in the anterior lobe, not in the pars nervosa.

[3] If the anterior half of a dark toad is joined by blood vessels to the posterior half of a light toad, the latter darkens. If the anterior half is light and the posterior half is dark, the latter becomes light. Therefore there is a hormonal factor produced in the anterior half which controls the color of the skin (Stoppani, A., *Endocrinology*, **30**, 782, 1942).

[1] Geiling, E. M. K., *Harvey Lect.*, **37**, 269, 1942; Chen, G., and E. M. K. Geiling, *J. Pharmacol. & Exper. Therap.*, **78**, 222, 1943.

of extracts or purified hormones, glandular grafts or implants); (*c*) hyperfunction obtained by implantation of the gland, or by injection of large doses of extracts or purified hormones, should produce effects opposed to those of insufficiency. All these proofs are needed for a complete demonstration; one or another alone is not sufficient evidence of the existence of the hypothetical function. In man similar evidence is obtained by (*a*) clinical, and eventually anatomical, examination of subjects suffering from diseases of the hypophysis; (*b*) treatment of the condition by injection of hypophyseal extracts or hormones, or by implantation of hormones in pellets; (*c*) surgical removal of the hypophysis or inhibition of the gland by x-rays, hormones, or other means.

Anterior hypophyseal hormones. Six hormones have been identified as secretions of the pars distalis. Usually they are called by the name of the organ or tissue or function on which they act. In some cases the suffix "-trophin" (Parkes, Corner) is added to indicate that the hormone stimulates the nutrition and functions of the cells it acts on, *e.g.*, thyrotrophin. The International Committee on Biological Assay has adopted this terminology. The suffix "-tropin," indicating that the hormone is directed to a certain tissue or organ, is also used, *e.g.*, thyrotropin. The six hormones are:

1. Growth (somatotrophic) hormone (GH), which accelerates body growth.
2. Prolactin (or luteotrophic hormone), which maintains and stimulates the secretion of the corpus luteum and stimulates the secretion of milk in mammals and the secretion of the crop glands in birds.
3. Thyrotrophin (TSH), which stimulates the thyroid gland.
4. Adrenotrophin (or corticotrophin, or adrenocorticotrophin [ACTH]), which stimulates the adrenal cortex.
5. Follicle-stimulating (or maturation) hormone (FSH), which provokes maturation of the ovarian follicle and spermatozoa.
6. Luteinizing (or interstitial-cell-stimulating) hormone (LH or ICSH), which provokes ovulation and the formation of the corpus luteum and stimulates the interstitial cells of the ovary and testicle.

These hormones are proteins; most of them have been obtained in crystallized form, and several are glucoproteins. They have been classified, according to the functions on which they exert their influence, into (*a*) metabolic hormones, and (*b*) gonadotrophins (Table 75). Some of them act directly on the tissues, *e.g.*, somatotrophin; others do so indirectly by stimulating the secretion of another gland, *e.g.*, adrenocorticotrophin stimulates the adrenal cortex, which secretes hormones acting on different tissues and functions.

Table 75. Hormones of the Pars Distalis

Function	*Hormone*	*Crystallized*	*Glucoprotein*	*Protein*
Metabolic	Somatotrophin	+	−	+
	Thyrotrophin	−	+	−
	Adrenocorticotrophin	+	−	+
Gonadotrophins	Follicle-stimulating	+	+	−
	Luteinizing	+	+	−
	Prolactin	+	−	+

Several other functions of the hypophysis and pharmacologic effects of the extracts have been observed, but the active substances responsible have not been isolated. It is not therefore justifiable to speak of hormones in these cases; it is more appropriate to refer to these as activities or factors. The main ones are (*a*) diabetogenic; (*b*) glycotropic (increase of resistance to insulin); (*c*) glycostatic (arrest of the fall in liver glycogen in hypophysectomized fasting rats); (*d*) glycogenolytic; (*e*) pancreatotrophic (hyperplasia of the islets of Langerhans); (*f*) parathyrotrophic (stimulation of the parathyroid glands); (*g*) ketogenic (increased formation of ketone bodies); (*h*) mammogenic (stimulates growth of the acini and ducts of the mammary glands); (*i*) renotrophic; (*j*) thymotrophic; etc. Purified extracts exert more than one of these effects, so probably there is not a separate principle for each one of them. Moreover, frequently more than one hormone acts on the same function.

It is not yet possible to say which of the cells of the hypophysis secrete the different hormones. There is evidence that acidophil cells secrete somatotrophin and prolactin and that basophil cells secrete gonadotrophins, thyrotrophin, and adrenocorticotrophin.

International units. International standards have been prepared and the units defined for the following hormones: (*a*) adrenocorticotrophin, 1 mg.; (*b*) prolactin, 0.1 mg.; (*c*) chorionic gonadotrophin, 0.1 mg.; (*d*) serum gonadotrophin (pregnant-mare serum), 0.25 mg.

Antihormones. After being repeatedly injected with some of the anterior hypophyseal protein hormones, animals respond less and eventually cease to respond. Globulins (antihormones) appear in the plasma of these animals which neutralize the effects of the hormone. Prolonged treatment with a hypophyseal hormone (thyrotrophin, gonadotrophin) causes atrophy of the glands involved (thyroid, gonads) of the same degree as is seen after hypophysectomy (see Antihormones, Chap. 51). The most typical and effective of the antihormones are those against thyrotrophin (antithyrotrophin) and gonadotrophins (antigonadotrophins.) The growth and diabetogenic factors also lose their potency after several injections have been given. Antihormones are specific for the hormones that they antagonize, but they are not strictly specific for the animal species that has produced them. Antihormone formation has also been observed in man; it is a serious obstacle in prolonged treatment with anterior hypophyseal hormones. In laboratory experiments it is possible to maintain the efficacy of an anterior hypophyseal preparation by periodically increasing the dose.

Animals do not produce antihormones against their own hormones. There are no antihormones normally circulating in the blood. Moreover if two animals are united in parabiosis[1] antihormones are not formed against the hormones secreted by the partners. For example, a castrate rat produces an abnormally high amount of gonadotrophin owing to hypertrophy of the anterior hypophysis; if it is united in parabiosis with a normal rat, the latter responds to the excess of gonadotrophin, and does not form antigonadotrophins.

Nervous control of the anterior hypophysis. Control of the antidiuretic secretion of the neurohypophysis by impulses arising in the supraoptic nuclei has been already discussed. Control of the secretion of the melanodispersing hormone by reflexes provoked by the action of light on the retina has also been mentioned. The pars distalis is also to a certain extent under nervous control, but the origin of the impulses and the path they follow to arrive at the hypophysis are still unknown. Moreover, few nerve fibers pass from the hypothalamus to the pars distalis. According to Harris,[1] the hypothalamus secretes substances which pass down to the hypophysis through the diencephalohypothalamic portal vessels which descend in the hypophyseal stalk and are distributed in the pars distalis. This seems to be an adrenergic effect (Markee).

Stimulation of the hypothalamus provokes secretion of gonadotrophins which cause ovulation followed by luteinization in rats and rabbits. It also provokes secretion of adrenocorticotrophin.[2]

Section of the hypophyseal stalk did not disturb the sexual cycle, ovulation, pregnancy, or lactation in some cases; in others, there were varying degrees of atrophy and hypofunction of the ovaries, testes, thyroid, and adrenals. According to Harris,[3] normal functions depended on the existence of a normal circulation between the labrum infundibularis and the hypophysis; when this circulation was not restored after section of the stalk, hypophyseal insufficiency occurred.

Certain circumscribed lesions of the hypothalamus are followed by atrophy and hypofunction of the gonads, apparently because gonadotrophin secretion is inhibited. In some cases only the secretion of the luteinizing hormone is inhibited (Dey). In others, secretion of adrenocorticotrophin caused by direct stimulation of the hypothalamus is no longer observed (Hume[4]). There is evidence that rhythmic activity of the hypothalamus controls the sexual cycle and ovulation (Everett[5]).

Intense, permanent illumination causes hypertrophy of the sexual glands and organs in certain species (ferrets, birds) during the winter season in which they are normally atrophied. Light acts on the retina and provokes reflex activity of the hypophysis; extirpation of the eyes or the hypophysis suppresses this effect of light. In species that do not ovulate spontaneously, but

only under the influence of copulation (rabbit, cat, ferret), visual stimulation (pigeons), or sexual clasping (toads), ovulation is suppressed by extirpation of the hypophysis (rabbit) or the pars distalis (toad), or by section of the hypophyseal stalk (rabbit).

Hypophyseal insufficiency. Extirpation of the hypophysis causes multiple and severe disturbances, mainly in metabolism, growth, and development. If the operation is performed in a young animal, growth is retarded or ceases, and the animal remains a dwarf with infantile characteristics. The skin remains thin and the hair is fine and soft like the lanugo of the fetus. There is hypoplasia or atrophy of the thyroid, the corticoadrenals, and the sexual glands and organs. Survival after hypophysectomy depends on the severity of metabolic disturbances, and it varies in different species. Dogs, which feed well, survive a long time if care is taken to preserve them from cold, hypoglycemia, and infection; rats, which do not eat much, lose weight and die in cachexia, after a much shorter interval; toads survive even less time.

Hypophysectomized animals must be fed frequently; otherwise the blood sugar and the liver and muscle glycogen decrease rapidly after a few hours of fasting, and they die in hypoglycemia if carbohydrate is not given in time. The BMR is low, and the body temperature is usually subnormal. The arterial blood pressure is low. Muscular tone and activity are diminished in varying degrees according to the species. If the animal is a lactating female, milk secretion ceases almost immediately after hypophysectomy and the mammary gland is rapidly atrophied. In animals that feed well (*e.g.*, the dog) there is frequently accumulation of fat which leads to moderate obesity. Hypophysectomized rats lose weight because they do not feed well. The hypophysis cannot be considered essential for life, since hypophysectomized animals survive, but they are very sensitive to cold, trauma, infections, fasting, and agents that cause hypotension or hypoglycemia. They suffer from severe metabolic disturbances which make them "frail," and great care must be taken of them or they die.

Hypophyseal insufficiency has been observed in man after surgical removal of the hypophysis, and in cases of Simmonds' disease. The latter is observed more frequently in women and is due to extensive destructive lesions of the anterior hypophysis, the most common cause of which is post-partum ischemic atrophy of the hypophysis. The principal signs are (*a*) atrophy of the gonads and sexual organs, amenorrhea, loss of libido and sexual impotence, atrophy of the mammary gland; (*b*) complete loss of pubic and axillary hair; (*c*) characteristic facies, pale and with sparse eyebrows; (*d*) dry skin; (*e*) physical and mental weakness; (*f*) low BMR, subnormal body temperature, and sensitiveness to cold; (*g*) hypersensitiveness to insulin, tendency to hypoglycemia, and low postabsorptive glycemic curve; (*h*) low urinary 17-ketosteroids. Cachexia was supposed to be a frequent outcome, but Sheehan has shown this is not so. Extreme emaciation is observed in anorexia nervosa,[1] but seldom in hypophyseal insufficiency. Autopsy shows atrophy of the endocrine glands.

Daily implantation of fresh anterior hypophysis easily corrects all the disturbances caused by hypophysectomy in the rat.[2]

Action on Growth

The pars distalis of the hypophysis is the most important endocrine factor in the stimulation and control of postnatal growth in vertebrates. Invertebrates have no hypophysis, and this gland is not necessary for the development of the vertebrate embryo and fetus; moreover growth continues in newborn mammals for several weeks after hypophysectomy. At a certain stage of development, however, the hypophysis is a necessary factor for further growth in birds and mammals. Hypophysectomy in young animals causes considerable delay, and in some cases complete cessation, of growth;[3] the animals remain dwarfs (Fig. 237). Anterior hypophyseal insufficiency in children also arrests development and they become dwarfs.

Hypophysectomized rats, forcibly fed by stomach tube to assure the ingestion of a normal

[1] In the course of anorexia nervosa some of the symptoms of hypophyseal insufficiency are observed. Prolonged undernourishment in rats causes a marked decrease in several anterior hypophyseal functions (Mulinos and Pomerantz).

[2] Treatment of hypophyseal insufficiency in man consists of injections of anterior hypophyseal extracts, which are not always efficacious. Testosterone and sometimes cortisone are also useful. Insulin injections are always dangerous because of the facility with which these patients fall into hypoglycemic shock. It is important that an adequate diet should be ingested.

[3] This was first seen by Caselli in the dog, and later was confirmed in many other vertebrate species.

amount of food, increase in weight less than normal animals; they form more fat, retain less nitrogen, and have great difficulty in forming body protein. The skeleton remains small, and bones do not grow normally, especially in length; this effect is due to a profound disturbance in the epiphyseal cartilages, where ossification is almost completely arrested. In all species the teeth grow slowly, and the eruption of the permanent teeth is retarded. In the dog the pulp cavity is large and the teeth are small (Erausquin); in the rat, dentine grows inward and obliterates the pulp cavity (Schour). All disturbances in growth caused by hypophysectomy are compensated by grafting or implanting anterior hypophyseal tissue, or injecting anterior hypophyseal extract (Smith); it is even possible by these methods to obtain growth that is greater than normal. Oral administration of anterior hypophyseal preparations has no effect in mammals.

a

b

FIG. 237. Effect of hypophysectomy on growth. *a*, four puppies from the same litter; the hypophysis had been removed from the two on the right 8 days before; *b*, three of the same animals 124 days after hypophysectomy; the dog on the left is the control.

Giantism has been provoked in rats by prolonged intraperitoneal administration of anterior hypophyseal extract (Evans and Long, 1934). The weight of the injected animals is twice that of the controls. This exaggerated growth is particularly marked in the bones and viscera. Protein and water are accumulated in relatively higher proportions than fat (Lee). The epiphyseal cartilages are widened, and there is active endochondral ossification. The acceleration of growth is more marked at first in females than in males; it is especially notable in castrated females. Anterior hypophyseal extracts also accelerate growth in dogs, causing disturbances similar to those observed in human cases of acromegaly (Fig. 238).
a
b

FIG. 238. Effect of anterior hypophyseal extract on growth. *a*, dog treated with bovine anterior hypophyseal extract (10 cc. daily intraperitoneally during 6 months) shows prominent signs of giantism; *b*, litter-mate control. (*Evans, H. M., et al., "Growth and Gonad-stimulating Hormones of the Anterior Hypophysis," vol. 2, Mem., University of California, Berkeley, Calif., 1933.*)

Li and Evans[1] have obtained a purified crystalline growth hormone, which acts directly on the tissues and produces its effects not only in

[1] LI, C. H., and E. M. EVANS, *Science*, **99**, 183, 1944; *Vitamins & Hormones*, **5**, 197, 1947.

normal animals but also after hypophysectomy, thyroidectomy, or castration. Simultaneous administration of thyroid increases the effect of the growth hormone. Insulin has a favorable effect on the action of the growth hormone. Adrenocorticotrophin and several of the corticoadrenal and ovarian hormones have an unfavorable effect on the action of the growth hormone.

After an injection of growth hormone, nonprotein nitrogen decreases in blood plasma and in the liver, apparently owing to nitrogen being taken up by the tissues at a higher rate. There is a positive nitrogen balance and the amount of body protein increases as long as the animal grows. There is also retention of P, Ca, and K. P and phosphatase in plasma increase. Body fat diminishes. Liver glycogen increases, and the animals become insulin-resistant. With sufficiently high doses a diabetogenic effect is observed. If the treatment is kept up for a sufficiently long time the rate of growth diminishes in the rat; in guinea pigs growth ceases, owing to the complete ossification of the epiphyseal cartilages.

Acromegaly (Fig. 239) is a disease in which the hands and feet are abnormally developed. Its name, given by Pierre Marie, in 1866, means literally "large extremities" (Greek, ακρο-, terminal or extreme, μεγαλη, large). There is a large, prominent jaw, the zygomatic and superciliary arches and the frontal sinuses are enlarged, and the bones of the skull are irregularly thickened. The viscera are abnormally large (splanchnomegaly). The skin and the subcutaneous connective tissue are thickened. After the disease has lasted for some time there are hyperphosphatemia, a negative calcium balance, and osteoporosis of the vertebrae which leads to kyphosis. The general aspect of patients with acromegaly is striking; they have the appearance of a primitive man or gorilla, and when there is kyphosis they resemble the classical figure of Punch.

The hypophysis is hypertrophied and the sella turcica enlarged, as can be seen in radiographs of the cranium. At autopsy eosinophil adenomata or an increase in eosinophil cells in the anterior hypophysis are found. Glycosuria and diabetes have been reported in 32 per cent of the cases published. Other endocrine disturbances in acromegaly will be considered further on.

Giantism (Fig. 239) is caused by hypophyseal
a
b

FIG. 239. *a*, acromegaly. (*Courtesy of Dr. E. B. del Castillo.*) *b*, giantism; the subject's height was 2.51 m. (*Cushing, H., "The Pituitary Body and Its Disorders," Lippincott, Philadelphia, 1912.*)

hyperfunction when the cartilages are still in the process of ossification. The subject's height may be 2.30 or even 2.60 m. Signs of acromegaly are frequently found in giants.

The different functions of the anterior hypophysis can be disturbed separately; thus a race of dwarf mice, which reproduces normally, has been described. There are no eosinophil cells in the hypophysis of these animals.

Hypophyseal extracts or growth hormone have not promoted growth in human dwarfs. The results cannot be compared with those obtained with gonadotrophins, testosterone, or thyroid preparations.

ACTION OF THE PARS DISTALIS ON THE DEVELOPMENT AND REGULATION OF ENDOCRINE GLANDS

The pars distalis is the central star in the endocrine constellation. It regulates other glands of internal secretion, and reciprocally, it is under the influence of certain endocrine glands. This can be summarized in the following diagram:

Adrenal cortex ⇄ (*stimulates* / *inhibits*) Pars distalis of the hypophysis ⇄ (*stimulates* / *inhibits*) Gonads

Pars distalis of the hypophysis ⇅ (*stimulates* / *inhibits*) Thyroid
The anterior hypophysis secretes hormones that stimulate the anatomical and functional development of the gonads, the thyroid, and the adrenal cortex, and which are necessary for the maintenance of the normal structure and functions of these glands. Extirpation of the anterior hypophysis in young animals causes structural and functional hypoplasia (insufficient development) of these glands; in adults it provokes atrophy and hypofunction.

Hormones secreted by the endocrine glands regulated by the anterior hypophysis have a specific effect on the structure and function of the pars distalis, as is seen in the above diagram. Castration provokes an increase in the secretion of hypophyseal gonadotrophins; adrenalectomy is followed by an increase in adrenocorticotrophin, etc. This hypophysoendocrine interrelation controls the functional state of the endocrine glands in normal and pathologic conditions.

The hormones of the anterior hypophysis act in one of three ways: (*a*) directly on the tissues, *e.g.*, the growth-stimulating factor; (*b*) by indirect stimulation, *e.g.*, gonadotrophins stimulate the ovaries, which secrete hormones stimulating the development of secondary sexual organs; (*c*) by indirect inhibition, *e.g.*, the anterior hypophyseal diabetogenic factor inhibits the pancreatic islets and suppresses insulin secretion; large amounts, injected for a sufficiently long time, damage the islet cells irreversibly and cause permanent diabetes.

Hypophysis and Thyroid

Effect of hypophysectomy on the thyroid. The pars distalis secretes thyrotrophin, a hormone that stimulates the thyroid to complete its structural and functional development. Thyroid secretion regulates the function of the pars distalis, diminishing its secretion, especially that of thyrotrophin. The hypophysis exerts a continuous effect on the thyroid; hypophysectomy therefore causes hypoplasia of the thyroid in young animals and considerable atrophy of the thyroid in adults. The same effects are observed after extirpation of the anterior lobe, but not after removal of the posterior lobe, if the pars distalis remains intact. The thyroid shows similar disturbances in human cases of hypophyseal insufficiency. The thyroid of hypophysectomized animals has a smaller volume and weighs less than that of controls. The most typical changes are flattening of the epithelium and cytological signs of hypofunction, such as a small nucleus, atrophy of the Golgi apparatus, disappearance of intracellular colloid droplets, etc. The follicles are enlarged in some species and smaller than normal in others; the colloid is not reabsorbed (Figs. 240 and 241).

The thyroid gland of hypophysectomized animals takes up less iodine than the normal, and the formation of thyroxine diminishes. Secretion of thyroxine also diminishes, and after an initial rise in blood iodine, the concentration of blood iodine diminishes and remains permanently below normal, as in cases of hypothyroidism.

There are several signs of hypofunction (not of complete functional suppression) of the thyroid in hypophysectomized animals: (*a*) BMR below normal; (*b*) low blood-iodine concentration; (*c*) increase in plasma globulins; (*d*) decrease in the phagocytic capacity of the leukocytes; etc. The thyroid is a necessary factor in the metamorphosis of amphibians, therefore if the hypophysis is extirpated in tadpoles, owing to thyroideal

hypofunction, the animals remain in the larval state. The thyroid of the axolotl always remains rudimentary, so these animals do not develop beyond the larval state, although they can reproduce. The administration of thyroid preparations, or the stimulation of the thyroid by the injection of thyrotrophin, causes metamorphosis to take place, and the animals are converted into salamanders. In adult amphibians hypophysectomy causes the normal shedding of the skin to cease, an effect also produced by thyroidectomy;[1] in birds there are disturbances in the plumage.

Effects of hypophyseal extracts on the thyroid. Anterior hypophyseal extracts have a thyrotrophic effect. A fairly pure thyrotrophin has been prepared; it has no other hypophyseal effects except a slight adrenocorticotrophic action. Thyrotrophin stimulates, anatomically and functionally, the thyroid of normal and hypophysectomized animals. Newborn chicks, guinea pigs, and toads are especially sensitive, but rats are not very sensitive to thyrotrophin.

The thyroid of animals injected with thyrotrophin increases in volume, weight, and vascularization. A characteristic response is the increase in height of the epithelial cells and the appearance of intraprotoplasmic colloid (de Robertis). Many of the cells are seen undergoing mitosis[2] (Figs. 240 and 241). The colloid is reabsorbed from the follicles; its iodized substances are mobilized, and the iodine content of the thyroid diminishes, while blood iodine increases. The thyroid takes up abnormally large amounts of iodine and forms organic iodized substances at a higher rate than the normal thyroid. Thyrotrophin produces intense effects very rapidly, acting directly on the thyroid tissue. This can be demonstrated by denervating the thyroid and in thyroid grafts; or by adding thyrotrophin to slices of thyroid tissue surviving *in vitro*. Thyrotrophin is inactivated, but not destroyed, when placed in contact with thyroid, thymus, or lymphoid tissue.

Fig. 240. Effect of hypophysectomy and anterior hypophyseal extract on the thyroid of the toad *Bufo arenarum* (Hensel) Left, hypophysectomized toad; middle, normal toad; right, toad injected with extract of pars distalis.

Thyrotrophin provokes the following symptoms of hyperthyroidism in animals with an intact thyroid, which do not appear if the thyroid has been previously removed: (*a*) increase in the BMR;[1] (*b*) polyuria; (*c*) increase in blood iodine; (*d*) decrease in liver glycogen; (*e*) increase in the heart rate; (*f*) decrease in resistance to anoxia. Metamorphosis is provoked in the axolotl and accelerated in tadpoles, but not if the animals have been previously thyroidectomized. Hypophysectomized amphibians shed their skin, and there are changes in the plumage of birds.

Thyrotrophin increases the BMR in man as well as in other species. This effect is not observed in thyroidectomized subjects or in patients in whom thyroid function has been depressed by iodine treatment or other means. Thyrotrophin produces hyperthyroidism in a first stage, but later the preparation loses its efficiency, and there are signs of hypothyroidism

[1] *Bufo arenarum* (Hensel) differs from other amphibians in that hypophysectomy causes this disturbance in the skin, but thyroidectomy does not.

[2] Injection of colchicin arrests mitosis before it is completed, so the cells undergoing division can be counted. Many more cells in mitosis are found in the thyroid of animals injected with thyrotrophin than in the thyroid of the controls.
[1] Total anterior hypophyseal extract causes a slight rise in the BMR even after thyroidectomy.

such as a low BMR and flattening of the thyroid epithelium. At this stage the blood plasma has an antithyrotrophic activity.

In human cases of hyperfunction of the hypophysis (acromegaly), hypertrophy of the thyroid has been observed in 57 per cent, and a high BMR has been reported in two-thirds of the cases published (Atkinson).

Thyrotrophin is inactivated by the thyroid and eliminated in the urine in this inactive form, but it can be reactivated by heating the urine. In normal subjects active thyrotrophin is also found in the urine, but in hyperthyroid patients only the masked, inactivated form is found, because the capacity of the thyroid to inactivate thyrotrophin is increased in these cases. On the contrary, in patients with thyroid insufficiency only free thyrotrophin is found in urine.[1]

Thyrotrophin causes exophthalmos (protruding eyeballs), which is more marked in thyroidectomized animals than in those with an intact thyroid.[2] According to Smelser, exophthalmos is produced in this case by edema of the tissues of the orbit; Dobyns considers that it is due mainly to an increase in the fatty tissues of the orbit.

The hypophysis of thyroidectomized animals. The thyroid has a definite influence on the pars distalis of the hypophysis. Thyroidectomy causes an increase in the volume and weight of the anterior lobe of the hypophysis, which on histologic examination is seen to contain considerably fewer eosinophil cells and more basophil cells than the normal hypophysis. Numerous fine colloid vacuoles, coalescing to form larger ones, are observed in the basophil cells, and in some instances a single very large vacuole.[3]

Hypophyseal colloid increases after thyroidectomy. This colloid substance differs from that in the thyroid by its lower iodine content and several other features.

The pars distalis of thyroidectomized animals

FIG. 241. Effect of hypophysectomy and anterior hypophyseal extract on the thyroid of the dog. Above, hypophysectomized dog; the epithelium is flat and atrophic. Below, animal injected with anterior hypophyseal extract; the epithelium is high and forms folds, the colloid is fluid and vacuolated.

[1] MEANS, J. H., *Am. J. M. Sc.*, **1**, 207, 1944.

[2] Schockaert in ducks; Marine and Rosen in guinea pigs.

[3] Castration also causes the appearance of vacuolated cells in the anterior hypophysis, but they can be differentiated by cytological methods from those seen after thyroidectomy. Thyroid treatment is more efficacious than the injection of sexual hormones for the normalization of hypophyseal cells of thyroidectomized animals, and sexual hormones are more efficacious than thyroid preparations for the normalization of hypophyseal "castration" cells.

has less thyrotrophin[1] and gonadotrophin[2] than is found in the hypophysis of normal rats.

Changes in the hypophysis produced by thyroidectomy are not compensatory responses to thyroid insufficiency, because they do not diminish the symptoms of hypothyroidism. Thus hypophysectomy following thyroidectomy does not cause a further fall in the already low BMR.

The effect of thyroid treatment on the hypophysis. Thyroid treatment restores the normal aspect of the anterior hypophysis in thyroidectomized animals. An excess of thyroid causes an increase in the number of eosinophil cells, a small increase in basophil cells, and reabsorption of the hypophyseal colloid. Thyrotrophin activity of the anterior hypophysis is considerably diminished and disappears completely if the treatment is sufficiently intense and prolonged. The sexual activity of the hypophysis increases in animals on thyroid treatment, if the treatment is not too intense (Reforzo-Membrives), but if thyroid is given in large doses over a long period, the gonadotrophin content of the anterior hypophysis diminishes (Arrighi).

Adrenotrophic Action of the Hypophysis

The pars distalis of the hypophysis secretes a substance which continuously stimulates the adrenal cortex and maintains its normal structure and function.[3] This substance is known as adrenocorticotrophin or adrenocorticotrophic hormone (ACTH).

Effect of hypophysectomy on the adrenals. Extirpation of the hypophysis, or of its anterior lobe, causes atrophy of the adrenal cortex (Fig. 242). No structural changes are seen in the adrenal medulla and its adrenaline content is not altered. Corticoadrenal atrophy has also been observed in human cases of hypophyseal insufficiency. Retrogressive changes are especially marked in the central part of the adrenal cortex, *i.e.*, the reticular zone and the deeper part of the fascicular zone. Compensatory hypertrophy of the adrenal cortex is not observed in hypophysectomized animals. Thus if subtotal adrenalectomy is performed in normal animals the remaining cortical tissue hypertrophies, but this does not occur in hypophysectomized animals; therefore adreno-

Fig. 242. Effect of hypophysectomy on the adrenal. Above, transverse section of normal rat adrenal. Below, transverse section of the adrenal from a rat 1 month after hypophysectomy. The medulla is normal; the cortex is atrophic, especially the inner layers (light); the outer layers appear dark because the cells have little protoplasm and the nuclei of the different cells are close to each other.

[1] If a thyroidectomized rat is joined in parabiosis with a normal one, there is no increase in the weight or activity of the normal animal's thyroid.

[2] Reforzo-Membrives, J., *Endocrinology*, **32**, 263, 1943.

[3] Houssay, B. A., *Prensa méd. argent.*, **20**, 1563, 1933; Swann, H. G., *Physiol. Rev.*, **20**, 493, 1940; Tepperman, J., F. L. Engel, and C. N. H. Long, *Endocrinology*, **32**, 373, 1943.

corticotrophin is a necessary factor in this process. The cytological process of atrophy varies in different species. In hypophysectomized rats the corticoadrenal cells are small and have no fatty droplets; there is a light zone near the medulla, where many of the cells have disappeared, surrounded by a zone that appears dark because it is made up mostly of nuclei, owing to the cells having lost most of their protoplasm. In dogs and toads the cells are at first overloaded with large droplets of fat; later, in the dog, there is vacuolar or areolar degeneration of the protoplasm, and the cells die gradually.

The adrenal cortex of hypophysectomized animals has the structural appearance of hypofunction, but it continues to secrete enough hormones to maintain the animals alive. Adrenalectomy is followed by a typical and fatal syndrome of adrenal insufficiency.

Adrenocorticotrophin. Injection of anterior hypophyseal extract or of ACTH stimulates the adrenal cortex. In hypophysectomized animals it prevents adrenal atrophy, or restores the normal condition of the adrenals if they are atrophied. In normal animals it causes adrenal hypertrophy.

This hormone was separated as an apparently pure thermolabile protein;[1] later, by electrophoresis or by adsorption on oxycellulose, a preparation 100 times more potent was obtained.[2] Active polypeptides have been obtained by hydrolysis. Probably ACTH is a complex substance, because parts with different properties have been split off the parent substance.

Adrenal hyperfunction produced by injection of ACTH or by an increase in the secretion of the hormone by the pars distalis is revealed by the following signs, which are not seen in adrenalectomized animals:

1. Atrophy of the thymus and lymphoid tissue.
2. Decrease in lymphocytes and eosinophil cells in the blood. Since eosinopenia does not occur if the adrenal is not functioning, it is used as a clinical test of adrenal function (Thorn).
3. Increase in blood sugar, liver glycogen, and resistance to fatigue in hypophysectomized animals.
4. Increase in protein catabolism, especially if large doses are given.
5. Increased urinary elimination of uric acid in man.
6. Increased urinary elimination of 17-ketosteroids, oxysteroids, and glucocorticoids.
7. Retention of water, Cl, and Na and increased elimination of K.
8. Increase in the severity of diabetes that has been attenuated by hypophysectomy (Long). In man occasionally diabetic signs have been observed (Conn *et al.*).
9. Increased resistance to insulin.
10. Increase in liver arginase.

In some species it retards ossification and general growth, behaving in this respect as an antagonist of the growth hormone (see page 622).

ACTH causes marked and rapid decrease in the ascorbic-acid and cholesterol content of the adrenal cortex. ACTH can be rapidly and accurately assayed by injecting it into a hypophysectomized rat and measuring the decrease in the ascorbic acid of the adrenal cortex provoked in 1 hr.[1]

There is a rapid increase in the secretion of ACTH, which stimulates the adrenal cortex in many circumstances in which the organism is under stress, such as cold, trauma, violent exercise, or the administration of certain drugs (histamine, formaldehyde, etc.).

The adrenal gland normally inhibits the hypophyseal secretion of ACTH. Adrenalectomy is followed by an increase in ACTH secreted into the blood.

In cases of hyperpituitarism in man, an increase in the size of the adrenals is frequently observed, and in some cases of acromegaly adenomas made up of corticoadrenal cells have been found (see Cushing's disease, Chap. 54).

The Hypophysis and the Sexual Glands

The anterior hypophysis secretes gonadotrophins, which contribute to the development and maintenance of the structure and function of the sexual glands and organs and play a part in

[1] Sayers, M. A., G. Sayers, and L. A. Woodbury, *Endocrinology*, **42**, 379, 1948.

the regulation of the sexual cycle, estrus and menstruation, ovulation, libido, pregnancy, and lactation. Reciprocally the hormones of the ovary and testes regulate hypophyseal structure and function. These facts will be considered when dealing with reproduction in Sec. VII.

Interrelations between the Hypophysis and other Endocrine Glands

Parathyroids. There is no definite proof that the anterior lobe of the hypophysis secretes a hormone that contributes to the development and maintenance of the parathyroid glands, but hypophysectomy is followed by certain changes in these glands. Thus they are smaller in hypophysectomized than in normal tadpoles (Smith) and are made up of abnormally small cells in the rat and monkey. Retrogressive lesions have been observed in the parathyroids of 60 per cent of hypophysectomized dogs and in only 10 per cent of the controls (Houssay and Sammartino). These lesions were seen only in limited areas. They consisted in accumulations of nuclei surrounded by very little protoplasm (syncytioid structures) and in hyaline areas deprived of cells. In hypophysectomized pancreatectomized dogs these lesions were more marked and frequent. They may be due to general nutritive disturbances and not to the absence of a specific parathyrotrophic hormone. Moreover hypophysectomized dogs have a normal blood-calcium level (Marenzi and Gerschman), therefore there cannot be a marked condition of parathyroid insufficiency. Anterior hypophyseal extracts have been reported to produce histologic signs of hyperactivity in the parathyroid with an increase in calcemia (Anselmino and Hoffman), which does not occur in parathyroidectomized animals. In only a few cases of acromegaly or hypophyseal basophilism has the condition of the parathyroids been reported; in some they were found to be normal; in others hyperplasia and in a few cases adenomas were found.

Pancreas. The anterior hypophysis has no pancreatotrophic effect. Hypophysectomy is not followed by atrophy of the pancreatic islets. In hypophysectomized animals the zymogenous and endocrine tissue of the pancreas is less developed than in normal animals, but since the deficiency in zymogenous tissue is greater, there is more islet tissue per unit volume or weight of pancreas. The islet structure, insulin content, and insulin secretion are normal.[1] Anterior hypophyseal extracts produce two types of response according to the dose, the animal, and the condition of the pancreatic islets: (*a*) an increase in the islets and insulin content, which Anselmino and Hoffman called the "pancreatotropic effect," attributing it to a specific hormone; (*b*) lesions in the islet cells, which are transitory or permanent, causing hypophyseal or metahypophyseal diabetes (see Chap. 41).

METABOLIC FUNCTIONS OF THE PARS DISTALIS

The pars distalis of the hypophysis has a regulatory effect on many metabolic processes. Some of these effects are exerted directly by the hypophysis, others indirectly through stimulation of another gland. These secondary effects may be of a general character, *e.g.*, the action of the thyroid on oxygen consumption by the tissues. Others are localized to a certain tissue, *e.g.*, the effects of ovarian hormones on the uterus.

Basal Metabolism

The pars distalis of the hypophysis has only a slight direct effect on the BMR; most of its action is exerted through the thyroid gland. Hypophysectomy causes atrophy of the thyroid and a decrease in the BMR, which is on an average −16 per cent in the dog, −25 to −40 per cent in the rat, and considerably below normal in patients suffering from hypophyseal cachexia. Thyroid function is depressed but not completely abolished, because thyroidectomy causes a further decrease in the BMR to the level usually found in thyroidectomized animals. The administration of anterior hypophyseal extract, or of thyrotrophin, causes hyperplasia of the thyroid and an increase in the BMR; but in thyroidectomized animals the same treatment produces only a small and transitory rise in BMR.

Specific dynamic action (SDA). Hypophysectomy does not modify the specific dynamic action of protein in dogs (Mazzocco, Artundo). In man it usually causes a decrease, but there is

[1] Houssay, B. A., *Medicina, Buenos Aires*, **2**, 205, 1941; Houssay, B. A., V. G. Foglia, F. S. Smyth, C. T. Rietti, and A. B. Houssay, *Rev. Soc. argent. de biol.*, **17**, 301, 1941; *J. Exper. Med.*, **75**, 547, 1942.

no strict correlation between the variations in the SDA and the symptoms of insufficiency or excessive function of the hypophysis. The diagnostic significance of a decrease in the specific dynamic action, as a sign of hypophyseal insufficiency, has been overrated, especially as many extrahypophyseal factors cause a decrease in SDA.

Protein Metabolism

The pars distalis is one of the main factors in the regulation of protein synthesis in the intact organism of mammals. The effect of the hypophysis on postnatal growth is due principally to its action on protein synthesis.

Hypophyseal insufficiency. In hypophyseal insufficiency growth is retarded, less nitrogen is retained, and less body protein is formed than in normal conditions. Hypophysectomized animals rapidly catabolize ingested protein and the urinary elimination of nitrogen is normal, but in emergencies the ability to mobilize and consume body protein is below normal. Hypophysectomized dogs excrete less nitrogen than the normal control during total or protein fasting (Aschner, Braier). Hypophysectomized rats, which eat little, lose weight rapidly and fall into cachexia; they excrete more nitrogen than the controls. In pancreatic or phlorhizin diabetes, hypophysectomized animals excrete less nitrogen, lose less weight, and convert less protein into glucose than the controls (Houssay and Biasotti).

The effect of anterior hypophyseal extracts. Injection of anterior hypophyseal extract, or better still of growth hormone, causes a decrease in the concentration of blood nonprotein nitrogen and in the urinary excretion of nitrogen in normal fed or fasting animals and in phlorhizinized animals. This seems to indicate that the tissues take up nitrogen at an increased rate. Repeated and prolonged administration of the extract provokes growth with the formation of body protein and a positive nitrogen balance.

Fat Metabolism

Hypophyseal insufficiency. Moderate obesity is sometimes observed in hypophysectomized dogs. Hypophysectomized rats and patients with hypophyseal insufficiency, on the contrary, have a poor appetite, lose weight rapidly, and fall into cachexia. Forcible feeding by stomach tube causes hypophysectomized rats to increase in weight; they form less body protein and grow less than the controls, but they accumulate much more fat.

Lesions in the hypothalamus of normal or hypophysectomized animals provoke obesity of enormous proportions. There is always a marked increase in appetite, and overeating seems to be the main cause of this type of obesity, but metabolic disturbances are also present.

Hypophysectomized dogs catabolize less fat and have a lower basal urinary excretion of ketone bodies. In pancreatic and phlorhizin diabetes and in fasting, ketonuria does not increase much in hypophysectomized animals (Rietti). These facts show that the capacity of these animals to mobilize and catabolize fat in emergencies is diminished.

Effect of anterior hypophyseal extract. Extracts of the anterior lobe of the hypophysis provoke a marked increase in blood-fat, and in the fat content of the liver and pancreas, with a decrease in muscle- and bone-fat. Ketonemia and ketonuria increase, indicating an increased rate of fat catabolism; but this is not observed in hepatectomized animals. Somatotrophin and adrenocorticotrophin increase liver-fat, ketonemia, and ketonuria. The hypophyseal growth hormone increases body protein and water, but diminishes the fat content of the body. ACTH sometimes increases body-fat. The anterior hypophysis, therefore, controls fat mobilization and consumption.

Carbohydrate Metabolism

The important part played by the hypophysis in carbohydrate metabolism has already been discussed (see Chap. 41).

Mineral Metabolism

Hypophysectomized animals retain less mineral elements because they form less body substance owing to the arrested growth. On the contrary hypophyseal extracts increase the retention of phosphorus, calcium, potassium, and other elements that are constituents of the tissues. ACTH provokes increased excretion of nitrogen, phosphorus, and potassium, especially when it has marked lympholytic effect. Anterior lobe extracts increase diuresis because they provoke hyperthyroidism; they do not have this effect in thyroidectomized animals.

CHAPTER 53

The Thyroid Gland

Comparative anatomy and embryology. The thyroid first appears in vertebrates as a gland that pours its secretion into the digestive tract. Later the glandular duct is closed and the thyroid becomes an endocrine gland, secreting an iodine-containing substance, which is an important factor in the regulation of metabolism, growth, and morphogenesis. In the human embryo the gland is formed by an outgrowth of the ventral aspect of the pharynx at the level of the first branchial cleft, and two lateral growths originating in the fourth branchial cleft. A duct (the thyroglossal duct) is formed which is later closed up and reabsorbed. The foramen caecum at the root of the tongue is a vestigial remainder of this duct. Small thyroid growths are occasionally found in the path of the fetal thyroglossal duct, which sometimes hypertrophy and become goitrous.

Physiologic anatomy. The thyroid of a normal adult weighs from 20 to 40 gm. (approximately 0.4 gm. per kg. of body weight), although in certain geographical areas it is found to be larger. It varies considerably in size, and responds with structural and functional changes to different internal or external factors. The thyroid shows signs of activity in the fetus, but it does not reach its maximum functional development until puberty. In old age it retrogresses. In the female it is larger than in the male and is subiect to changes coinciding with the sexual cycle, pregnancy, lactation, and menopause. Diseases of the thyroid are more frequently observed in women than in men. In certain species the thyroid develops considerable activity (*e.g.*, the rat); in others its functions are never fully developed (*e.g.*, the axolotl).

There is a definite seasonal variation in the thyroid. At the end of winter and the beginning of spring it is larger and its iodine content is lower than in summer. The highest iodine content and lowest weight are found toward the end of summer and the beginning of the fall. In goitrous areas the incidence of goiter (enlargement of the thyroid) increases when the iodine content is lowest, *i.e.*, at the end of winter.

The thyroid, like other endocrine glands, has a very active circulation. The minute volume (3.5 to 6.9 cc. per gm.) is greater than that of the brain or the kidney. It has also a rich lymphatic network. It is innervated by fibers of the sympathetic arising in the first six or seven thoracic segments, and of the parasympathetic (laryngeal nerves). There are fibers with vasomotor activity. The existence of secretory fibers has been postulated (Asher, Cannon) but has not been satisfactorily demonstrated, and it is a well-proved fact that the thyroid functions and responds to different stimuli after complete denervation or when grafted (*i.e.*, when it has no nervous connections). Several clinical and experimental observations show that the central nervous system exerts an influence on the thyroid, but with the exception of vasomotor responses, this influence seems to be exerted indirectly through the hypophysis.

The thyroid follicle or vesicle is the anatomical and functional unit of the gland; in man its diameter is approximately 300 μ. The follicles are lined by a layer of cuboidal cells, of more or less 15-μ height, which secrete and deposit in the cavity of the follicle a colloid substance. This substance is more fluid and more intensely basophilic in the more active glands. The epithelial cells form colloid and secrete it into the acini, where it is stored. Later they reabsorb it, and there is apparently a two-way current. When the cells reabsorb colloid they emit pseudopodia into the follicle, and colloid droplets are formed in the protoplasm (Langen-

dorff, Severinghaus, De Robertis). Reabsorption seems to be carried out by a proteolytic and mucolytic process.[1] The principal structural signs of hypofunction and hyperfunction of the thyroid are summarized in Table 76.

Table 76. Structural Variations of the Thyroid in Hypofunction and Hyperfunction

	Hypofunction	*Hyperfunction*
Epithelium........	Flat	High
Follicles...........	Usually large	Size varies, many are small
Colloid............	Dense, no vacuoles* acidophil	Fluid, vacuoles* basophil
Secretory granules...	None	Many
Mitochondria......	Diminished	Increased
Golgi apparatus....	Undeveloped	Highly developed
Oxidase and cytochromoxidase granules........	....	Increased

* By means of examination *in vivo*, and the freezing and drying technique, it has been shown the vacuoles in the colloid are technical artefacts; they signiry that the colloid is fluid and retracts when fixed.

REGULATION OF THYROID FUNCTION

Interaction between the thyroid and the hypophysis. There is a reciprocal correlation between the thyroid and the hypophysis (see Chap. 52). The pars distalis of the hypophysis secretes thyrotrophin, which is a factor in the development and maintenance of the structural and functional activity of the thyroid. Removal of the hypophysis, or of the pars distalis, is followed by marked atrophy and decrease in functional activity of the thyroid. On the other hand an excess of thyrotrophin provokes hypertrophy and increases its functional activity. Treatment with thyrotrophin preparations, after a few days, provokes the appearance in the blood of an antithyrotrophic activity which neutralizes not only the thyrotrophin injected but also thyrotrophin secreted by the subject's hypophysis, thus producing thyroid atrophy and hypofunction. This rapid formation of antihormone prevents the prolonged use of thyrotrophin in therapeutics.

Thyroid secretion controls the function of the hypophysis. An increase in thyroid secretion causes a decrease in the secretion of thyrotrophin; on the contrary in hypothyroidism, or after thyroidectomy, there is an increase in thyrotrophin found in the blood and urine. Apparently there is an optimum rate of thyroid secretion which regulates normal hypophyseal function.

Thyrotrophin is selectively taken up and inactivated by thyroid and lymphoid (thymus, lymph nodes) tissue. It stimulates the thyroid, provoking the following changes:

1. *Morphologic:* formation of intracellular colloid droplets (De Robertis), increase in the height of the epithelial cells, reabsorption of colloid, increase in vascularization and weight of the thyroid (cellular hypertrophy and hyperplasia).
2. *Chemical:* the taking up of inorganic iodine by the thyroid and its conversion into organic compounds of iodine (di-iodotyrosine and thyroxine) is stimulated; organic iodine compounds (mainly thyroxine) increase.
3. *Functional:* increase in BMR and signs of hyperthyroidism (see page 601).

Circulating thyroxine inhibits thyrotrophin secretion partially or completely. On the contrary the suppression (by thyroidectomy) or a decrease of circulating thyroid hormone diminishes thyrotrophin secretion by the hypophysis (see "Antithyroid mechanisms").
Thyroid and hypophysis. *a*, normal interrelation; *b*, hypophysectomy causing atrophy of the thyroid; *c*, excess thyrotrophin secretion producing thyroid hypertrophy and hyperfunction; *d*, excess thyroid secretion or iodine causing a decrease in thyrotrophin secretion, therefore thyroid atrophy and insufficiency (there is also a direct inhibitory effect on the thyroid). The width of the arrows indicates the rate of secretion.

Thyrotrophin is found in small quantities in the urine of normal subjects. It increases in hypothyroidism, but it is not found in the urine of subjects with hyperthyroidism, apparently because it is taken up and inactivated by the thyroid.

[1] De Robertis, E., *Anat. Rec.*, **80**, 219, 1941; *Trans. Am. A. Study Goiter*, 1947, p. 1.

An excess of iodine interferes with the production and secretion of thyrotrophin by the hypophysis, inactivates thyrotrophin (Rawson), and makes the thyroid thyrotrophin-resistant.

The effect of thyrotrophin on the thyroid is also inhibited by thyroxin and some of the corticoadrenal steroids. On the other hand, thiouracil and other antithyroid drugs increase the effects of thyrotrophin (Rawson).

Factors that modify the thyroid. Most of the factors that modify thyroid structure or activity act on the anterior hypophysis, increasing or diminishing the secretion of thyrotrophin. Some of those factors also have a direct effect on the thyroid.

The principal factors that cause atrophy of the thyroid and diminish its activity are the following:

1. Extirpation of the anterior lobe of the hypophysis, which suppresses thyrotrophin secretion, necessary for the structural development and maintenance of thyroid function.
2. Excess iodine, which has a double effect: (*a*) it acts on the anterior hypophysis and diminishes thyrotrophin secretion (Loeser); (*b*) it acts directly on the thyroid, even after hypophysectomy (Chapman). Moreover, it neutralizes thyrotrophin *in vitro.*
3. Excess thyroid or thyroxine, which also has a double effect: (*a*) it decreases thyrotrophin secretion (Reforzo); (*b*) it has a direct inhibitory effect on the thyroid.[1]
4. Heat, which diminishes the activity of the thyroid.
5. Corticoadrenal hormones (cortisone, etc.) in large quantities, which act on the thyroid, diminishing the fixation of iodine and thyroid hormone secretion.
6. Several factors which, after an initial phase of stimulation, cause thyroid atrophy and insufficiency owing to exhaustion of the gland.

Many factors produce hypertrophy and hyperfunction of the thyroid by increasing the secretion of thyrotrophin or sensitizing the thyroid toward thyrotrophin. Hypertrophy, however, is not always coincident with hyperfunction; sometimes it is observed in hypofunction of the thyroid. The following are some of the principal factors that cause hypertrophy of the thyroid:

[1] Iodothyroglobulin diminishes the oxygen consumption of a surviving isolated thyroid (Galli-Mainini).

1. Excess function of the anterior hypophysis produces hypertrophy of the thyroid (increase in size), hyperplasia (increase in number of cells), reabsorption of colloid, and marked hyperactivity.
2. Compensatory hypertrophy of the thyroid is produced by extirpation of three-fourths or more of the thyroid gland; the remaining tissue undergoes a process of hypertrophy and hyperplasia. Compensatory hypertrophy does not take place if the anterior hypophysis has been removed.[1]
3. Iodine deficiency, *i.e.*, ingestion of an insufficient amount of iodine, causes hypertrophy of the thyroid, which can be prevented or cured by iodine treatment. This will be discussed in the next section.
4. A number of dietary factors tend to produce hypertrophy: (*a*) ingestion of certain proteins, such as liver protein (dogs and cats); (*b*) ingestion of certain fats, *e.g.*, butter (dogs· the hypertrophy can be prevented by cod-liver oil); (*c*) excess calcium in the diet, as occurs in rats with rickets due to an unbalanced P:Ca ratio in the diet; (*d*) deficiency in vitamin C; (*e*) preferential feeding with certain plants[2] such as some of the cabbages, rutabaga, cauliflowers, turnips, soja, etc., which provokes goiter. A crystallized antithyroid substance (L-5-vynil-2-thio-oxazolidone) has been obtained from the seed of turnips and rutabaga (Astwood, Graer, Ettlinger, 1949).
5. Cold stimulates thyroid development and activity (Cramer, Dempsey, Astwood).
6. Infections stimulate the thyroid during an initial phase; later they cause atrophy and depression. This type of response is seen in typhoid fever, tuberculosis, rheumatic fever, sepsis, etc.
7. Thiourea and thiouracil (especially propylthiouracil), thiocyanate, and some of the sulfonamides provoke thyroid hyperplasia with a marked decrease in activity (Mackenzie, Rawson).

IODINE AND THYROID FUNCTION

Iodine content of the thyroid. Baumann discovered the existence of iodine in the thyroid

[1] Houssay, Biasotti, and Magdalena demonstrated this fact in the dog and Magdalena in the toad.

[2] The most potent vegetable families are the Chenopodiaceae, Compositae, Cruciferae, Cupuliferae, Juglandaceae, Leguminosae, Rosaceae and Umbelliferae.

in 1895. He prepared an organic substance containing iodine, called iodothyrin, which was not chemically defined. Later Oswald obtained an iodized globulin (thyroglobulin). These pioneer discoveries showed the importance of iodine in thyroid function and stimulated work in this direction.

A man weighing 70 kg. has approximately 50 mg. of iodine in the whole body; from one-fifth to one-third of this amount (*i.e.*, 10 to 15 mg.) is found in the thyroid. Thyroid tissue contains 100 to 200 mg. (average 182 mg.) per 100 gm. dry weight; no other tissue has such a high concentration. Muscles have only 0.03 mg. iodine per 100 gm., but owing to the large mass of muscular tissue, approximately half the iodine in the body is found in muscles. Most of the iodine in the thyroid is in the colloid substance of the follicles; there is very little in the cells. The concentration of iodine in the colloid, or in thyroglobulin, varies considerably. The iodine content of the thyroid cannot be taken as an index of thyroid activity or thyroid secretion; it merely indicates the amount of iodine deposited in the thyroid at the time. Thus in patients with hyperthyroidism (Graves' disease) there is little iodine deposited in the thyroid, but considerable amounts are secreted, so the iodine concentration increases in the blood and tissues.

Iodine compounds in the thyroid. Iodine forms part of protein molecules, the most important of which is Oswald's thyroglobulin. Kendall (1914) obtained thyroxine from the thyroid by a process of hydrolysis; it has a very strong thyroid activity. Thyroxine has been obtained in pure crystallized form; it is a cyclic amino acid with four atoms of iodine in its molecule (iodine makes up 65 per cent of the total weight). Harington (1924–1926) established its molecular structure and later prepared it by synthesis (Harington and Barger, 1927). Di-iodotyrosine (Harington and Randall, 1929) and mono-iodotyrosine (Fink, 1948) have been isolated from thyroid tissue. Another iodine compound, 3:5:3-L-tri-iodothyronine, is more potent and acts more rapidly than thyroxine in many of its effects. It has been suggested that thyroxine is converted into tri-iodothyronine in the cells where it is active. Tri-iodothyronine, therefore, would be the active form of thyroid hormone in the periphery.[1]

Thyroxine ($C_{15}H_{11}O_4NI_4$), also called tetra-iodothyronine,[1] is L-β[3,5-di-iodo-4(3′,5′-di-iodo-4′-hydroxyphenoxy)-phenyl] -α-amino-propionic acid. Possibly it is formed from tyrosine, which is first converted into di-iodotyrosine, then into thyroxine.

HO–⟨ring⟩–$CH_2 \cdot CHNH_2 \cdot COOH$

Tyrosine

HO–⟨ring, I, I⟩–$CH_2 \cdot CHNH_2 \cdot COOH$

Di-iodotyrosine

HO–⟨ring, I, I⟩–O–⟨ring, I, I⟩–CH_2CHNH_2COOH
Thyroxine

The total amount of thyroxine in the body is calculated to be from 8 to 14 mg.; and the daily consumption of thyroxine 0.25 mg. (Boothby) or 0.33 mg. (Plummer).

Thyroxine produces a marked increase in the BMR after a latent period of 7 to 48 hr. Its effect lasts 1 to 10 weeks (Fig. 245). This remarkable activity is similar to that of enzymes. One dose of 1 mg. of thyroxine can provoke a 2.5 per cent increase in the BMR and a total production of 1,000 extra calories. Adrenalectomy causes a considerable decrease in the calorigenic effect of the thyroxine in the rat; the administration of corticoadrenal hormones restores the capacity of the animals to respond to thyroxine.[2]

The activity of L-thyroxine is much greater than that of D-thyroxine. The substitution of Br for I reduces activity to one-seventeenth, and that of Cl for I reduces it to one two-hundred-and-fiftieth.

Iodine in the form of iodide is rapidly taken up by the thyroid and converted into ionic or active iodine, apparently by oxidation by an enzymatic system, of which possibly iodine itself forms part. In a further stage the thyroid hormone is formed, by iodization of tyrosine to mono-iodotyrosine then di-iodotyrosine, and oxidative coupling of two molecules of the latter into thyroxine, which is stored as thyroglobulin in the colloid and finally secreted into the blood.

[1] Gross, J., and R. Pitt-Rivers, *Lancet*, **262**, 593, 1952.

[1] Thyronine has the same structure as thyroxine, but the four iodine atoms are replaced by four atoms of hydrogen.

[2] Hoffmann, F., *et al.*, *J. Physiol.*, **107**, 251, 1948; *Acta physiol. Latinoam.*, **1**, 84, 1951.

Formation of thyroxine outside the thyroid. Thyroxine can be produced outside the thyroid. By treating casein and other proteins with iodine *in vitro*, thyroxine is produced (Ludwig and Mutzenbecher, 1939). If radioactive iodine is given to thyroidectomized animals, a small amount of radioactive thyroxine is formed. Small quantities of thyroxine are ingested with meat (muscle). Iodized proteins have a similar, but not as potent, activity as thyroid hormone. They are active by mouth and have been used with the object of increasing milk secretion or the production of eggs.

Blood iodine. The iodine content of the blood is not easily measured; values found vary between 5 and 20 μg per 100 cc., according to the method used. Iodine that precipitates together with plasma or serum protein—protein-bound iodine (PBI) or hormonal or precipitable iodine—is of special interest in medical practice, because it is a good index of thyroid function in subjects which do not receive iodine in the food, or iodine treatment. More than 90 per cent PBI is in the form of thyroxine[1] mainly in serum albumin and in smaller amounts in α and β globulins and other proteins. Triiodothyronine, which is more active than thyroxine, has also been found. Thyroxine seems to be the preferential form of secretion, since it makes up 90 per cent of blood iodine, and only 26 to 30 per cent of thyroid iodine.

Protein-bound iodine is found in a concentration of 4 to 8 μg (average 5.2 μg) per 100 cc. of plasma or serum in subjects with normal thyroid function; it increases above 8 μg per 100 cc. in hyperthyroidism and falls to 3 μg per 100 cc. or less in hypothyroidism. Stimulation of the thyroid by thyrotrophin provokes a rise in PBI. It increases slightly in pregnancy (6 to 11 μg). Thyroidectomy, hypophysectomy, and treatment with antithyroid drugs cause a decrease in PBI.

A homeostatic mechanism regulates synthesis of organic iodized substances in the thyroid.[2] If the concentration of iodine in blood rises above 15 to 25 μg per 100 cc., iodine is no longer bound to organic substances in the thyroid; when blood-iodine concentration falls, iodine is again bound to organic substances in the thyroid.

Fixation and utilization of iodine by the thyroid. Radioactive isotopes of iodine[1] have been important aids for the advancement of knowledge of thyroid function. They have been used in the study of (*a*) the uptake of iodine by the thyroid (amount, and time-concentration curve); (*b*) its combinations with organic substances in the thyroid, especially its appearance in thyroxine; (*c*) thyroid secretion, indicated by the speed at which it leaves the thyroid and increases in protein-bound iodine in the blood; (*d*) its elimination in the urine.

Iodine is essential for the production and control of the secretion of thyroid hormone. It is obtained from foodstuffs. In the course of the catabolism of thyroid hormone, part of its iodine is excreted in the urine, and part is retained and again used by the organism.

The amount of iodine taken up by the thyroid depends on the condition of the gland and the secretion of thyrotrophin. Thyrotrophin increases the uptake of iodine, its incorporation into organic compounds (thyroxine), and its secretion into the blood. It also provokes hypertrophy, hyperplasia, and hyperfunction of the thyroid.

Deficiency of thyrotrophin, due to hypophyseal insufficiency, causes atrophy of the thyroid, which weighs less and has a low, hypofunctioning follicular epithelium. The uptake of iodine is diminished, but as there is a low rate of secretion, the concentration of iodine in the gland remains normal. The protein-bound iodine in blood is below normal.

A hyperplastic thyroid[2] takes up more iodine than a normal gland and converts it more rapidly into thyroxine. This activity is observed in exophthalmic goiter, in which there are thyroid hyperplasia and hyperfunction, and in endemic goiter, in which there is hyperplasia without hyperfunction. Antithyroid drugs inhibit the uptake of radioactive iodine by hyperplastic thyroid tissue.

In hypothyroidism (*e.g.*, myxedema) and after hypophysectomy the uptake of radioactive iodine is diminished. Antithyroid drugs also diminish the uptake of iodine, but when the

[1] Isotopes of iodine are I^{130}, I^{131}, I^{125}, and astatine (element 85). I^{131} is the one most frequently used in physiology and therapeutics.

[2] In nodular hyperplasia the nodules can be located by giving the patient radioactive iodine and applying a radiation detector (Geiger-Müller counter).

treatment is discontinued, if it has provoked thyroid hyperplasia, the uptake is above normal. The thyroid and other tissues of subjects with hypothyroidism given radioactive iodine take up less iodine, and in 24 to 72 hr. excrete more in the urine, than normal subjects. In hyperthyroid subjects the reverse occurs, *i.e.*, they take up more iodine than normal subjects and excrete less.

If large quantities of radioactive iodine are incorporated into the thyroid, the β radiation may destroy part or even the whole gland. This effect has been used in the treatment of hyperthyroidism and, in larger doses, in the treatment of cancer of the thyroid. The results vary according to the capacity of the neoplastic tissue for taking up radioactive iodine.

Response of the thyroid to iodine deficiency or excess. When the iodine content of the thyroid falls below 100 mg. per 100 gm. of tissue, the thyroid becomes hypertrophied (Marine). The process occurs in the following stages: (*a*) the height of the cells lining the follicles increases and the thyroid increases in size (hypertrophy); (*b*) the cells multiply and increase in number (hyperplasia); (*c*) the gland is exhausted and becomes atrophied or large amounts of colloid are accumulated in the follicles (colloid goiter). A gland in this condition of lower activity or at rest can again become active and pass into hypertrophy, hyperplasia, etc., repeating the cycle several times.

Normal → hypertrophy → hyperplasia → atrophy due to exhaustion
↘ colloid
↓
hypertrophy → hyperplasia → atrophy due to exhaustion
↘ colloid

Hypertrophy and hyperplasia of the thyroid can be produced experimentally by feeding animals on diets deficient in iodine. Thyroid response to iodine deficiency is provoked by a double mechanism; (*a*) there is an increase in thyrotrophin secretion; (*b*) there is a direct effect on the thyroid. The direct effect has been demonstrated by feeding hypophysectomized rats a diet deficient in iodine. In these circumstances the thyroid responded with hypertrophy and hyperplasia, but less markedly than the controls (Chapman). Thyroid hyperplasia can be prevented or cured by the administration of iodine (Marine); the cells become flattened, and the follicles are filled with colloid. This inhibitory effect of iodine is observed whenever factors, such as thyrotrophin, etc., which cause thyroid hypertrophy, become active. It is utilized in therapeutics in order to control excessive thyroid function, especially in thyrotoxicosis. Administration of iodine provokes a decrease in the BMR and improves the general condition of such patients, so that they can be submitted to subtotal thyroidectomy with considerably less risk. Iodine treatment prevents the appearance of the so-called "postoperative crises" and has greatly diminished operative mortality. If iodine treatment is unduly prolonged, symptoms of hyperthyroidism reappear with the initial or even greater severity. In these cases it is said that the patient has become refractory or resistant to iodine; therefore iodine treatment should not be administered to patients suffering from hyperthyroidism except under strict medical supervision. Propylthiouracil and mercaptoimidazol are now used in therapeutics instead of or together with iodine, in order to control excess thyroid activity.

Iodine has a double effect on the hypophysothyroid mechanism: (*a*) it diminishes the secretion of thyrotrophin by the hypophysis (Loeser), and (*b*) it inactivates thyrotrophin (Rawson). The inhibitory effect on the thyroid is due to (*a*) inhibition of enzyme systems, and (*b*) inhibition of the proteolytic enzyme which takes part in the reabsorption of colloid (De Robertis). Small doses of iodine stimulate the thyroid; medium and large doses inhibit it, but after a time they lose their effect. Hyperplastic thyroids are more sensitive to the inhibitory action of iodine than normal thyroids.

Prophylaxis of goiter and cretinism. Endemic goiter and cretinism are due to iodine deficiency; therefore iodine administration is the

fundamental factor in the prophylaxis of these diseases. Chatin in 1850 and later Fellenberg[1] showed that in districts where goiter was endemic the iodine content of the air, soil, water, and foods, and the daily ingestion of iodine, were lower than in districts free from goiter. The thyroid is enlarged and shows signs of hyperplasia in a large percentage of the population of districts deficient in iodine. Boussingault in 1831 and later Marine (1907–1911) and many others have demonstrated that the administration of adequate doses of iodine not only has a preventive effect on goiter, but also diminishes the incidence of endemic goiter, cretinism, deaf-mutism, and thyrotoxicosis and improves the general condition (*e.g.*, increases the average height) of the population in goitrous areas. The existence in water of a factor causing goiter has been postulated, among other reasons because thyroid hyperplasia can be provoked in animals reared in nongoitrous areas by giving them water from a goitrous area (Bircher, Houssay). This experimental thyroid hyperplasia can also be prevented or cured by iodine.

The incidence of goiter increases toward the end of winter. It is more frequent in women than in men, especially in adolescents and in pregnant women. Iodine treatment should be given during pregnancy, in goitrous districts, in order to assure the healthy development of the fetus. Cretins are born in goitrous areas from mothers with goiter, if they have not been given iodine.

The most efficient method of goiter control consists in the addition of iodine to table salt (usually KI and a stabilizer to prevent loss of iodine). In Switzerland 5 mg. iodide is added to each kilogram of salt. In England the addition of 10 mg. per kg. of common salt and 25 mg. per kg. of table salt has been advised.[2] Larger amounts of iodide (100 mg. per kg. of salt) have been considered advisable for goitrous areas in the United States,[3] and 10 mg. per kg. (Kimball) for the whole country. The optimum amount of iodine for a normal subject is 100 to 200 μg daily; two or three times this dose should be administered in goitrous areas.

[1] Fellenberg, T., *Ergebn. d. Physiol.*, **25**, 176, 1926.

[2] Salt consumption per capita has been calculated to be 10 gm. per day; therefore 100 μg iodide, equivalent to 76 μg iodine, would be the average amount consumed (*Lancet*, **1**, 107, 1944; **1**, 913, 1948).

[3] The average consumption of salt is calculated to be 6.2 gm. per day, therefore 620 μg iodide, equivalent to 470 μg iodine, is given in this case. (Curtiss, G. M., and M. B. Fertman, *J. A. M. A.*, **121**, 423, 1943. See *J. A. M. A.*, **130**, 81, 1946; **135**, 434, 1947.)

Antithyroid mechanisms. The thyroid gland can be inhibited by several mechanisms:

1. The secretion of thyrotrophin is diminished by the effect of thyroid, thyroxine, or iodine on the hypophysis and by irradiation of the hypophysis.
2. Thyrotrophin is inactivated by iodine (Rawson) and by antithyroid serum prepared by immunization (Harington).
3. Iodine uptake by the thyroid is inhibited by thiocyanate, which also releases iodine from the thyroid. As there is no iodine in the thyroid, organic iodine compounds including thyroxine are not synthesized. The normal inhibitory effect of thyroxine on the hypophysis is absent; therefore thyrotrophin secretion increases and provokes thyroid hyperplasia and goiter. The administration of iodine suppresses all these effects. When treatment with thiocyanate is suspended, the hyperplastic thyroid takes up iodine at a high rate.
4. Thiourea and thiouracil derivatives inhibit the production of thyroid hormone. The uptake of iodine may or may not be below normal, but active iodine is not formed and bound in organic compounds, nor is thyroxine synthesized. Thus the inhibitory action of thyroxine on the hypophysis diminishes, and thyrotrophin secretion increases, causing thyroid hyperplasia. Iodine is not very efficacious in counteracting the effect of these drugs. Methyl-thiouracil, propyl-thiouracil and later 1-methyl-2-mercaptothiouracil have been used in the treatment of hyperthyroidism; they are employed before thyroidectomy in order to diminish the size and activity of the thyroid, thus facilitating the operation.
5. Agents that inhibit the effect of thyroid hormone on the tissues are not well known.

THE FUNCTIONS OF THE THYROID

Methods of study. The principal methods for the study of thyroid function are:

1. The anatomical method, consisting in the observation of gross and microscopic changes in the thyroid under different conditions.
2. Observation of spontaneous or experimental thyroid insufficiency. Experimental thyroid insufficiency can be provoked by (*a*) thyroidectomy;[1]

[1] Early experimenters unwittingly removed the para-

(*b*) irradiation of the thyroid with x-rays or radioactive iodine; (*c*) hypophysectomy; (*d*) antithyrotrophic agents; (*e*) inhibition of thyroid secretion (iodine, thiouracil, etc.). Knowledge of thyroid function in man was first obtained by the observation of spontaneous myxedema,[1] postoperative myxedema,[2] and cretinism. Symptoms observed should be attributed to thyroid insufficiency only if they are controlled by "substitution therapy," *i.e.*, by restoring thyroid function by thyroid grafts or by the administration of thyroid by mouth or by injections of thyroxine.[3]

3. Observation of spontaneous or experimental hyperthyroidism. Experimental hyperthyroidism can be provoked by the administration of an excess of thyroid, or injections of thyroxine or thyroglobulin, or injections of thyrotrophin if the thyroid is intact and capable of responding. Pathologic or spontaneous hyperthyroidism is observed most frequently in man in cases of Graves' disease or toxic adenoma of the thyroid.
4. Tyroid function can be explored by (*a*) determination of the BMR; (*b*) determination of protein-bound iodine in the blood; (*c*) administration of radioactive iodine in order to measure its uptake by, and concentration in, the thyroid and the rate of its elimination in the urine.

Morphogenetic Function of the Thyroid in Amphibians

Thyroid secretion is a necessary factor for metamorphosis in amphibians; *i.e.*, for reabsorption of the tail and gills and the development of the limbs. Thyroidectomized tadpoles do not develop for lack of the thyroid (Allen); hypophysectomized tadpoles do not develop because the thyroid atrophies (Smith). The axolotl remains in the larval state because it has a rudimentary thyroid. The administration of thyroid, on the contrary, accelerates metamorphosis in normal and thyroidectomized or hypophysectomized tadpoles. If thyroid treatment is given prematurely, metamorphosis takes place before the animals have grown to their normal size, and the resulting adult frogs are very small (Gudernatsch). The results of thyroid treatment are particularly remarkable in the axolotl. This species remains all its life in an aquatic larval condition, with external gills, reproducing itself without metamorphosis into an adult form. Thyroid treatment converts it into a terrestrial salamander. Acceleration of metamorphosis is due to iodine and can be brought about not only by thyroid, thyroxine, or di-iodotyrosine, but also by iodine alone (Swingle).

thyroids at the same time as the thyroid, and attributed many of the effects of parathyroid insufficiency to the thyroid. Schiff was the first to perform thyroidectomy (1858).

[1] Gull, 1873; Ord, 1877.

[2] Reverdin, 1879–1882; Kocher, 1883, who gave the name "cachexia strumipriva" to the condition.

[3] Fresh or powdered thyroid can be given by mouth because the active principle resists digestion. Thyroxine is given by injections because it is partially inactivated when given by mouth.

a

b

Thyroid Insufficiency

Growth and morphogenesis. The earlier the age at which thyroid insufficiency is established, the greater the severity of its effects. They are especially severe when the disturbance is initiated during fetal life[1] or during the first months after birth. Insufficiency is more pronounced if the iodine in the diet is inadequate.[2] The sever-

[1] Hence the importance of iodine treatment in pregnant women living in a goitrous district.

[2] LEBLOND, C. P., and H. EARTHY, *Endocrinology*, 51, 26, 1952.

ity also varies with the species; man is one of the most sensitive and suffers most from thyroid deficiency.

Thyroidectomy in the young of all vertebrate species arrests growth and development; the animals do not attain a normal size and do not develop harmoniously. Animals in which thyroid deficiency begins during fetal life or in the first years after birth are cretins and dwarfs (Figs. 243 and 244). Their height is subnormal. Ossification is markedly retarded; the bones of the face grow less than those of the cranium, the nose is flattened, and the limbs are short. The abdomen is prominent, with a protruding umbilicus. The eruption of the permanent teeth is retarded, and they are frequently irregularly placed, badly developed, and poorly calcified; there is a high incidence of caries. In man the skin is dry, rough, and cold. There is a characteristic infiltration of the subcutaneous tissues, which is soft but does not "pit" on pressure. This infiltration was called "myxedema" by Ord; it is marked in man but is not seen in other species. The face is round and puffed out, with swollen eyelids (Fig. 246); the skin is usually pale, but sometimes the cheeks are red. The tongue is swollen and sometimes protrudes between thickened lips. The hair is coarse and straight; frequently it falls in patches or diffusely. The eyebrows are thin, and there is little hair in the axillae. Thyroid treatment, especially if it is begun at an early age, cures all these disturbances, but if it is delayed the results are less satisfactory.

Fig. 244. Congenital cretinism. Age, twenty-seven years; weight, 41 kg.; height, 1.19 m.; BMR, −19 per cent. (*Courtesy of Dr. E. B. del Castillo.*)

Basal metabolism. Thyroidectomy is followed by a marked decrease in heat production (Fig. 245). The BMR falls 30 to 45 per cent below the normal.[1] The fall takes place gradually, reaching its lowest level in 60 to 80 days after thyroidectomy. Myxedema appears later. The skin is cold, and the body temperature is frequently below normal. Thyroidectomized subjects are usually very sensitive to cold and they do not tolerate low temperature of 0 to 2°C. as well as normal subjects. In conditions causing fever or hyperthermia, the rise in temperature is less than in subjects with normal thyroid function. The specific dynamic action of food is low, partly because of slow intestinal absorption. Thyroidectomized animals are more resistant to anoxia than normal animals.[2]

Thyroid preparations given by mouth or injections of thyroxine restore the BMR to a normal or even higher level in cases of thyroid insufficiency and in thyroidectomized animals (Fig. 245).

[1] It is important to keep in mind that the majority of subjects with a BMR of −15 to −20 per cent do not suffer from thyroid insufficiency (Boothby).

[2] Duran, Streuli, De Quervain, Rietti, Leblond, etc.

Protein metabolism. Animals with thyroid insufficiency take up less nitrogen for the formation of body protein than normal animals. This is especially marked in young animals, in which growth ceases. Protein catabolism is also subnormal, as is shown by the low nitrogen excretion in total or protein fasting.

Fat metabolism. There is usually a high lipemia in cases of thyroid insufficiency, and plasma cholesterol is increased. The fat content of the liver also increases. Occasionally there is accumulation of storage fat, but hypothyroidism is not the cause of most cases of obesity. In severe thyroid insufficiency there is loss of appetite, the subjects lose fat and weight, and finally end in cachexia.[1]

Carbohydrate metabolism. Blood sugar and liver and muscle glycogen are usually normal or subnormal, except in cases with cachexia, in which there is a definite decrease. The intestinal absorption of glucose and galactose is retarded (Althausen), and the blood-sugar curves following ingestion of these sugars are flattened and prolonged compared with those observed in normal subjects. Sugar is normally oxidized by the tissues. Sensitiveness to insulin is usually increased in thyroidectomized animals; insulin hypoglycemia is more marked and prolonged, and convulsions occur with greater frequency than in normal animals.[2]

Mineral and water metabolism. The passage of water through the body is usually retarded in thyroid insufficiency; thus after ingestion of water diuresis appears later than in normal subjects and is less marked but more prolonged. Myxedema (Fig. 246) is caused by the accumulation of water, sodium chloride, and over 13 per cent of protein. This protein has the appearance of mucin, the protein in mucus (whence the name "myxedema"), but its chemical nature is not well known. Young individuals retain less calcium and phosphorus than normal ones, owing to retarded ossification and underdevelopment of the skeleton, but the bone formed is usually compact and resistant. Protein-bound iodine in blood is diminished. If radioactive iodine is given, less than normal amounts are taken up by the thyroid and more is excreted in the urine. In a previous paragraph the importance of the thyroid as the main factor in iodine metabolism was fully discussed.

[1] This severe form was observed after total thyroidectomy performed for the treatment of goiter (Kocher's "cachexia strumipriva"); now usually subtotal thyroidectomy is practiced.

[2] Ducheneau, 1923; Bodansky, 1923; Houssay and Busso, 1924.

Blood and circulation. Secondary anemia is frequently observed; it is usually slight or moderate; in exceptional cases it may be of considerable severity. There is a typical increase in plasma globulins and in the viscosity of the blood.[1]
FIG. 245. Effect of thyroidectomy and thyroxine on the BMR. Upper curve, BMR of patient with adenoma of the thyroid with hyperthyroidism, before and after thyroidectomy; lower curve, BMR of patient with myxedema, effect of two intravenous injections of 8 and 16 mg. of thyroxin. (*Boothby, W. M., and Irene Sandiford, Physiol. Rev., vol. 4, p. 104, 1924.*)

Circulating plasma volume and minute volume decrease in thyroid insufficiency; the latter may fall to 2.5 liters per min. The circulation is slow and the circulation time is therefore increased.[2] Intracellular and extracellular edema of the heart is observed in some cases of thyroid insufficiency, which may lead to cardiac dilatation and a weak heartbeat. The deflections of the electrocardiogram are of subnormal amplitude, and the T wave is sometimes inverted.

Changes in the blood and circulation usually respond satisfactorily to thyroid treatment.

Digestive functions. There is usually a poor appetite and constipation is frequently observed.

Nervous and psychic disturbances. These are particularly marked in human cases of thyroid insufficiency, especially those which occur at an early age, because the thyroid is an important factor in the normal development of the central nervous system. The patients are apa-

[1] Fano and Rossi, 1905; Rossignoli *et al.*, 1932; Goldberg, 1938.

[2] Thyroidectomy has been performed in some cases of irreducible circulatory insufficiency and of severe angina pectoris, in order to slow down the circulation and diminish the load on the heart.

thetic, their mental processes are slow, they have a poor memory, and they are frequently obtuse. Children do not learn easily and are backward in their school rating.

The muscles are frequently weak and easily fatigued. On percussion, the muscles sometimes respond with a localized contracture. Muscle tonus is usually decreased, causing laxitude of the joints and abdominal dilatation.[1] Speech is slow and the voice has a peculiar intonation owing to myxedematous infiltration of the laryngeal mucosa.

Immunity. The skin and mucosae are less resistant to infections in hypothyroid individuals than in normal ones. The phagocytic capacity of the leukocytes is subnormal. The formation of hemolysins and agglutinins is usually normal, but the production of antitoxin is subnormal in thyroidectomized animals. It is difficult to sensitize these animals, but if they have been sensitized before thyroidectomy, anaphylactic shock is easily provoked.[2]

[1] Hypothyroid subjects with myotonia have muscular hypertrophy (Lanari).

[2] HOUSSAY, B. A., and A. SORDELLI, "Tiroides e Inmunidad," Espasa-Calpe, Madrid, 1924.

Thymus. The thymus gland usually retrogresses at an early age in thyroidectomized animals, but there are no constant changes in this organ.

Sexual functions. Changes observed in thyroid insufficiency will be considered in Sec. VII.
FIG. 246. Myxedema in woman forty-nine years old. Left, before treatment, marked infiltration on hands, face, and eyelids, BMR −35 per cent; right, after 1½ months' thyroid treatment, BMR +5 per cent. (*Courtesy of Dr. E. B. del Castillo.*)

Treatment. Thyroid insufficiency is controlled by the so-called "substitution treatment." There are three methods: (*a*) thyroid graft; (*b*) oral administration of thyroid preparation; (*c*) injection or oral administration of thyroxine. Thyroid grafts have been made in animals and man; if they "take," *i.e.*, if vascular connections are established and the grafted tissue survives, all the effects of thyroid insufficiency are cured. Hyperthyroidism cannot be provoked by multiple grafts; therefore it is advisable to perform many small grafts in order to assure the survival of an adequate amount of glandular tissue.

Oral administration of thyroid preparations in a case of myxedema was first practiced by Murray in 1891, and the patient survived in good health for many years. This method is the one most commonly used for the treatment of thyroid insufficiency, because the active princi-

ple of the thyroid resists the effects of digestion and is easily absorbed. Furthermore, the dose can be accurately controlled and the treatment suspended whenever it is advisable.

Thyroxine (the sodium salt) is given in intravenous injection. It has a prolonged effect, so that the injections can be given at fairly long intervals, but if an excessively large dose has been administered or the patient is abnormally sensitive, the undesired effects last for several days.

Small doses of thyroid preparations stimulate the anterior hypophysis in some cases, but large doses depress this gland (see Chap. 52).

Hyperthyroidism

Excessive thyroid function provokes disturbances, which are particularly marked in man. In the following description, therefore, the symptoms of human hyperthyroidism will be emphasized.

Basal metabolism. Oxygen consumption and heat production increase in hyperthyroidism. The increase in the BMR is a sign of considerable importance for the diagnosis and treatment of hyperthyroidism, because it is an accurate measure of the level of thyroid function. Oral administration of thyroid preparations and injection of thyroxine also provoke an increase in the BMR. The body temperature is usually high but within the normal range; exceptionally it may rise a little above the normal. The skin of the hands and face is frequently warm or hot, but this is not a sign of fever.

Anoxia is not well tolerated by animals with hyperthyroidism, probably because of the greater need of oxygen caused by the increase in heat production. If they are submitted to low oxygen tension they die at higher oxygen partial pressures than the controls. This contrasts with the greater resistance to anoxia observed in thyroid insufficiency.

Protein metabolism. Protein catabolism increases in hyperthyroidism, and the minimum protein requirement is higher than in normal subjects. This fact, reported by F. von Müller in 1893, was one of the first disturbances in metabolism to be observed in hyperthyroid subjects. It led Magnus Levy (1895) to the discovery of the increase in oxygen consumption and heat production typical of the condition. Thyroid treatment also increases protein catabolism (increased urinary elimination of nitrogen) in adults. In young animals, especially in hypothyroid dwarfs, small doses of thyroid cause an increase in the retention of nitrogen owing to the formation of body protein needed for growth; but even in the young, large doses of thyroid increase nitrogen excretion. Creatinuria and a high creatinine excretion are frequently observed in hyperthyroid subjects.

Fat metabolism. A popular fallacy attributes to the thyroid the capacity of especially accelerating fat consumption, and thyroid treatment is given in order to cure obesity. The thyroid does increase the oxidation of fat, but not in preference to protein or carbohydrate.

Hyperthyroidism, especially if it is marked, rapidly leads to loss of fat. Ketosis is also frequently observed, because carbohydrate stores are depleted and the high metabolic rate has to be kept up at the expense of storage fat; the capacity of the tissues to burn fat is thus often exceeded. This should be kept in mind when treating diabetic patients suffering from hyperthyroidism; they easily fall into ketosis and acidosis. Blood cholesterol is usually low and sometimes below normal.

Carbohydrate metabolism. The fasting blood-sugar level of hyperthyroid subjects is usually normal or slightly above normal. The postabsorptive increase in blood sugar is generally greater than that observed in normal subjects; it frequently rises above the renal threshold and causes a small degree of glycosuria. Selective intestinal absorption of glucose, and especially of galactose, takes place at a higher rate than normal (Althausen) and is the cause of the rapid increase in blood sugar and the marked and prolonged hyperglycemia observed after ingestion of these sugars (Figs. 201 and 202). These high and prolonged hyperglycemic curves following the absorption of sugar may also be due partly to a lower rate of glycogen formation by the liver. These curves differ from diabetic hyperglycemic postabsorptive curves because the blood sugar returns to a normal level. Moreover during hyperglycemia the oxidation of glucose is increased in hyperthyroidism, but not in diabetes.

Thyroid treatment causes a rapid decrease in liver glycogen; the decrease is particularly rapid after a few hours of fasting. The formation of glycogen by the liver after the ingestion of sugar is also delayed in severe hyperthyroidism. Liver glycogen is the most sensitive to an increase in

thyroid function; heart glycogen decreases later; muscle glycogen is diminished only in severe and prolonged hyperthyroidism.

Insulin resistance is usually, but not always, increased by a slight or moderate increase in thyroid function. In severe hyperthyroidism, when the glycogen stores are depleted, there is frequently hypoglycemia in fasting and considerable hypersensitiveness to insulin.

Experimental or spontaneous hyperthyroidism does not provoke diabetes if the pancreas is intact, but if the pancreas has been partially extirpated or the islets damaged (*e.g.*, by anterior hypophyseal diabetogenic extract), large doses of thyroid preparations given over a sufficiently long period may provoke diabetes by further damaging the β cells of the pancreatic islets. This thyroid diabetes is transitory, and the animals return to a normal condition after the thyroid treatment is discontinued, if it has not been given for an excessively long time. On the other hand, if the thyroid treatment has been kept up for several weeks, the islet lesions become irreversible, the β cells are destroyed, and the animals remain permanently diabetic even after the thyroid treatment is discontinued (metathyroid diabetes). The incidence of diabetes in hyperthyroid subjects is twice that in the general population. This is due probably to further damage of an already weakened pancreas caused by excessive thyroid secretion (see Chap. 41).

Mineral and water metabolism. In the first stages of experimental hyperthyroidism, or during the first days of thyroid treatment, diuresis is increased, and there is loss of weight due to loss of body water.[1] Thyroid treatment in myxedematous patients causes a considerable increase in the urinary elimination of water, sodium chloride, and urea, which is due to the mobilization of the myxedematous fluid. The elimination of ingested water is performed slowly in hyperthyroid subjects; edema, especially of the eyelids and around the ankles, may be observed after copious drinking of water in these patients.

Protein-bound iodine in blood is increased. The thyroid takes up more radioactive iodine than a normal gland, and the urinary excretion of radioactive iodine in the 48 to 72 hr. after it has been given is below normal.

[1] This loss of weight is often mistakenly attributed to oxidation of fat.

During the initial stages of hyperthyroidism and in hyperthyroid crises, calcium and phosphorus elimination in the urine and feces is increased, and there is a negative Ca and P balance. After a time the calcium and phosphorus equilibriums are restored; nevertheless the bones of hyperthyroid patients are often poorly calcified and sometimes osteoporosis is observed.

Growth. In some cases of hyperthyroidism in infancy and adolescence, a slight acceleration of growth has been observed; but in the majority of cases, although the period of growth is prolonged, the normal height is not surpassed. Giantism is never observed in human or experimental hyperthyroidism, and if an excessively large dose of thyroid is given, growth may be below normal. Hyperthyroid subjects are usually thin. Some of them have prematurely gray hair. The skin is usually warm and moist.

Blood and circulation. Lymphocytosis is often seen in hyperthyroid subjects, but it also occurs in cases of thyroid insufficiency. The phagocytic capacity of the leukocytes is usually increased in hyperthyroidism. Plasma proteins are decreased, and the viscosity of the blood is subnormal.

The circulating blood volume increases in hyperthyroidism, and there are typical and marked disturbances in the heart such as tachycardia, palpitations, a large minute volume, and a rapid circulation with a reduced circulation time. Crises of vasodilatation (hot flashes) are often observed.

Nervous and psychic disturbances. Animals with experimental hyperthyroidism are restless and irritable. Patients with hyperthyroidism, especially those with exophthalmic goiter, are excessively emotional and unstable. Insomnia and general irritability and nervousness often demand rest in bed and sometimes complete quiet and seclusion. There is hypersensitiveness to adrenaline, which provokes pseudoaffective crises (tremor, anguish, weeping).

Hyperthyroid patients are easily fatigued and muscular efficiency is below the normal. Muscular weakness and slight or even marked muscular atrophy are often seen.

Hoffmann[1] has observed that in experimental hyperthyroidism peripheral nerve stimulation pro-

[1] Hoffmann, F., and E. J. de Hoffmann, *Bol. Soc. biol. de Chile*, **5**, 44, 1948.

duces less effect than in normal animals, a higher frequency of stimulation is needed to provoke tetanus, exhaustion occurs rapidly, and the recovery period is prolonged. Stimulation of the vagus nerve often fails to stop the heartbeat, and if it does stop, "vagus escape" soon occurs. The response to acetylcholine is diminished, but during peripheral nerve stimulation a substance is released which causes contraction in the denervated eye muscles and circulatory collapse.

Digestive functions. Hyperthyroid patients usually have a large appetite. Diarrhea occurs in hyperthyroid crises and in severe cases. It is often accompanied by vomiting and causes rapid loss of weight.

Thyroid intoxication. Large doses of thyroid preparations produce polyuria, loss of weight, weakness, nervousness, insomnia, tachycardia, palpitations, diarrhea, acidosis, and severe lesions in the liver, heart, and other tissues. If large doses are given over a long period they may be fatal. In the advanced stages of thyroid intoxication, muscle glycogen is decreased, the blood sugar is low, and hypoglycemic crises are easily provoked by insulin or occur after the hyperglycemic response to glucose ingestion; in the rabbit hypoglycemic crises occur spontaneously.

Vitamins. Vitamin A causes a decrease in the severity of the disturbances caused by hyperthyroidism in the rat, but in man this effect has not been clearly demonstrated. The fall in liver glycogen provoked by thyroid treatment is diminished by the administration of vitamins B_1 and B_2.

The increase in metabolism which is the consequence of hyperthyroidism apparently increases vitamin requirements. It is therefore advisable to give hyperthyroid patients larger amounts of vitamins than those considered adequate for normal individuals.

Abnormal Thyroid Conditions in Man

Goiter. This is the name given to the enlargement of the thyroid, due to an increase in thyroid tissue or to the accumulation of colloid. Goiter is compatible with a normal thyroid function, and most people with endemic goiter in goitrous districts do not suffer from a disturbed thyroid secretion. In some cases goiter is accompanied by thyroid insufficiency, in others by hyperthyroidism.

Cretinism. Thyroid insufficiency occurring at an early age causes deficient physical and mental development. The subjects may be complete idiots. They are usually of small stature with short limbs and a disturbance in the development of the bones in the face and cranium which gives them a typical aspect (Fig. 244). There may be a goiter, or the thyroid may be atrophic. Cretinism is observed in goitrous areas, but occasionally a case is seen outside these areas. Iodine administration during pregnancy and lacta-
Fig. 247. Exophthalmic goiter. BMR +55 per cent. (*Courtesy of Dr. E. B. del Castillo.*)

tion prevents the appearance of cretinism in the offspring.

Myxedema. Primary myxedema may occur spontaneously, *i.e.*, without an apparent cause, in adults and in children; it occurs more frequently in women (especially near the menopause) than in men. Myxedema is provoked by total, and sometimes by subtotal, thyroidectomy (postoperative myxedema); it is also a complication of certain infectious diseases (postinfectious myxedema). Prolonged and excessive treatment with iodine, radioactive iodine, or thiouracil and other antithyroid drugs may also produce myxedema. Secondary myxedema is observed in certain cases of severe anterior hypophyseal insufficiency, and in some patients suffering from Addison's disease (see Chap. 54).

Thyroid hyperfunction. There are three forms of hyperthyroidism in man: (*a*) exophthalmic goiter; (*b*) toxic adenoma of the thyroid; (*c*) hyperthyroidism without goiter. Exophthalmic goiter[1] (Fig. 247) has the following signs and symptoms: (*a*) a soft vascular goiter; (*b*) exophthalmos, *i.e.*, protruding eyes with widely open lids (in two-thirds of the cases); (*c*) tachycardia and sometimes palpitations; (*d*) tremor, which is fine and rapid; (*e*) a BMR of +20 or more; (*f*) muscular signs, such as incoordination of the eye and eyelid muscles (Graefe's sign), incomplete convergence of the eye (Möbius's sign), muscular atrophy and weakness, fatigue; (*g*) a tendency to lose weight; (*h*) increased respiratory frequency, diminished vital capacity, and occasionally dyspnea; (*i*) rapid circulation with a large minute volume and a short circulation time. If radioactive iodine is given, it is rapidly taken up by the thyroid, where it is accumulated in higher concentrations than in the normal thyroid. Urinary elimination in the first 48 to 72 hr. is subnormal. The protein-bound iodine in plasma is increased (more than 8 μg per 100 cc.).

Toxic adenoma is seen in subjects who have had a goiter for some time without functional disturbances, hyperthyroidism appearing later. Ocular signs are usually absent.

All forms of thyroid disease, but especially hyperthyroid conditions, are more frequent in women than in men.

[1] Known as "Parry's disease" or "Graves' disease" in England, "Basedow's disease" in Germany, and "Flaiani's disease" in Italy.

CHAPTER 54

The Adrenal Glands

THE ADRENALS ARE endocrine glands which fulfill functions of vital importance, and total adrenalectomy is fatal in most vertebrates if adequate treatment is not given.

Historical note. The adrenals were discovered by Eustachius in 1563. Bartholinus (1611) attributed to them the secretion of the atrabile or black bile. Winslow gave them the name of "suprarenal glands," a term that is appropriate for the human adrenal but not for that of certain other species. The term "adrenal," which means "near the kidney," is now in common usage. Addison (1855) described the symptoms caused by destructive lesions of the adrenals, and Brown-Séquard performed experimental adrenalectomy for the first time in 1856. The blood-pressure-raising effect of adrenal extracts was reported by Oliver and Schäfer in 1894 and led to the discovery of adrenaline by Takamine and Aldrich in 1901. At first all the functions of the adrenals were supposed to be due to the secretion of adrenaline by the adrenal medulla, but by 1921 definite proof had been obtained that the cortex and not the medulla is essential for life. Since 1929 several active principles have been isolated from the adrenal cortex, their chemical structure has been established, and their physiologic significance is fairly well understood.

Physiologic anatomy. The adrenal glands of mammals consist of two parts, which differ by their origin, structure, and functions. The medulla arises in the ectoderm from cells that are also the origin of the sympathetic ganglia. These primitive cells, or sympathoblasts, become differentiated into the neurons of the sympathetic ganglia or into glandular cells which are called "chromaffin" (Henle, 1865) or "chromophil" (Stilling) cells because they stain a dark brown with chromates. The adrenal medulla is made up of these chromaffin cells. The medulla is completely surrounded by the cortex in mammals. The cortex has its origin in the mesoderm. The adrenal develops rapidly to a large size in the fetus. The cortex grows relatively faster than the medulla. Two zones can be clearly differentiated in the fetal cortex, an external and an internal layer. The latter retrogresses toward the end of fetal life and the first months after birth; by the end of the first year of life it has been completely reabsorbed. At birth the adrenals are still very large; their size is more than one-third that of the kidney. In the adult the adrenals are relatively much smaller; both weigh only 10 to 12 gm. in adult man.

In certain fishes, the *Elasmobranchii*, the two parts of the adrenal are not joined. In other vertebrate species (amphibians and reptiles), the tissues come together and are intermingled; only in mammals are they segregated into cortex and medulla. In mammals there are also small masses of chromophil cells outside the adrenals, known as paraganglia (Kohn). The most prominent of these masses is Zuckerkandl's aortic body, situated near the root of the inferior mesenteric artery, but others are found in the celiac plexus and in the neighborhood of the sympathetic ganglia. The so-called "accessory adrenals" usually are formed only by cortical tissue. Accessory adrenals are seldom found in certain species (cat, dog); in others they occur frequently (rabbit, white rat).[1] In man, accessory adrenals have been found in the kidney, liver, pancreas, epididymus, the broad ligament, and the neighborhood of the ovary.

The adrenals have a very active circulation; the minute volume varies from 5.3 to 6.4 cc. per gm. of gland.[2] The adrenals receive numerous sympathetic fibers from the solar and renal plexuses, which leave the spinal cord in the

[1] LASCANDO-GONZÁLEZ, J. M., *Rev. Soc. argent. de biol.*, **10**, 28, 1934.

[2] HOUSSAY, B. A., and E. A. MOLINELLI, *Rev. Soc argent. de biol.*, **2**, 117, 1926.

major and minor splanchnic nerves and in the rami of the lumbar roots. Most of these fibers end in the medulla. Some are vasomotor; others stimulate the secretion of adrenaline. The latter exert a continuous tonic effect on the chromophil cells; after they have been cut, adrenaline secretion is reduced to traces.[1] The adrenals also receive fibers from the vagus nerves, but their significance is unknown.

It has often been mistakenly affirmed that complete denervation of the adrenals leads to atrophy of the medulla. This is not so, because several weeks after complete denervation the chromophil cells not only have a normal aspect on histological examination, but respond with a copious discharge of adrenaline if they are stimulated directly (*e.g.*, by nicotine). Atrophy, when it occurs, is due to damage of the blood vessels in the course of the denervation.[2]

Three layers can be distinguished in the adrenal cortex; from without inward, these are the glomerulosa, fasciculata, and reticularis. Some workers maintain that the cells of the glomerular layer multiply and become differentiated into the cells of the other layers, but this opinion is not universally accepted. When there is hypertrophy or atrophy of the adrenals, changes in the inner layers are more marked than in the outer layers. The zona fasciculata is the widest of the three. It has polyhedral cells with many vacuoles filled with fat droplets—neutral fats, cholesterol esters, phospholipids, and specific sterols which are the active principles of the adrenal cortex. These cells reduce osmic acid because they contain a high percentage of oleic acid. The vacuoles give these cells a spongelike aspect; they are therefore known as spongiocytes. Cortical cells have a high ascorbic-acid content; this substance was obtained first from the adrenal cortex and only later from plant tissues (Szent-Györgyi, 1928).

INTERRELATION BETWEEN THE ADRENALS AND THE HYPOPHYSIS

There is an important functional reciprocal relation between the pars distalis of the hypophysis and the adrenals.

The pars distalis secretes adrenocorticotrophin, which is one of the main factors in the

[1] Lewis, J. T., and R. O. Prieto, *Rev. Soc. argent. de biol.*, **14**, 555, 1938.

[2] Sgrosso, J. A., *Rev. Soc. argent. de biol.*, **11**, 139, 1935.

development and maintenance of corticoadrenal structure and function. Adrenocorticotrophin exerts its effect continuously; therefore hypophysectomy (or extirpation of the pars distalis) is rapidly followed by marked atrophy of the adrenal cortex. Corticoadrenal function is considerably diminished but not completely suppressed by hypophysectomy, since subsequent adrenalectomy causes a typical and fatal corticoadrenal insufficiency.

a: AHL; + −; Adrenal cortex
b: Hypophysectomy; Corticoadrenal atrophy
c: AHL; +++; Adrenalectomy
d: AHL; AHL; Adrenalectomy; Corticoadrenal hypertrophy
Adrenals and hypophysis: *a*, normal white rat; *b*, hypophysectomized rat; *c*, adrenalectomized rat; *d*, parabiosis between a normal and an adrenalectomized rat.

Corticoadrenal hormones regulate the secretion of hypophyseal adrenocorticotrophin. In the normal animal corticoadrenal hormones inhibit adrenocorticotrophin secretion; total adrenalectomy is followed by an increase in adrenocorticotrophin secretion, which is less marked and transitory if only one adrenal, or one adrenal and part of the other, are removed. This can be demonstrated by joining in parabiosis a normal and an adrenalectomized rat. The latter secretes an excess of adrenocorticotrophin, which passes into the intact partner and causes the adrenals to hypertrophy. By a similar mechanism, if the adrenals are removed from a pregnant rat, the adrenals of the fetus are seen to be hypertrophied at birth.[1] Adrenocorticotrophin has been assayed in the blood and found to be increased in adrenalectomized animals (Genzell, Snydor).

Compensatory hypertrophy, *i.e.*, hypertrophy of the fragment of adrenal tissue remaining after subtotal adrenalectomy, does not take place if the hypophysis has been removed. Total adrenalectomy in the rat is followed by hypertrophy of the accessory adrenals, which are found in this species. These accessory glands develop gradually into large masses, which at a certain stage of development pass through a phase of hyperactivity. The adrenals have a

[1] Houssay, B. A., and R. M. Pinto, *Rev. Soc. argent. de biol.*, **20**, 38 and 108, 1944; **21**, 316, 1945.

considerable capacity for regeneration in the rat, but it is not so marked in other species.

Changes in size and activity of the adrenals, in response to different factors, are almost always due to an increase or a decrease in adrenocorticotrophin secretion.

Agents which increase adrenocorticotrophin secretion act in the following ways: (*a*) by stimulating hypothalamic centers which control the hypophysis; (*b*) by direct stimulation of the hypophysis; (*c*) by releasing substances, *e.g.*, adrenaline, which stimulate the hypothalamus or the hypophysis (see Functions of the Hypophysis, Chap. 52).[1]

Adrenocorticotrophin was first obtained as a pure protein (Li *et al.*, 1943; Sayers *et al.*, 1943); then a small very active part was separated by adsorption, or chromatography, from a residue with little activity. Partial hydrolysis does not destroy the activity of adrenocorticotrophin, which is found in an ultrafilterable substance, apparently a polypeptide (Li). A fraction which diminishes ascorbic acid in the adrenal and another which causes adrenal hypertrophy have been separated from adrenocorticotrophin.

Assay of adrenocorticotrophin. Injection of adrenocorticotrophin provokes the following effects, which have been used to assay the potency of adrenocorticotrophin preparations: (*a*) increase in weight in the infantile or adult adrenal; (*b*) prevention of corticoadrenal atrophy or recovery of the adrenal size and aspect after hypophysectomy in rodents; (*c*) early reappearance of substances staining with sudan in the adrenal cortex of hypophysectomized rats; (*d*) rapid decrease of cholesterol and ascorbic acid in the adrenals. It would also be possible to assay corticoadrenotrophin by its effect on the secretion of corticoadrenal hormones by an isolated surviving perfused adrenal.

The most rapid and sensitive method of assaying adrenocorticotrophin preparations is the following: One of the adrenals is removed from hypophysectomized rats and the preparation to be assayed is injected; 1 hr. later, the second adrenal is removed. Ascorbic-acid concentration is estimated in both adrenals, and it will be found diminished in the second adrenal if the preparation contained adrenocorticotrophin.[2]

[1] HUME, D., G. HARRIS, J. DE GROOT, D. JACOBSOHN, and C. FORTIER, "Ciba Foundation Colloquia on Endocrinology," Vol. 4, J. & A. Churchill, London, 1952.

[2] SAYERS, G., and M. A. SAYERS, *Recent Progress in Hormone Res.*, **2**, 81, 1948; *Endocrinology*, **42**, 379, 1948.

Anatomic or functional changes in the organism should be attributed to corticoadrenal secretion provoked by adrenocorticotrophin if the following evidence is available: (*a*) the effect is observed in intact animals, but not in hypophysectomized or adrenalectomized animals; (*b*) the effect is obtained by injection of adrenocorticotrophin in intact or hypophysectomized, but not in adrenalectomized, animals. The following supplementary evidence may also be obtained: (*a*) there is an increase in the urinary elimination of substances with the activity of corticoadrenal hormones, or known to be derived from them; (*b*) one or more of the corticoadrenal hormones has the same effect in normal and adrenalectomized animals as the injection of adrenocorticotrophin.

The effects of adrenocorticotrophin are estimated in man indirectly by the effects produced by the excess of corticoadrenal hormones secreted, such as (*a*) rapid decrease of eosinophil cells in the blood and increase in uric acid excretion;[1] (*b*) decrease in the lymphocyte count in the blood; (*c*) increased excretion of substances in the urine which have corticoadrenal activity, such as a protective effect against the lethal action of cold on adrenalectomized animals[2] or the storage of glycogen in the liver of adrenalectomized mice; (*d*) estimation of the urinary elimination of steroids (17-ketosteroids, corticoids, or oxycorticoids) which can be derived from corticoadrenal hormones.[3]

INTERRELATION BETWEEN THE ADRENALS AND OTHER ENDOCRINE GLANDS

Thyroid gland. The thyroid gland stimulates the adrenals indirectly through the hypophysis. The administration of thyroid preparations, thyroxine, or thyrotrophin (if the thyroid is intact and capable of responding) provokes an increase in size and weight of the adrenals due to hypertrophy of the cortex. This effect is not obtained in hypophysectomized animals, except in the pigeon, in which the thyroid has a direct effect on the adrenals. Thyroidectomy is followed by a decrease in the size of the adrenals in the rat, and in patients suffering from hypo-

[1] THORN, G. W., *et al.*, *J. A. M. A.*, **137**, 1005, 1948.

[3] MASON, H. L., *et al.*, *J. Clin. Endocrinol.*, **8**, 1, 1948.

thyroidism there is a depression of corticoadrenal function and the response to adrenocorticotrophin is diminished. Large doses of thyroxin, which inhibit hypophyseal function, cause hypofunction of the adrenal. Prolonged treatment with corticoadrenal steroids, *e.g.*, cortisone, transitorily depresses thyroid function.

Many of the effects of thyroxin, such as the rise in the BMR and nitrogen catabolism, are considerably diminished after adrenalectomy, but a normal response is obtained if corticoadrenal hormones are previously injected.[1]

Sexual glands. The adrenals are of larger size in the female than in the male owing to greater development of the cortex. The difference is particularly marked in the deeper layers of the zona fasciculata and the zona reticularis, especially in female mice, in which species there is a differentiated internal layer known as the X zone.

This sexual difference is due to the stimulating effect of female hormones and inhibitory effect of male hormones on the adrenal cortex. Thus castration causes a slight increase in the weight of the adrenals in the male and a slight decrease in the female.[2] The effect of female sexual hormones is carried out through the hypophysis and is suppressed by hypophysectomy. Prolonged treatment with large doses of estrogens strongly inhibits the hypophysis, thus causing atrophy of the adrenals (Zondek).

Certain strains of mice and rats develop corticoadrenal tumors after castration, which secrete male or female hormones having a strong stimulating effect on the sexual organs.

PHYSIOLOGIC AND PATHOLOGIC CHANGES IN THE ADRENALS

The adrenal gland responds readily to many physiologic and pathologic factors by changes in size, structure, and activity.[3] These changes are brought about by two mechanisms: (*a*) variations in the amount of adrenocorticotrophin secreted by the pars distalis of the hypophysis; (*b*) a direct effect on the adrenal cortex.

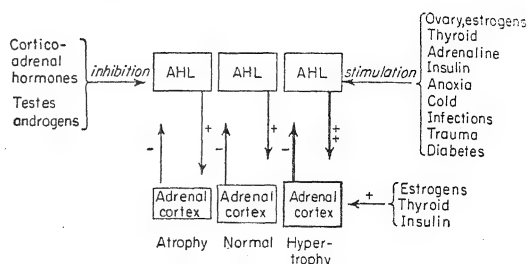
Cortico-adrenal hormones, Testes androgens — inhibition → AHL | AHL | AHL ← stimulation — Ovary, estrogens, Thyroid, Adrenaline, Insulin, Anoxia, Cold, Infections, Trauma, Diabetes

Adrenal cortex (Atrophy) | Adrenal cortex (Normal) | Adrenal cortex (Hypertrophy) ← + — Estrogens, Thyroid, Insulin


Adrenal Atrophy

Adrenal atrophy is due mainly to the decrease or suppression of hypophyseal secretion of adrenocorticotrophin.

Hypophysectomy. Removal of the hypophysis suppresses the source of adrenocorticotrophin; therefore it is followed by marked atrophy of the adrenal and a certain degree of adrenal insufficiency (Fig. 242). Atrophy is especially notable in the internal layers of the cortex. Signs of adrenal insufficiency have been reported in patients with hypophyseal insufficiency. Hypophysectomy suppresses adrenal response to the administration of thyroid, estrogens, and other agents which cause adrenal hypertrophy in animals with the hypophysis intact. Adrenal grafts do not "take" in hypophysectomized rats as readily as in normal animals

Adrenal hormones. Repeated injections of large doses of adrenal hormones inhibit the secretion of adrenocorticotrophin with the following results: (*a*) adrenal weight decreases because of atrophy of the cortex (see diagram) and there is adrenal hypofunction; (*b*) after unilateral adrenalectomy the remaining adrenal does not hypertrophy; (*c*) adrenal grafts do not "take." The principal effect of adrenal hormones is carried out through the hypophysis, but there is also a slight direct action on the adrenal cortex, which is made evident by the injection of adrenal hormones in hypophysectomized rats with atrophic adrenals; in this case the adrenals undergo further atrophy. In cases of adrenal tumor with cortical hyperactivity, the other adrenal is frequently atrophic and its function is subnormal.

Male hormones. Male hormones inhibit the adrenal cortex (see diagram). Castration in males is therefore followed by an increase in the size of the adrenals. Testosterone injections cause a decrease in the size of the adrenals and inhibit the secretion of corticoadrenal hormones. These effects are followed in man by a decrease in the

urinary excretion of glucocorticoids. Testosterone treatment in the rat, however, at first delays adrenal atrophy following hypophysectomy.

Adrenal Hypertrophy

Adrenal hypertrophy is caused by an increase in the secretion of adrenocorticotrophin by the pars distalis of the hypophysis. Only the cortex is involved in this process, which does not take place if the hypophysis has been removed. There is usually dilatation of the sinusoids, especially in the inner layers of the cortex. Sometimes the dilatation is so marked (*e.g.*, in guinea pigs that have been given a fatal dose of diphtheria toxin) that it has the appearance of a hemorrhage and is mistakenly called "adrenal hemorrhage." The increase in size is accompanied by functional hyperactivity of the cortex at least during certain stages of the process.

Excess adrenocorticotrophin. The administration of adrenocorticotrophin causes hypertrophy of the adrenal cortex. Total anterior hypophyseal extract also produces corticoadrenal hypertrophy, acting directly on the adrenal cortex by means of the adrenocorticotrophin it contains, and indirectly because thyrotrophin and gonadotrophins stimulate the secretions of the thyroid and sexual glands respectively, and the hormones of these glands stimulate adrenocorticotrophin secretion. The direct effect of adrenocorticotrophin can be demonstrated by injecting it into hypophysectomized rats, which respond with hypertrophy of the adrenal cortex.

Compensatory hypertrophy. Extirpation of one adrenal and part of the other is followed by hypertrophy of the fragment of adrenal tissue remaining in the animal. Bilateral adrenalectomy causes hypertrophy of the accessory adrenals. This compensatory response is due to an increase in the secretion of adrenocorticotrophin; it does not take place in hypophysectomized animals.

Female hormones. Injection of estrogens, or gonadotrophin (if the ovary is intact and functioning) is followed by corticoadrenal hypertrophy if the anterior hypophysis is capable of response, but not after hypophysectomy.

Thyroid hormones. Thyroid administration, or the injection of thyroxine or of thyrotrophin (if the thryoid is intact), causes corticoadrenal hypertrophy. This is not observed in hypophysectomized aniamls, except in the pigeon, in which the thyroid hormone acts directly on the adrenal cortex, even after thyroidectomy or hypophysectomy.

Metabolic factors. Excess protein in the diet, or an increase in protein catabolism, is a favorable factor for adrenal hypertrophy. The adrenals are found enlarged in animals with severe, but not in those with mild, diabetes. Malnutrition and inanition cause adrenal hypertrophy or, in severe cases, atrophy of the adrenals, which is nevertheless not so intense as the atrophy of other organs.

Accidental hypertrophy. Many physical, chemical, and biological (microorganisms) agents provoke adrenal hypertrophy (see The general adaptation syndrome, p. 622).

THE FUNCTIONS OF THE ADRENAL MEDULLA

The only well-demonstrated function of the adrenal medulla is the secretion of adrenaline and noradrenaline, which are synthesized from phenylalanine. Adrenaline is secreted continuously by a "tonic" action of cholinergic sympathetic fibers. Section of these fibers does not completely suppress this secretion, but reduces it to traces.

The adrenal medulla is not essential for life. It can be removed completely without causing disturbances in any of the main functions of the organism. The blood pressure, BMR, blood-sugar level, sympathetic responses, etc., do not vary significantly if the adrenal cortex remains intact.[1] Adrenaline secreted by the adrenal is not indispensable for the performance of these functions, but sympathin is still released at sympathetic nerve endings after the adrenal medulla has been extirpated. Sympathin is a mixture of varying amounts (0 to 100 per cent) of noradrenaline and adrenaline (Von Euler, Bacq). The fetal adrenal produces mainly noradrenaline; the adult adrenal produces more adrenaline.

The adrenal medulla forms part of the sympathicoadrenal system, and its secretion increases and diminishes together with the activity of the sympathetic nervous system. Adrenaline and noradrenaline secreted by the adrenal have the same effects as stimulation of the sympathetic fibers which release sympathin (adrenergic fibers), but they have a more widespread

[1] During a few days after the removal of the adrenal medulla there is slight corticoadrenal insufficiency, due to the surgical trauma caused by the extirpation of the medulla. This is rapidly compensated.

effect than the latter, which acts locally. Adrenaline secretion will be considered in detail after the study of the sympathetic nervous system (Chap. 85). Adrenaline also stimulates the secretion of corticoadrenal hormones.

THE FUNCTIONS OF THE ADRENAL CORTEX

Hormones secreted by the adrenal cortex regulate many important functions, among which the following are the best known:

1. *Salt and water metabolism.*
   a. Regulation of distribution of water, sodium, potassium, and chloride in the body. This is of vital importance to the organism.
   b. Regulation of renal excretion of water, sodium, potassium, and chloride.
   c. Regulation of blood volume and maintenance of arterial blood pressure.

2. *Carbohydrate, fat, and protein metabolism.*
   a. Regulation of the blood-sugar level, of glycogen concentration in the tissues, and of production and consumption of glucose.
   b. Increase in protein catabolism and in glyconeogenesis from protein.
   c. Action on fat metabolism.

3. *Neuromuscular function.*
4. *Action on sexual functions*, the development of secondary sexual characters, hair growth, and skin.
5. *Resistance to many physical and chemical agents and to infections.*
6. *Interrelation with other endocrine glands and tissues* (thymus, lymphoid tissue, etc.).

Corticoadrenal Hormones

When it was found that death following adrenalectomy was due to cortical insufficiency, further experiments led to the discovery of cortical extracts which could maintain life in adrenalectomized animals.[1] Up to now 28 steroids have been separated from these extracts, though it is not known whether all of them are produced by the adrenal or whether some arise in the process of extraction.[2] The majority of these steroids are derivatives of allopregnane; they belong to the group of substances known as the perhydrocyclopentenephenanthrene ring system[1] and therefore are closely related to the sexual hormones. Six of the adrenal steroids have physiologic activity. The first to be identified was called corticosterone, and others were given names derived from this term or called by letters (Kendall), *e.g.*, compound E (cortisone).

Only 10 per cent of the active substance has been obtained in pure crystalline form and identified chemically. The remaining 90 per cent is the more active part, but its chemical structure has not yet been established.

Some of the steroids have a *masculinizing* effect, *e.g.*, adrenosterone, androstenedione, 11-hydroxyisoandrosterone, and 17-hydroxyprogesterone. Others have *feminizing* activity, *e.g.*, estrone (secreted by the ovary), or *progestational* activity, *e.g.*, progesterone (the hormone of the corpus luteum) and desoxycorticosterone. The adrenal gland also contains ascorbic acid and large quantities of sulfur.

The most important of the corticosteroids is 17-hydroxy-corticosterone, because it is the predominant one found in adrenal blood and has the greater number of physiologic activities. Desoxycorticosterone has been found only in a few cases in adrenal extracts, although it appears in the blood perfused through an isolated adrenal; there is therefore some doubt that it is a hormone produced by the normal gland. It is widely used because it maintains adrenalectomized animals and is efficacious in Addison's disease (chronic adrenal insufficiency). Aldosterone,[2] at first called electrocortin, has been isolated recently; it has a potent effect on sodium retention, between 25 and 50 times that of desoxycorticosterone. Cortisone (compound E, 11-dehydro-17-hydroxy-corticosterone) is frequently used in therapeutics, since Hench and his associates observed that it produced spectacular improvement in rheumatoid arthritis. Both these substances are prepared by synthesis from plant steroids or sapogenins (soia, Dioscoridae, or Strophanthus), from ox bile, or by the action of microbes.

[1] Between 1929 and 1931 Stewart and Rogoff, Hartman, and especially Swingle and Pfiffner obtained these extracts by different methods.

[2] Mainly by Reichstein, Kendall, Wintersteiner, and Pfiffner.

[1] For steroid nomenclature see Selye, H., "Textbook or Endocrinology," Acta Endocrinologica, University of Montreal, 1947. Mason, H. L., *J. Clin. Endocrinol.*, **8**, 190, 1948.

[2] Simpson, S. A., J. F. Tait, A. Wettstein, R. Neher, J. v. Euw, and T. Reichstein, *Experientia*, **10**, 132, 1954.

Corticosteroids in the body seem to derive from cholesterol. The perfused isolated adrenal produces, or transforms, several corticosteroids; *e.g.*, it substitutes an OH for one H on C^{11}, and desoxycorticosterone is converted to corticosterone; cortisone is converted into hydrocortisone by substitution of OH on C^{17}; progesterone is converted into several corticosteroids (Hechter *et al.*).

Allopregnane

17-hydroxycorticosterone (Hydrocortisone)
17-hydroxy-11-dehydrocorticosterone (Cortisone)
Corticosterone

Dehydrocorticosterone
Desoxycorticosterone

The following molecular structure is essential for great activity: a ketone on C^3, a double bond between C^4 and C^5, and a lateral chain of $CO \cdot CH_2OH$ on C^{17}. Corticosteroids with an oxygen atom or a βOH on C^{11} are active in carbohydrate metabolism (Thorn), retard the onset of fatigue (Ingle), increase protein catabolism (Long), and provoke reabsorption of lymphoid tissue cells (Dougherty, White). The elimination of oxygen from C^{11} suppresses almost completely the activity on carbohydrate metabolism but increases the effect on sodium and chloride retention (*e.g.*, desoxycorticosterone). Addition of OH on C^{17} increases the effect on carbohydrate metabolism but decreases the retention of Na and Cl and, in some cases, provokes loss of these elements (Thorn). Only cortisone (compound E) and hydrocortisone (compound F) are efficacious in rheumatoid arthritis.

Approximate quantitative effects of several corticosteroids and the amorphous fraction are given in Table 77.

According to their therapeutic effect, cortico-adrenal hormones have been classified in three groups:

1. Corticoids with activity in mineral metabolism, *e.g.*, aldosterone, desoxycorticosterone, and Reichstein's compound S, which provoke retention of Na, Cl, and water and an increase in the excretion of potassium and nitrogen.
2. Glycocorticoids (with oxygen on C^{11}), which increase the fasting blood-sugar and liver-glycogen concentration, increase diabetic hyperglycemia and glycosuria, stimulate glyconeogenesis from protein, increase protein catabolism, and decrease glucose consumption.
3. Androgenic corticoids, which increase muscular development and hair growth, provoke virilization in women (hypertrophy of the clitoris, hirsutism, etc.), and increase urinary excretion of 17-ketosteroids.

The difference between corticoids active on mineral metabolism and glycocorticoids is only relative; thus 17-hydroxycorticosterone has both activities (Table 77).

Secretion of Corticoadrenal Hormones

In adrenal blood (dog, ox, man) mainly 17-hydroxycorticosterone has been found, but

there is also corticosterone and other corticosteroids that are so far unidentified.

Vogt[1] has measured the amount of corticoadrenal hormones in blood of the adrenal vein by testing its power of increasing the resistance to cold of adrenalectomized rats. She found extraordinarily large quantities, equivalent to 17 kg. of adrenaline per day for a 10-kg. dog (the equivalent of 0.6 gm. of gland per kg. per min. from each gland). Other indirect methods have given similar results. Injection of adrenaline increases corticoadrenal hormone secretion. The hormone disappears rapidly from the blood, and it cannot be estimated in arterial blood.

Excretion. Urinary extracts with "corticoid" effects have been prepared. These extracts have an activity similar to that of the adrenal hormones, such as (*a*) maintenance of survival in adrenalectomized animals; (*b*) increased resistance to cold; (*c*) increased glycogen. In cases of adrenal insufficiency this activity disappears. Part of the 17-ketosteroids in the urine comes from the adrenal, and patients suffering from Addison's disease excrete smaller amounts of these substances than normal subjects.

The daily elimination of corticoids (and oxycorticoids) increases in the following circumstances[2] (*a*) surgical operations, burns, cold, hemorrhage, flying at great heights, etc.; (*b*) Cushing's disease. It decreases in (*a*) Addison's disease; (*b*) hypophyseal insufficiency; (*c*) treatment with testosterone. In cases of hirsutism usually a normal amount of corticoids is eliminated in the urine. Urinary elimination of 17-ketosteroids increases (*a*) in the alarm reaction (transitorily); (*b*) in many cases of corticoadrenal tumors or hyperplasia; (*c*) usually in cases of hirsutism; (*d*) in some cases of Cushing's disease, but not in all; (*e*) following injection of adrenocorticotrophin. More than 60 steroids so far have been extracted from urine, and many of them have been chemically identified.[1]

Table 77. Approximate Quantitative Effects of Known Active Principles of the Adrenals*

Active principle	*Maintenance of life (rat)*	*Renal function (dog)*	*Electrolyte metabolism (dog)*	*Muscular contraction (rat)*	*Hepatic glycogen (rat)*	*Diabetogenic effect (rat)*

* Activity is graduated from 1 (slight) to 5 (marked).

ADRENAL INSUFFICIENCY

Total extirpation of the adrenals is followed by a short period in which there are no disturbances and the animal appears normal. Later signs and symptoms gradually begin and increase progressively until the animal dies (Fig. 248). In the dog and cat an early sign is loss of appetite, followed by weakness, and the animal easily tires. Later digestive disturbances become evident, *e.g.*, vomiting, and diarrhea streaked with blood. There is difficulty in standing and walking, the blood pressure begins to fall, and death occurs with symptoms of shock or, more seldom, in convulsions.

Vital importance of the adrenals. Total adrenalectomy is followed by death within a short time in most species. This is due to cortical insufficiency, not to the loss of the medulla. Death is usually due to disturbances in water and electrolyte metabolism, and can be pre-

vented by the administration of sodium chloride, corticoadrenal hormones, or adrenal grafts. Less frequently death is due to hypoglycemia or circulatory collapse.

Unilateral adrenalectomy is well tolerated; it does not provoke any disturbances. In the dog it is possible to remove from five-sixths to seven-eighths of the adrenal tissue without fatal results, but total bilateral adrenalectomy is always fatal in fishes, amphibians, reptiles, birds, and mammals. Most animals survive for only a few days: cats, 6 to 10 days; dogs, 2 to 16 days. A survival of less than 24 hr. is usually due to surgical trauma or the anesthetic; according to Swingle, local anesthesia of the sympathetic ganglia near the adrenals prevents these early deaths. Birds die soon after adrenalectomy, and toads (*Bufo arenarum*) in 2 to 4 days. The ferret survives several weeks (Hartman). In rabbits accessory adrenals are frequently found, and approximately 20 per cent of the animals survive indefinitely. Rats differ in their resistance to adrenalectomy according to the strain from which they come. Some strains have a high mortality; in others, a high percentage survive.[1] The latter show signs at first of corticoadrenal insufficiency, which gradually retrogress as the accessory adrenals, which are found in these strains, hypertrophy (Lascano-González).

Death is due to extirpation of the cortex, not to that of the medulla. This is demonstrated by the following facts: (*a*) extirpation of the interrenal bodies in fishes, which are the equivalent of the adrenal cortex, is always fatal (Biedl); (*b*) extirpation of the adrenal medulla is not followed by symptoms of adrenal insufficiency unless the cortex is severely damaged,[2] but removal of the remaining cortex is always followed by a typical and fatal syndrome of adrenal insufficiency; (*c*) cases of atrophy of the adrenal cortex with symptoms of adrenal insufficiency, but without changes in the medulla, have been reported; (*d*) adrenaline does not relieve the symptoms of adrenal insufficiency or prevent death; (*e*) corticoadrenal grafts that "take" permit survival after double adrenalectomy; (*f*) active corticoadrenal extracts and some of the steroids extracted from the adrenal cortex relieve the symptoms of adrenal insufficiency and keep adrenalectomized animals alive as long as they are treated with these extracts.

[1] LEWIS, J. T., *Am. J. Physiol.*, **64**, 503, 1923.

[2] Wheelon and Vincent, 1917; Houssay and Lewis, 1921; Crowe and Wislocki, 1924; and others. During a few days following the operation there may be a slight degree of adrenal insufficiency (Foglia and Gerschman).

The vital importance of the adrenal glands is due mainly to the effects of their secretion on the regulation of water and salt metabolism.
FIG. 248. Adrenal insufficiency. Characteristic changes in metabolism, circulation, and blood concentration in adrenalectomized animals following withdrawal of extract. (*Loeb, R. F., J. A. M. A., vol. 104, p. 2177, 1935.*)

The administration of sodium chloride alone will keep adrenalectomized animals alive. As stated, death is occasionally due to hypoglycemia or circulatory collapse. The adrenals are not indispensable to life if the disturbances in salt and water and carbohydrate metabolism are controlled.

Subtotal or even total adrenalectomy has been performed in man[1] in cases of cancer of the adrenal or the prostate, malignant hypertension, etc. The patients were kept alive by treatment with salt (5 to 10 gm. daily), desoxycorticosterone (0.1 to 1 mg. daily), and cortisone (25 to 50 mg. daily).

Disturbances in electrolyte metabolism. Adrenal hormones control reabsorption of sodium, potassium, and water by the renal tubes. In adrenal insufficiency sodium is lost in the urine because its reabsorption from the glomerular filtrate is diminished. Together with Na, Cl (but in smaller amounts) and water are also lost. Blood plasma, thus, has less sodium, chloride, bicarbonate, and water; the blood becomes

[1] THORN, G., *et al.*, *J. Clin. Endocrinol.*, **11**, 774, 1951; BERGENSTAL, D. M., and C. B. HUGGINS, *J. Clin. Investigation*, **31**, 616, 1952; PEARSON, O. H., *et al.*, *J. Clin. Investigation*, **31**, 653, 1952.

concentrated; and there is a relative increase in erythrocytes, hemoglobin, and plasma protein. Sodium, chloride, and water also diminish in extracellular fluids; there is dehydration, the blood volume diminishes, and a tendency to shock develops.

Potassium reabsorption increases simultaneously with the decrease in sodium reabsorption. Less K is excreted in the urine and its concentration in plasma increases. Intracellular fluid loses sodium, its water content increases, and K concentration rises or remains normal.

The concentration of potassium in plasma may reach toxic levels, and the severity of the effects of adrenal insufficiency becomes greater (Zwemer). The administration of K clearly increases the intensity of these effects, and may cause them to appear in patients with compensated chronic adrenal insufficiency.

Baumann (1927) observed the decrease in blood sodium, and Loeb (1932) demonstrated its importance. Adrenalectomized animals can be kept alive by giving them sodium (usually NaCl). If K in the diet is reduced, sodium is more efficacious, *e. g.*, K may be diminished from 4 gm. per day to 2 gm.

Corticoadrenal extract and several corticosteroids diminish the loss of Na and increase the excretion of K in adrenalectomized animals, because they increase reabsorption of Na and diminish that of K. Aldosterone and desoxycorticosterone are the most active; corticosterone, 11-dehydrocorticosterone, and 17-hydroxycorticosterone follow in activity.

Aldosterone is the most potent sodium-retaining steroid so far discovered; it has been found in adrenal venous blood. Other steroids have only a brief effect, or may increase sodium excretion, *e.g.*, cortisone. Desoxycorticosterone maintains adrenalectomized animals alive and is efficacious in patients suffering from adrenal insufficiency.

Disturbances in water metabolism. The adrenals exert an indirect effect on water metabolism by their activity on electrolyte reabsorption by the renal tubes, but they also have a direct effect on renal excretion of water. Following adrenalectomy, in a few species, there is increased elimination of water simultaneously with the loss of Na and Cl. This increase persists in animals treated with sodium chloride. When, however, severe insufficiency develops, the amount of urine eliminated diminishes, especially when there is dehydration. A typical disturbance is the slow rate of elimination of ingested water in adrenalectomized animals and in patients with Addison's disease. This disturbance, together with the decrease in NaCl in the body, increases sensitiveness of adrenalectomized animals toward water intoxication. The deficiency in the elimination of water is mainly of renal origin, as is shown by the following facts: (*a*) glomerular filtration decreases owing to diminished renal blood flow, caused by lower blood pressure and speed of circulation; (*b*) tubular reabsorption of water increases, this factor seeming to be the principal one (Gaunt); (*c*) sensitiveness to the posthypophyseal antidiuretic hormone increases, and there is a higher concentration of this hormone in the blood plasma (Gaunt). There is some evidence, but no definite proof, of an extrarenal mechanism.

Corticoadrenal hormones control these disturbances by their effects on electrolyte metabolism and on the kidney. Desoxycorticosterone, adrenocorticotrophin, and large doses of cortisone may produce edema by retention of NaCl which causes an increase in extracellular and a decrease in intracellular fluid. Thirst is usually increased (especially when desoxycorticosterone is administered) and the excretion of urine rises. In certain conditions prolonged treatment with desoxycorticosterone—or, in the dog, with cortisone—provokes intense polyuria similar to diabetes insipidus.

According to Gaunt, hormonal control of water excretion by the kidney is governed by (*a*) the neurohypophysis (antidiuretic hormone), and (*b*) the pars distalis of the hypophysis (adrenocorticotrophin, somatotrophin, and thyrotrophin). The neurohypophyseal hormone and the adrenal cortex apparently exert antagonistic effects, and the renal excretion of water depends on the maintenance of an equilibrium between them.

Sodium chloride maintains adrenalectomized animals alive, but does not compensate for all the effects of adrenal insufficiency, *e.g.*, disturbances in carbohydrate metabolism.

Adrenal insufficiency is not due exclusively to the loss of NaCl and water in the urine. Circulatory collapse and other symptoms of adrenal insufficiency are seen in adrenalectomized animals in which the kidneys have been removed. Cortical extracts prolong the survival of these animals. Moreover cases of

Addison's disease have been reported in which collapse and death occurred without any disturbance in plasma-electrolyte concentration.

Renal disturbances. Renal functions are gradually impaired as adrenal insufficiency increases in severity. At first there is a deficient reabsorption of Na, which is excreted in excess in the urine, and the body loses not only Na, but also Cl and water. Dehydration, hemoconcentration, and loss of body weight follow. Later K and water are reabsorbed in excess, and the urinary excretion of K and water diminishes. Urea and creatinine clearance diminishes, as also the clearance of other substances. The decrease in diuresis causes retention and an increase in blood plasma of several of its components: nonprotein nitrogen, urea, potassium, phosphates, and sulfates. Renal function is improved in adrenal insufficiency by several corticosteroids; the most active are the total extract, the amorphous fraction, and desoxycorticosterone.

Circulatory disturbances. The following disturbances in the circulation are seen in adrenal insufficiency: (*a*) a decrease in circulating blood volume, the size of the heart, and the speed of circulation; (*b*) a fall in blood pressure, especially marked and rapidly progressive during the phase of shock; (*c*) increased capillary permeability during shock. Adrenalectomized animals and patients suffering from adrenal insufficiency are very susceptible to all factors that provoke shock, such as trauma, hemorrhage, anesthesia, hypertonic glucose injections, or excessive heat or cold; exercise, and sometimes even the administration of a saline purge will provoke an adrenal crisis.

Adrenalectomy causes a fall in blood pressure and of hypertensinogen in the blood of animals suffering from hypertension provoked by renal ischemia. This fall in blood pressure is prevented by the injection of corticoadrenal hormones, but not by the administration of sodium chloride. Vascular response to several vasoconstrictor substances is diminished in adrenal insufficiency,[1] and when it is severe stimulation of sympathetic vasoconstrictor nerves is also followed by a subnormal response. Treatment with several corticosteroids improves vascular reactivity. These and other facts have led to the practice of total or subtotal adrenalectomy in the treatment of patients with malignant hypertension.

According to Swingle, Hartman, and others, changes in capillary and cell permeability are of special importance in adrenal insufficiency. Injections of saline solutions or blood transfusions do not raise the blood pressure of adrenalectomized animals, because the injected fluid passes out of the blood vessels into the tissues and edema is produced. Corticoadrenal extracts prevent this loss of fluid from the blood vessels (Swingle). Another demonstration of increased capillary permeability in adrenal insufficiency is obtained by joining in parabiosis a normal and an adrenalectomized rat. The latter soon becomes congested and edematized, owing to the higher blood pressure of the normal partner and increased capillary permeability in the adrenalectomized animal (Pinto and Houssay). Adrenal extract also inhibits or controls increased capillary permeability produced by leukotaxin (Menkin). Adrenal extracts and steroids have been used for the prevention and treatment of shock with good results in certain forms of experimental shock, but with less constant and satisfactory results in man.

[1] Cleghorn, R. A., *et al.*, *Am. J. Physiol.*, **161**, 21, 1950.

Digestive disturbances. In the course of acute adrenal insufficiency, the following signs of disturbance in digestive functions are observed: (*a*) anorexia; (*b*) vomiting; (*c*) diarrhea, sometimes streaked with blood. Intestinal absorption of sugars and fat is retarded in the adrenalectomized rat, but returns to normal if the animal is given sodium chloride.

Disturbances in carbohydrate metabolism. These have been fully discussed in Chap. 41, Carbohydrate Metabolism. In brief the principal disturbances observed in adrenal insufficiency are (*a*) tendency to hypoglycemia in fasting; (*b*) hypersensitiveness to hypoglycemic agents (insulin, phlorhizin, fasting, etc.); (*c*) marked decrease in the fasting level of hepatic and muscle glycogen; (*d*) disturbance in the selective intestinal reabsorption of sugar; (*e*) increased consumption of glucose by the adrenalectomized rat; (*f*) decreased severity of pancreatic and phlorhizin diabetes.

The administration of total cortical extract, adrenocorticotrophin, or the so-called "glycocorticoids" has the following effects in adrenalectomized animals: (*a*) a normal blood-sugar level is maintained; (*b*) glycogen, especially liver glycogen, increases; (*c*) insulin resistance increases; (*d*) sugar tolerance diminishes; (*e*) glucose consumption diminishes when large doses of corticosteroids are given; (*f*) diabetes attenuated by adrenalectomy or hypophysec-

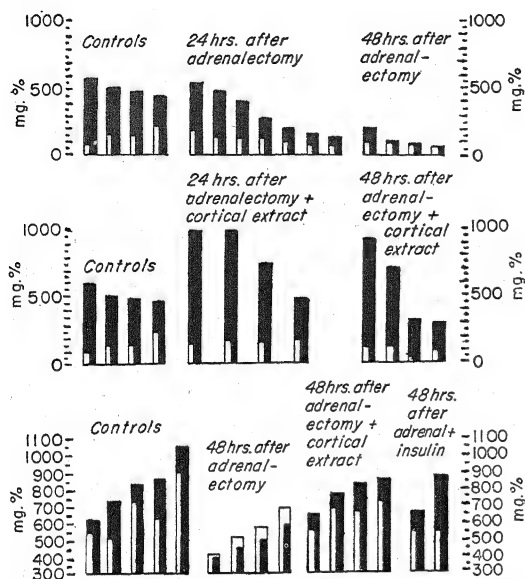
tomy increases in severity; (*g*) large doses (far above those used in therapeutics) may provoke a transitory diabetes in the rat, and therapeutic doses increase the severity of an existing diabetes in man.


FIG. 249. Effect of adrenal cortex on muscle glycogen. Each column represents one experiment on a chloralosed dog. Two upper series: white, glycogen after fatigue; black, glycogen after 1 hr. recovery. Recovery is retarded in some animals 24 hr. after adrenalectomy and in all animals 48 hr. after adrenalectomy. Corticoadrenal extract accelerates recovery; in some cases, muscle-glycogen concentration is above that of normal untreated controls. Lower series: white, muscle glycogen before intravenous injection of 2 gm. glucose per kilogram; black, after the injection. Glycogen formation is deficient in adrenalectomized animals. Corticoadrenal extract and insulin restore the normal rate of muscle-glycogen formation in adrenalectomized animals. (*Dambrosi, E. G., L F. Leloir, and A. Novelli, Rev. Soc. argent. de biol., vol. 9, pp. 408 and 417, 1933.*)

Disturbances in protein and fat metabolism. Adrenalectomized animals usually do not grow well, and lose weight. In conditions of emergency protein catabolism does not increase in adrenalectomized as in normal animals, *e.g.*, in diabetes (Long and Lukens), following fractures and burns (Ingle), after the administration of thyroxin,[1] etc. Protein catabolism increases in all these circumstances if the animals are treated with small doses of corticosteroids; a basal level, not an increase in corticoadrenal secretion, is necessary.[1]

[1] HOFFMANN, F., *et al.*, *Bol. Soc. biol. Santiago, Chile*, **7**, 60, 1950.

In vitro experiments have shown that tissue slices taken from adrenalectomized animals have a subnormal deaminating activity when certain amino acids are used as substrates.

Adrenalectomy diminishes ketonuria in experimental diabetes, which may be a sign of a lower catabolism of fats. It is difficult to provoke fatty infiltration of the liver in adrenalectomized animals, possibly because of a decrease in the mobilization of storage fat toward the liver. Intestinal absorption of fats is retarded in adrenalectomized animals, and storage fat is considerably diminished (anorexia).

Other metabolic disturbances. The basal metabolic rate is well below normal (−25 per cent) in the acute stages of adrenal insufficiency, and oxygen consumption *in vitro* of surviving tissue slices taken from adrenalectomized animals is lower than that of normal tissues. Thyroxine has less effect on the BMR of adrenalectomized rats than in the controls.

Muscular disturbances. Addison, in his classical description of human adrenal insufficiency, reported the loss of strength (asthenia) and the rapidity of the onset of fatigue as a typical sign of the disease. Susceptibility to fatigue has been clearly demonstrated in adrenalectomized animals. This disturbance is controlled in part by the administration of glucose and completely by treatment with glycocorticoids which have oxygen on C^{11}, such as (in decreasing order of activity) 17-hydroxycorticosterone, cortisone, corticosterone, and 11-dehydrocorticosterone; 11-desoxycorticosterone has little activity.

In man adrenal insufficiency is accompanied by psychic depression.

Metabolism of pigments. An outstanding symptom of Addison's disease is a dark pigmentation of the skin, owing to an increase in the melanin of the epidermis. Nevertheless in acute or chronic adrenal insufficiency in experimental animals little or no disturbance in pigmentation has been observed.

The thymus and lymphoid tissue. The adrenal glands have an inhibitory effect on the thymus, the lymphatic glands, and lymphoid tissue. Adrenalectomy is followed by hypertrophy of the thymus and lymphatic glands.[2] Ad-

[1] INGLE, D. J., *Ann. New York Acad. Sc.*, **50**, 576, 1949.
[2] PINTO, R. M., *Am. J. Physiol.*, **144**, 652, 1945.

ministration of corticoadrenal hormones causes a decrease in size in these organs, which is permanent in some cases.

Adrenocorticotrophin injection is followed after a few hours (if the adrenals are intact) by marked involution of the thymus and lymphoid tissue, with widespread reabsorption of lymphoid cells.[1]

Decrease in the resistance of the organism. Adrenalectomized animals are very sensitive to factors that cause stress, and in situations of emergency they are easily exhausted, falling into collapse which is frequently fatal. This is especially evident when these animals are exposed to cold (Marval), or submitted to conditions that cause a fall in blood pressure (hemorrhage, histamine, trauma, etc.) or a decrease in blood sugar (insulin, phlorhizin). These animals are also sensitive to most drugs, poisons, and toxins, such as morphine, cobra venom, diphtheria toxin,[2] and potassium (Zwemer, Cicardo).

Injection of corticoadrenal extracts, or corticosteroids, especially glycocorticoids, increases the resistance of adrenalectomized animals, but it has little or no effect on the resistance of normal animals.

In the last century it was commonly believed that the effects of adrenal insufficiency were due to the accumulation of toxic substances, normally produced by the organism and neutralized by the adrenals,[3] but the toxic substances were never found. Later the metabolic disturbances of adrenal insufficiency and their control by the administration of corticoadrenal hormones or NaCl were discovered, and the toxic theory of adrenal insufficiency was definitely abandoned.

The role of the adrenals in sexual functions and in lactation will be discussed in the chapters on those subjects.

Treatment of adrenal insufficiency. Adrenalectomized animals can be kept alive indefinitely by the following methods: (*a*) injection of active corticoadrenal extracts or steroids; (*b*) a diet with a high sodium chloride but a low potassium content; (*c*) corticoadrenal grafts.

[1] RAPELA, C. E., *Rev. Soc. argent. de biol.*, **20**, 423, 1944; DOUGHERTY, T. F., and A. WHITE, *Endocrinology*, **35**, 1, 1944; **39**, 370, 1946; *Am. J. Anat.*, **77**, 81, 1945; *J. Lab. & Clin. Med.*, **32**, 584, 1947.

[2] LEWIS, J. T., *Am. J. Physiol.*, **64**, 506, 1923.

[3] Brown-Séquard, 1858; Abelous and Langlois, 1892; Langlois, 1897, and, more recently, Riml.

Certain species in which accessory adrenals are frequently found (*e.g.*, the rat and rabbit) survive indefinitely if they are adequately treated during the first few weeks after adrenalectomy, so that the accessory adrenals have time to develop sufficiently to replace the corticoadrenal tissue that has been removed.

Immediately after adrenalectomy, adrenal extracts or hormones should be given together with NaCl. Later the dose of extract can be decreased, and finally it is possible to maintain the animals in good condition with sodium chloride alone. If the treatment with salt or extract is discontinued, the animals fall into acute adrenal insufficiency, unless accessory adrenals have developed. Extracts are more efficient than salt in the treatment of acute adrenal insufficiency. Adrenalectomized rats can be kept alive permanently, or their survival can be prolonged, by the administration of NaCl. If they can choose freely between pure water and 1 per cent NaCl solution they will prefer the latter (Richter). This is due to a lowered threshold for salt taste caused by the decrease in sodium in the blood and tissues.

There is apparently a certain antagonism between the effects of sodium and those of potassium in adrenalectomized animals. Sodium chloride is more efficient if there is little potassium in the diet; on the contrary an increase in K diminishes the effect of sodium and may cause acute adrenal insufficiency in an animal or a patient in which adrenal insufficiency has been previously compensated.

It should be noted that corticoadrenal grafts do not "take" easily in most species.

Corticoadrenal extracts improve the condition of adrenalectomized animals and restore them to a normal state. Renal reabsorption of Na increases, less sodium and chloride are excreted, and the urinary excretion of potassium increases. The concentration of sodium and chloride in plasma increases; that of potassium decreases. Plasma volume and arterial blood pressure return to normal levels. No single corticoadrenal steroid produces all the effects of the total extract. The activity of these extracts is due to the steroids they contain; therefore their effects and potency vary according to the method of preparation.[1]

Desoxycorticosterone (usually the acetate dis-

[1] Usually the potency of an extract is measured by its capacity to maintain alive totally adrenalectomized animals. It would be better to express their potency in terms of each one of the active steroids they contain.
solved in oil) is widely used in therapeutics. This substance controls the disturbances in salt metabolism and permits indefinite survival (Fig. 251). It causes an increase in the reabsorption of sodium in the renal tubes and therefore diminishes the loss of sodium, chloride, and water. It increases sodium and chloride and diminishes potassium in blood. It has little or no effect on carbohydrate metabolism, and adrenalectomized animals treated with desoxycorticosterone are liable to have hypoglycemic crises, which may prove fatal if they do not receive a sufficient amount of carbohydrate.

Large doses of desoxycorticosterone, especially if given together with salt treatment, may have unfavorable and even dangerous results. Plasma sodium and chloride increase above the normal, and in spite of polyuria there is a tendency to retain water. In the more advanced stages of intoxication by desoxycorticosterone, the following disturbances are observed: (*a*) marked subcutaneous edema, with accumulation of sodium chloride; (*b*) venous hypertension, dilatation of the heart, and sometimes fatal pulmonary edema; (*c*) arterial hypertension (not in all cases); (*d*) excessive decrease in plasma potassium, sometimes accompanied by cardiac disturbances and paralysis, in which case the potassium content of muscle is diminished and the sodium content increased; administration of potassium salts controls these disturbances. These toxic disturbances are prevented by keeping the dose of desoxycorticosterone below 5 mg. per day (except when treating an adrenal crisis), by keeping the ingestion of sodium chloride between 3 and 6 gm. per day without reducing the potassium intake, and by giving an adequate amount of carbohydrate to prevent hypoglycemia. If there is a sudden increase in weight (edema) the dose should be reduced immediately.[1]

Prolonged treatment with desoxycorticosterone produces in some animals signs of chronic intoxication, with nephrosclerosis, arterial hypertension, and cardiac hypertrophy.[2] Abundance of sodium in the diet causes these toxic effects of desoxycorticosterone to appear earlier and with increased severity.

Adrenal Insufficiency in Man

The principal forms of adrenal insufficiency that have been observed in man are (*a*) Addison's disease; (*b*) chronic adrenal insufficiency without pigmentation; (*c*) hypophyseal myxedema; (*d*) acute adrenal insufficiency.

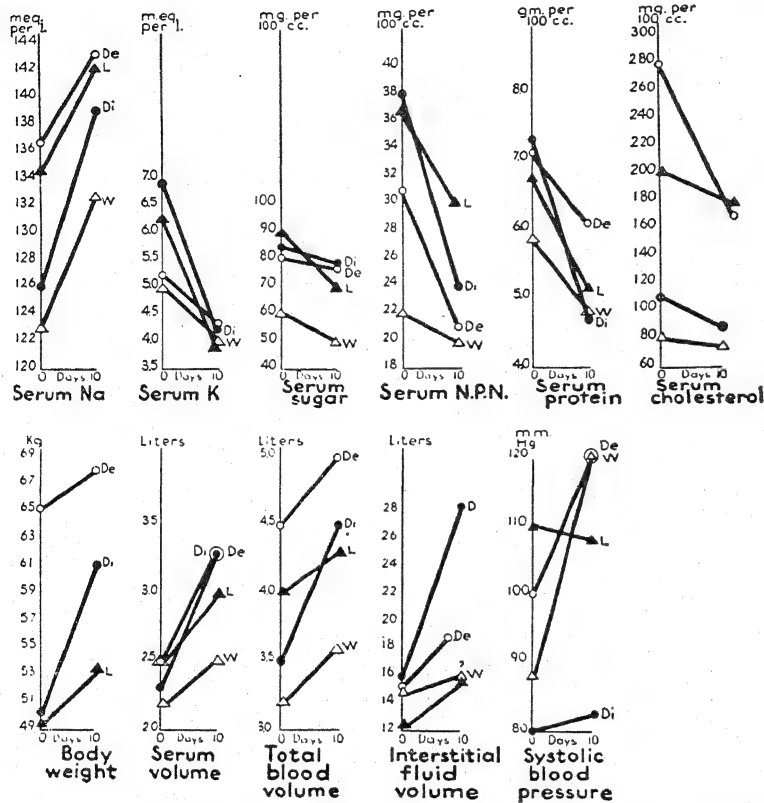
The outstanding signs and symptoms of Addison's disease are asthenia, pigmentation of the skin and mucosae, low blood pressure, digestive disturbances (vomiting, diarrhea) and loss of body weight, but there are many other functional disturbances (Fig. 251).


Fig. 251. Effect on patients with Addison's disease of 10 days' treatment with desoxycorticosterone derivative. (*Loeb, R. F., J. A. M. A., vol. 116, p. 2495, 1941.*)

Addison's disease. The disease is produced by extensive destructive lesions of the adrenals, most commonly due to tuberculosis of the glands (50 to 70 per cent of cases), or to simple atrophy of the cortex. The statistics of Addison's disease in certain countries show that 20 to 50 per cent of cases are due to simple atrophy of the adrenal cortex.

Three stages are observed in the course of the disease: (*a*) phase of compensation, in which the disturbances are slight or nonexistent; (*b*) phase of decompensation, in which all the effects of adrenal insufficiency are in evidence; (*c*) phase of acute adrenal insufficiency or adrenal crisis, which may lead to death by shock or circulatory collapse.

Asthenia consists of muscular weakness and physical and psychic fatigue. Pigmentation of the skin (melanodermia) is observed in 94 per cent of the cases. The skin takes on a bronze color and dark patches are seen in the mucosae.[1] The systolic blood pressure is usually below 90 mm., except in hypertensive subjects. The heart volume, as appreciated by radiography, is small. The loss of weight is due in part to anorexia.

Digestive symptoms consist of anorexia (which appears in the early stages and is marked and persistent), vomiting, and diarrhea; in some cases, there is abdominal pain.

The BMR is below normal in approximately one-

[1] These dark patches are sometimes seen in normal individuals with a dark skin.

half the cases; the body temperature is low. The following disturbances in carbohydrate metabolism are seen: (*a*) low fasting blood-sugar level (Porges); (*b*) hypersensitiveness to insulin;[1] (*c*) a slight increase in blood sugar after the ingestion of glucose, followed by marked secondary hypoglycemia. The RQ is usually high and rises considerably after the ingestion of glucose. There are no disturbances in salt metabolism during the compensation phase, but decompensation is preceded by loss of sodium in the urine, a fall in Na and Cl, and a rise in K in plasma; these changes are marked during the adrenal crisis.

Robinson, Power, and Kepler[2] have devised a diagnostic test for adrenal insufficiency. It is based on the fact that copious ingestion of water is followed by only slight diuresis and very little dilution of the urine, and that chlorides are excreted in abnormally large quantities, while urea and sodium are retained. Cutler, Power, and Wilder[3] have proposed another test which consists in restricting the intake of sodium and increasing the intake of potassium. This causes an increase in the severity of the urinary and plasma signs and general symptoms of adrenal insufficiency; acute insufficiency may be provoked. Frequently the lymphocyte and eosinophil count are high. Thorn's test[4] consists in the intravenous injection of 20 mg. of adrenocorticotrophin in the course of 8 hr.; an eosinophil count is made at the tenth hour, and the 24-hr. excretion of 17-ketosteroids is determined. Eosinopenia and an increase in 17-ketosteroid excretion are seen in normal subjects but not when the adrenal cortex does not function.

Sexual disturbances such as loss of libido and impotence in men and amenorrhea in women are frequently observed. The urinary elimination of 17-ketosteroids diminishes. Treatment with adrenal extracts or steroids and salt improves the patient's condition.

Hypophyseal myxedema. Certain patients with myxedema and a low BMR (−20 to −45 per cent) on receiving thyroid treatment enter into an adrenal crisis which may be fatal if it is not adequately treated. In cases of myxedema, adrenal function is usually more or less depressed.

Hypophyseal cachexia. Adrenal insufficiency is evident in some cases of Simmonds' disease.

[1] According to Marañon, insulin should never be given to patients with Addison's disease, because it may cause fatal hypoglycemia.

Adrenal crisis. Acute adrenal insufficiency is seen in the course of Addison's disease (adrenal crisis) and after operations for corticoadrenal tumors or adrenalectomy performed in cases of cancer of the adrenals or the prostate and malignant hypertension. Typical signs of adrenal insufficiency appear, but they can be controlled by treatment with desoxycorticosterone, cortisone, and NaCl.

In the course of chronic adrenal insufficiency several causes may provoke an adrenal crisis, *e.g.*, infections, surgical operations, violent exercise, exposure to cold, intravenous injection of glucose, saline purges, administration of thyroid preparations, morphine, or barbiturates. The patient falls into circulatory collapse, the blood pressure falls, and the pulse rate increases. The skin becomes cold and cyanotic. There are signs of dehydration and hemoconcentration. Plasma sodium and chloride fall, and urea and potassium rise. There are nausea, vomiting, and diarrhea. Asthenia is marked, mental reactions are sluggish, and sometimes the patient becomes delirious.

Acute adrenal insufficiency. This condition is sometimes called the *Sergent-Bernard syndrome.*[1] There are three different types, according to the nature of the symptoms: (*a*) the abdominal, pseudoperitoneal, or choleriform type; (*b*) the nervous or pseudomeningeal type; (*c*) the cardiovascular type.

The *Waterhouse-Friderichsen* syndrome is due to adrenal hemorrhage, provoked, in the majority of cases, by meningococcus. Its principal signs are cyanosis and edema of the face, red and hemorrhagic patches on the skin, oliguria or anuria, progressive peripheral circulatory collapse, and stupor or coma.

Treatment. Chronic adrenal insufficiency is treated by the following methods: (*a*) ingestion of 5 to 20 gm. daily of sodium chloride, reducing the intake of potassium from the usual 4 gm. to 2 gm. daily; (*b*) desoxycorticosterone (usually the acetate) injected subcutaneously (5 mg. daily) or by the implantation of pellets (125 to 500 mg.) associated with sodium chloride (3 gm. daily); (*c*) cortisone (25 mg. daily or more) associated with NaCl and desoxycorticosterone (0.5 to 1 mg. daily).

Corticoadrenal extracts are very efficacious but used less frequently, except in adrenal crises or when there is danger of a crisis (surgical operations, fever, etc., in patients with adrenal insufficiency). Desoxycorticosterone maintains life and the electrolyte and water balance, but care should be taken that hypo-

[1] SERGENT, E., *Presse méd.*, May 12, 1943; *Journées méd. Paris*, p. 528, 1937.

glycemia does not occur, as it may if the patient is not adequately fed. An excess of desoxycorticosterone may cause edema, hypertension, cardiac dilatation, and pulmonary edema, and the patient may die. The dose should be diminished as soon as the patient's condition improves or there is an increase in weight (1 lb. per day), or edema, or signs of cardiac dilatation.

Fig. 252. Corticoadrenal virilism. *a*, preoperative appearance of woman, unshaved; *b*, preoperative appearance, arms shaved; *c*, 2 years and 10 months after removal of tumor. (*Lukens, F. D. W., and J. D. Palmer, Endocrinol., vol. 26, p. 941, 1940.*)

Cortisone has a slower action; it is marked only after 5 to 10 days' treatment. The blood sugar and sugar tolerance return to normal, electrolyte balance is restored, the electroencephalogram becomes normal, etc.

In an adrenal crisis special care should be taken to maintain a normal blood-plasma volume and blood pressure and to see that hypoglycemia does not occur. Large amounts (1 to 1.5 liters) of NaCl solution (0.9 per cent) and glucose solution (5 per cent) are given, adrenal extract is injected subcutaneously or intravenously, desoxycorticosterone (20 mg.) is injected intramuscularly, and the patient is fed frequently with carbohydrates.

Adrenal extracts do not modify the melanodermia. The skin, however, becomes paler as a patient recovers from a crisis because of hydration of the tissues.

ADRENAL HYPERFUNCTION

Under this heading the following subjects will be discussed: (*a*) effects of treatment with adrenocorticotrophin or cortisone; (*b*) the general adaptation syndrome; (*c*) chronic adrenal hyperfunction in man.

Effects of adrenocorticotrophin and corticoadrenal hormones. Adrenocorticotrophin (ACTH) causes adrenal hypertrophy, hyperplasia, and hyperfunction. Its activity increases considerably if it is given in continuous injection. Its most typical effects (which are not seen if the adrenals have been removed or destroyed by disease) are a fall in blood eosinophils (80 to 100 per cent) and an increase in the urinary excretion of 17-ketosteroids and 11-oxysteroids. Both these are due to an increase in corticoadrenal secretion.

Prolonged treatment with cortisone in animals causes inhibition of the adrenals (atrophy and hypofunction). A similar effect has been observed in man; in these cases interruption of cortisone treatment is followed by signs of adrenal hypofunction: asthenia, decreased urinary excretion of 17-ketosteroids, and diminished response to ACTH.

Prolonged administration of ACTH or cortisone provokes the appearance of many signs of Cushing's disease (see pages 623–624); the principal disturbances are increase in appetite and body weight, rounding of the face, acne and hirsutism (signs of androgenic activity), and cutaneous striations.

ACTH frequently produces pigmentation in the skin. Some preparations contain the melanodispersing hormone, which can be separated from the corticotrophic activity (Li), although it has been maintained that they are secreted together (Sulman).

During treatment there are remarkable psychic changes; usually there is euphoria, but

in some cases the patient becomes depressed. Convulsions and mental disturbances have also been reported.

There is little or no change in blood pressure (Sprague). In patients with Addison's disease there is not much retention of sodium, contrasting in this with the effect of desoxycorticosterone. In subjects with functioning adrenals it may cause retention of Na and water which is later compensated. ACTH also causes transitory retention of Na, Cl, and water in subjects with intact adrenals. Both substances increase potassium excretion and may cause the K concentration in plasma to fall below the normal, with K deficiency in extracellular and intracellular fluids. In some cases there is alkalosis with low Cl and K concentration in blood (hypokalemic alkalosis), as may occur in patients with Cushing's disease.

In man the blood sugar usually remains normal; there is no glycosuria; sugar tolerance occasionally diminishes, but in most cases it is not affected; sensitiveness to insulin diminishes. In a few cases ACTH has provoked hyperglycemia and glycosuria, partly of renal origin (Conn). It increases the severity of the disease in diabetic subjects (Sprague, Thorn). Large doses may produce a temporary diabetes in the rat. Cortisone does not provoke diabetes in dogs with an intact normal pancreas, but after the pancreatic mass has been reduced surgically, cortisone may provoke transitory, corticoid, diabetes or permanent, metacorticoid, diabetes.

In the rat cortisone increases the capacity for muscular work, but in man it may cause muscular weakness, especially in cases of hypokalemia.

Large doses increase protein catabolism and the excretion of N, P, and K; effects which are not produced by small or medium doses. Animal experiments have shown an increase in protein catabolism and a decrease in protein anabolism.

Uric-acid excretion increases a few hours after injection of cortisone (Thorn), owing to its action on the kidney.

An optimum level of adrenal secretion is necessary for growth. Adrenalectomized animals either fail to grow or show retarded growth. An excess of cortisone, or of ACTH in animals with intact adrenals, also retards growth.

Storage and liver fat may increase. Ketonuria increases in diabetics and occasionally in normal subjects.

There is marked atrophy of lymphoid tissues in several species, but less in man. A transitory lympholytic effect has also been seen on malignant lymphatic tumors.

The blood picture shows neutrophilia, lymphopenia, and marked eosinopenia. In man lymphopenia is not so constant or so intense as in other species.

Inhibition and atrophy of the sexual organs have been observed in males; this effect is mediated by the hypophysis and does not occur in hypophysectomized animals. In women amenorrhea may occur, and in men the libido may diminish.

Thyroid function is more or less depressed in the course of treatment with ACTH or cortisone.

Large doses inhibit growth, osteogenesis, and chondrogenesis. The skin becomes thin, sebaceous glands are atrophied, and hair growth ceases. Hyperactivity of the mesenchyma in response to aggression by chemical or biological agents, and in allergy, is also inhibited. Cortisone diminishes inflammatory reaction and the development of fibroblasts and fibrous tissue; it retards healing of wounds and inhibits hyaluronidase, and in some cases antibody formation is subnormal. This decrease in defensive reactions favors the growth and dissemination of bacteria and other germs; thus, in patients suffering from tuberculosis the disease frequently increases in severity and has a tendency to spread. Inhibition of local inflammatory reaction may, however, be advantageous, *e.g.*, in some cases of allergy, or inflammatory processes of the eye or joints.

Treatment with ACTH or cortisone rapidly improves the symptoms of rheumatoid arthritis; in some cases within a few hours spectacular results are obtained,[1] Relapses, however, occur when the treatment is suspended, and occasionally even in the course of treatment.

Resistance to cold, hypoxia, fasting, histamine, etc., is increased by treatment with cortisone in adrenalectomized animals, and in a lesser degree in normal animals.

The general adaptation syndrome.[2] Selye has given this name to "the sum of all nonspecific systemic reactions of the body which ensue upon long exposure to stress." The reac-

[1] HENCH, P. S., *et al.*, *Ann. Rheumat. Dis.*, **8**, 90 and 97, 1949.

[2] SELYE, H., *J. Clin. Endocrinol.*, **6**, 117, 1946; "Textbook of Endocrinology," 2d ed., Acta Endocrinologica, Montreal, 1949; "Stress," Acta, Inc., Montreal, 1950.

tions are the same to all harmful agents, but they vary to some extent from one species to another.

The following circumstances provoke the appearance of the adaptation syndrome: (*a*) trauma (accidental, surgical, obstetrical); (*b*) violent muscular exercise; (*c*) infections; (*d*) hemorrhage; (*e*) cold; (*f*) fever; (*g*) anoxia; (*h*) burns; (*i*) poisons, or drugs and hormones in abnormally large doses; (*j*) bacteria; (*k*) radiation; (*l*) nervous shock; etc.

The syndrome develops in three stages: (*a*) the *alarm reaction* to sudden exposure to stimuli to which the organism is not adapted (this reaction has two phases, shock and countershock); (*b*) the *stage of resistance*, during which symptoms improve or disappear; (*e*) the *stage of exhaustion*, during which the symptoms reappear.

During the alarm reaction there are notable structural and functional changes in many organs, together with certain metabolic disturbances.

The functions of the hypophysis are rapidly and markedly disturbed. Adrenocorticotrophin secretion increases and causes corticoadrenal hypertrophy with a decrease in the ascorbic-acid, cholesterol, and fat content of the adrenal tissue. There is also an increase in the secretion of corticoadrenal hormones, which is responsible for some of the disturbances observed. These disturbances do not occur in adrenalectomized or hypophysectomized animals. They are the following: (*a*) atrophy of the thymus and lymphoid tissue, with a decrease in the blood lymphocyte count; (*b*) disturbances in water, salt, carbohydrate, and protein metabolism; (*c*) increase in the urinary elimination of corticoadrenal steroids. The increase in adrenocorticotrophin secretion has been demonstrated by the rapid decrease in the ascorbic-acid content of the adrenal, which does not occur in hypophysectomized animals.[1]

The increase in adrenocorticotrophin in man[2] causes a rapid decrease in the blood lymphocyte count, which has been observed in aviators flying to great heights, after the injection of adrenaline or insulin, etc. There is also an increase in the urinary elimination of "corticoids," *i.e.*, of

[1] LONG, C. N. H., *Federation Proc.*, **6**, 461, 1947; SAYERS, G., and M. A. SAYERS, *Recent Progress in Hormone Res.*, **2**, 81, 1948; Symposium on the Adrenals, *J. Endocrinol.*, **5**, No. 4, 1947.

[2] VENNING and BROWNE, *op. cit.*, FORBES, *et al.*, *op. cit.;* SHIPLEY, *et al.*, *op. cit.;* PINCUS, G., *Recent Progress in Hormone Res.*, **1**, 123, 1947.

substances with adrenal hormonal activity such as increasing the resistance of adrenalectomized rats to cold, or increasing the liver-glycogen content of adrenalectomized animals. These substances release formaldehyde when oxidized with periodic acid.[1] Another sign of corticoadrenal hyperactivity is an increase in the urinary excretion of 17-ketosteroids. Increases to 20 and 30 times the normal amount of urinary corticoadrenal steroids during approximately 2 days, followed by a decrease, have been observed in subjects submitted to surgical operations, flying to great heights, or suffering from burns, hemorrhage, anoxia, etc.

Adrenocorticotrophin secretion increases considerably and very rapidly. This provokes a decrease in the ascorbic acid,[2] cholesterol, and fat content of the adrenal, which becomes congested and later is hypertrophied. The secretion of corticoadrenal hormones is increased, and this increase is the cause of several signs which do not appear if the adrenals have been removed, *e.g.*, (*a*) atrophy of the thymus and lymphoid tissues, and lymphopenia in the blood; (*b*) marked decrease of blood eosinophils; (*c*) changes in water, salt, carbohydrate, and protein metabolism; (*d*) increase in the urinary excretion of 17-ketosteroids and corticosteroids.

In man accidental or surgical trauma, burns, hemorrhage, hypoxia, etc., are accompanied by the appearance of similar signs, *e.g.*, eosinopenia, and sometimes lymphopenia; increase in urinary corticosteroids, 17-ketosteroids, or 11-oxysteroids. In some cases increases up to twenty or thirty times the normal amount of urinary corticosteroids are observed for about two days, followed later by a decrease.

Chronic adrenal hyperfunction. There are several clinical forms of corticoadrenal hyperfunction (also called hypercorticalism), depending on age and sex of the patient and on which hormones are secreted in excess. In Cushing's disease metabolic disturbances predominate. Excess of androgenic hormones causes somatic or sexual precocity and, in adult women, virilization. Less frequently there is an excessive estrogenic activity which causes feminization in males.

[1] This reaction is usually attributed to "oxycorticosteroids" originated in the adrenal, but it is not specific for these substances.

[2] SAYERS, G., and M. A. SAYERS, *Recent Progress in Hormone Res.*, **2**, 81, 1948; *Physiol. Rev.*, **30**, 241, 1950.

Cushing found basophil-cell adenomas in the hypophysis, and attributed to hypophyseal basophilism the disturbances seen in the syndrome now called "Cushing's disease." The clinical signs and symptoms were seen to be those of corticoadrenal hyperfunction. Moreover, modifications in the basophil cells of the hypophysis are usually observed in cases of hypercorticalism (Crookes), and treatment with corticosteroids produces similar changes in the basophil cells. Therefore corticoadrenal hyperfunction is considered to be usually (perhaps always) the primary cause, and hypophyseal disturbances secondary to adrenal hyperfunction.

The most frequent signs and symptoms are the following: (*a*) *adiposity* of face, neck, and trunk, but not of the limbs; (*b*) *kyphosis*, due to osteoporosis of the cervicodorsal vertebrae (sometimes osteoporosis affects other bones, and frequently there is a negative calcium balance); (*c*) *arterial hypertension*, which usually develops in the later stages; (*d*) *diabetes*, or a diminished glucose tolerance, frequently observed; (*e*) *weakness*, asthenia, muscular atrophy, and a tendency to become tired easily; (*f*) *cutaneous signs*, such as purple atrophic striae and thinning of the skin, keratosis of the hair follicles, sometimes hypertrichosis, and a tendency to hemorrhages; (*g*) *sexual disturbances*, such as amenorrhea in women, loss of libido and impotence in men; (*h*) changes in *blood plasma*, *i.e.*, alkalosis with low Cl and K concentration; (*i*) changes in the *blood picture*, lymphopenia, eosinopenia and occasionally polycythemia; (*j*) *psychic* disturbances.

In a few cases of Cushing's disease irradiation of the hypophysis with x-rays has been followed by improvement. Subtotal adrenalectomy has given better results with considerable improvement in many cases.[1]

Adrenogenital syndromes are observed when there is hypersecretion of corticosteroids with sexual activity. When hypercorticalism develops during fetal life the child is a female pseudohermaphrodite with peniform clitoris and other signs of virilization. Boys affected in early childhood have a precocious puberty, *e.g.*, in a five-year-old boy the development of the penis and sexual hair may be that of a full-grown man. In girls heterosexual development (virilization) is observed: there are hypertrophy of the clitoris and abnormal hair growth (Fig. 252), the female sexual organs (ovaries, uterus, mammary glands) are not enlarged, and menstruation does not occur at an early age. Great muscular development and obesity in some cases give these children a herculean aspect. Girls are large and fat and take on a matronly appearance.

In adult females there is virilization and great development of the body hair (hirsutism). The hair on the head has the distribution and aspect of the male, there is a thick beard and mustache, and in many cases the whole body is covered with hair (Fig. 252). The skin is rough and thickened, and acne is often seen. The body build is that of a male, with broad shoulders and well-developed muscles. The voice is deep owing to the development of the larynx. There are many sexual disturbances: (*a*) menstruation is scarce or may be absent (amenorrhea); (*b*) sterility is observed in 50 per cent of the cases; (*c*) the mammary glands are atrophic; (*d*) anomalies in the libido occur frequently. With age other symptoms appear, such as obesity; purple striae in the skin; high blood pressure; osteoporosis, limited to the cervicothoracic vertebrae (kyphosis) or more widely spread; latent or manifest diabetes.[1] Often there is a negative nitrogen balance, accompanied by muscular weakness.

Hypercorticalism is observed more frequently in women than in men, but a few cases of feminization have been reported in men who have testicular atrophy and development of the mammary gland.

Hypertrichosis and the abnormal development of male or female sexual characters have been attributed to androgenic and estrogenic steroids secreted by the hyperactive adrenal cortex.

In many cases surgical extirpation of the adrenal tumor was followed by the total disappearance of the signs and symptoms of hypercorticalism. The tumor may have caused inhibition of the normal adrenal tissue, and when it is removed frequently acute corticoadrenal insufficiency develops. Precautions should therefore be taken during the preoperative and postoperative stages to avoid an adrenal crisis.

[1] Priestley, J. T., *et al.*, *Ann. Surg.*, **134**, 464, 1951; Kuppermann, H. S., *et al.*, *J. Clin. Endocrinol.*, **11**, 774, 1951.

[1] The Achard-Thiers syndrome (diabetes in bearded women) is one type of hypercorticalism.

The determination of the urinary excretion of steroids may give valuable information on the functional state of the adrenal cortex. In cases of Cushing's disease the excretion of 17-ketosteroids is usually normal or only slightly above normal; the excretion of glycocorticoids (11-oxysteroids) is increased (Venning and Browne). In adrenogenital syndromes and in hirsutism, 17-ketosteroid elimination is increased and that of 11-oxysteroids remains normal. In Addison's disease, after adrenalectomy, in hypophyseal insufficiency and in anorexia nervosa, excretion of 17-ketosteroids and 11-oxysteroids diminishes considerably. In acromegaly it is usually increased. In adrenal hyperplasia and hyperfunctioning tumors of the adrenal cortex urinary 17-ketosteroids are considerably increased; they return to normal levels after the tumor has been removed. Trauma and violent exercise increase urinary corticosteroids; an increase is also observed during the last weeks of pregnancy.

Abnormal hyperactivity of the adrenal medulla. In patients with chromophil-cell tumors, paroxysmic or permanent hypertension is observed. These tumors contain and secrete adrenaline and noradrenaline in variable proportions; frequently noradrenaline predominates. Hypertensive crises occur spontaneously and may be provoked by intravenous injection of 0.025 mg. of histamine (Kvale and Roth). Permanent hypertension due to chromaphil-cell tumors is reduced and hypertensive paroxysms are prevented by the injection of adrenolytic drugs (benzodioxane, regitine, etc.). Extirpation of the tumors lowers the blood pressure, if it was above normal, and suppresses the hypertensive crises.

CHAPTER 55

The Parathyroid Glands

THE PARATHYROIDS ARE small endocrine glands of great physiologic importance. Their removal or insufficiency causes serious disturbances, which may be fatal if adequate treatment is not given. Parathyroid secretion controls homeostasis of phosphorus and calcium; it maintains a normal blood-calcium level and raises it if it falls below the normal. It regulates the deposition and mobilization of calcium salts in the bones and teeth; therefore it modifies the structure and consistency of the skeleton. It controls calcium and phosphorus metabolism and the renal excretion of calcium and phosphate. Through its effect on calcium metabolism and blood calcium, it controls the ionic equilibrium of body fluids and is thus an important factor in the maintenance of the normal excitability of the tissues and the permeability of cell membranes.

Historical note. The parathyroids were seen by Remak in 1855, but they were not fully described until Sandström published a very complete paper on them in 1880. Gley (1891) attributed to them some of the results observed after thyroidectomy and considered them undeveloped thyroid tissue. Moussu (1896) and Vassale and Generali (1896) demonstrated the differences in the functions of the thyroid and parathyroids. Before this work was published most so-called "thyroidectomies" were really thyroparathyroidectomies, and the "acute symptoms" of thyroidectomy, *e.g.*, tetany, were really due to parathyroidectomy. It is now fully understood that the thyroid and parathyroids have different structure, embryologic development, and functions.

Physiologic anatomy. There are usually two parathyroids on each side. One, situated on or near the thyroid, is the upper, or external, parathyroid. It is also known as "parathyroid IV" because it develops from the endoderm of the fourth branchial cleft. The lower, or internal, parathyroid is usually found within the thyroid gland. It is also called "parathyroid III" because it develops from the endoderm of the third branchial cleft. In the rabbit the external parathyroids are situated some distance from the thyroid; in the dog and cat they are placed on the upper pole of the thyroid. When thyroidectomy is performed in the rabbit the external parathyroids are not damaged, but thyroidectomy in the dog or cat must be performed with great care if the external parathyroids are to remain intact. Anomalies in position and accessory parathyroids occur frequently. The principal parathyroids in man have the shape of oval disks measuring 6 to 7 mm. by 3 to 4 mm. by 1 to 2 mm. All the parathyroid tissue together weighs approximately 140 mg.

There are two main types of parathyroid cells:

1. The principal, or chromophobe, cells are the most numerous. They have a large nucleus and no granules.
2. The eosinophil cells are less numerous, and larger than the former. They contain eosinophil granules. Eosinophil cells are not seen in man in early childhood; they appear about the tenth year of age. They are not found in the dog and other species.

PARATHYROID INSUFFICIENCY

Total parathyroidectomy can be performed without removing the thyroid, but usually thyroparathyroidectomy is performed when all the parathyroid tissue is to be removed, because the internal parathyroids are not always easily found. In certain cases there are accessory parathyroids situated some distance from the thyroid; they are often found included in the thymus.

Total parathyroidectomy is followed by tetany (parathyroid tetany). The cat and dog have been used most often for the experimental

study of parathyroid tetany, but it has been observed in many other species, *e.g.*, rats and other mammals, reptiles, and amphibians, and it has been observed in man after thyroidectomy performed in cases of goiter. Tetany appearing spontaneously has also been reported.

FIG. 253. Chronic hypoparathyroidism. Carpospasm provoked by compression of the arm by a pneumatic cuff (Trousseau's sign).

The name "tetany" was given by Corvisart in 1852 to convulsive conditions similar to those provoked by tetanic infection of wounds and certain drugs, such as strychnine. The different types of tetany were described in Chap. 45 when dealing with calcium metabolism.

There are three types of parathyroid insufficiency: (*a*) acute; (*b*) chronic; (*c*) latent. Total parathyroidectomy usually provokes acute tetany in the dog and cat, which ends in death within a few days in the majority of the animals. In man chronic tetany is more commonly observed.

Neuromuscular hyperexcitability. Hyperexcitability is a typical sign in all forms of tetany. It is the cause of the convulsions of acute tetany, but it is present and can be revealed by adequate tests in latent tetany. The following tests are those most commonly used: (*a*) if the arm is constricted by an armlet and the circulation is obstructed, there is a spasm of the muscles of the forearm and hand (carpospasm) which causes the hand to adopt a typical posture (Fig. 253) (Trousseau's sign); (*b*) tapping over the facial nerve where it is near the surface (in front of the ear) causes a spasm of the facial muscles on that side (Chvostek's sign); (*c*) the galvanic threshold of nerves and muscles is below normal (Erb's sign); (*d*) the rheobase is lower and chronaxie higher than in normal subjects (see Chap. 66); (*e*) hyperpnea of a few minutes duration provokes muscular twitchings and convulsions in subjects with latent tetany, owing to alkalosis.

The signs of tetany are mainly involuntary muscular contractions. In mild forms only twitchings or tremor are observed; in the severer forms, sometimes called spasmophilia, the following signs occur: (*a*) carpopedal spasm, *i.e.*, spasm of the hands and feet, in which
FIG. 254. Tetany. Carpopedal spasm. (*According to Falta, in Biedl, "Innere Sekretion," 4th ed., Urban & Schwarzenberg, Vienna, 1922.*)

the hands are flexed at the wrist, the fingers flexed at the metacarpophalangeal joint, extended at the interphalangeal joints, and brought together by adduction (the so-called "accoucheur's hand," Figs. 253 and 254); (*b*) laryngeal spasm, causing inspiratory stridor;

(*c*) a typical sardonic risus and a pained expression of the face; (*d*) spasms of other muscles and sometimes of the whole body (convulsions); (*e*) less frequently, spasms in smooth muscles, *e.g.*, the iris, esophagus, stomach, intestines, and bladder (visceral tetany); (*f*) changes in the electrocardiogram, which disappear with calcium treatment; these have been reported in the dog (Segura, 1937) and in man (Gotta and Pinto, 1941). The spasms are usually painful.

Spastic rigidity and convulsions in the form of epileptoid crisis are sometimes observed in man. The electroencephalogram shows signs of cortical hyperactivity in some cases, but not in all; they are related to the low blood-calcium level.[1]

In dogs and cats, contracture of the masticatory muscles keeps the jaws clamped. There is rigidity of the spinal muscles, and the limbs are spastically extended. Tremor and muscular twitchings increase gradually and merge into crises of generalized convulsions, separated by intervals of hypotonia and paresia. Muscular hyperactivity causes a rise in rectal temperature and thermal polypnea with salivation and tachycardia. Hepatic and renal lesions with albuminuria have been reported. The majority of untreated animals die in 4 to 7 days.

Spasticity and convulsions are due to hyperexcitability of the nerve centers. Extirpation of the cerebral cortex or decerebration (section of the brain stem) increase these symptoms. Spasticity is due to hyperactivity of the reflexes that produce normal muscle tone; it can be suppressed by section of the dorsal roots or the ventral roots, or by destruction of the spinal cord. Denervation of a muscle group suppresses spasticity and convulsions in that group, but fine fibrillar contractions may still be observed.

Disturbances in calcium and phosphorus metabolism. There are four typical signs of parathyroid insufficiency: (*a*) hypocalcemia; (*b*) hyperphosphatemia; (*c*) hypocalciuria; and (*d*) hyperphosphaturia. Blood calcium falls after parathyroidectomy from the normal level (9.5 to 11 mg. per cent) to 7 mg. per cent and in some cases 5 mg. per cent (McCallum and Voegtlin). Calcium ion concentration also decreases. The fall in blood calcium causes the excretion of calcium in the urine to diminish; calciuria ceases when the blood calcium is below 6 mg. per cent. The calcium in the feces is not significantly changed, but total calcium excretion diminishes owing to the decrease in urinary calcium elimination.

[1] Gotta, H., and J. B. Odoriz, *J. Clin. Endocrinol.*, **8**, 674, 1948.

Blood phosphate increases to 6 or 8 mg. per cent and in some cases to 12 mg. per cent. Urinary excretion of phosphate diminishes, but there is little or no change in the excretion of phosphorus in the feces. Alkaline phosphatase in blood increases.
Fig. 255. Effect of parathyroid insufficiency on teeth. Erosion and discoloration of teeth in a patient with tetany. (*According to Phelps, in Biedl, "Innere Sekretion," 4th ed., Urban & Schwarzenberg, Vienna, 1922.*)

Other symptoms. Chronic hypoparathyroidism is accompanied by trophic disturbances, among which the following can be mentioned:

1. *Cataract* (opacity of the eye lens) is gradually established in prolonged hypocalcemia.
2. *Dental lesions* (Fig. 255) are marked in infantile tetany, less marked if the onset of the disease does not occur until the eighth to thirteenth year; they are not observed in adults. The rat is particularly appropriate for the experimental study of these lesions, because of the continuous growth of the incisors (Erdheim, Erausquin). The teeth take on a dull white aspect, and later brown stains appear (Fig. 256). They are easily deformed and fractured. The enamel is hypoplastic. The odontoblasts are irregularly placed and show signs of degeneration. The dentine is poorly calcified (areolar or globular dentine), and there is a large pulp cavity. According to Erdheim, if a parathyroid is grafted normal dentine is again formed.
3. *Bone lesions* are not prominent, but in young animals ossification is delayed, and consolidation of fractures is retarded in adults.

4. *Deficient development of the hair and nails* is observed. The nails are easily broken, and the hair falls.
5. *Cutaneous disturbances*, such as erosions and ulcerations, are sometimes observed.
Fig. 256. Teeth of parathyroidectomized rat. Discoloration; fractured right upper incisor; excessive growth of left upper incisor.

Chronic and latent hypoparathyroidism. In some animals parathyroidectomy is not followed by acute tetany. The disease has a chronic course; the animals lose weight, trophic disturbances, such as cataract, appear after a time, and if the animals are young, growth is retarded. Calcemia is low in these animals, but spasticity is not observed, or may occur intermittently. In the so-called "latent tetany" there is persistent hypocalcemia, and sometimes trophic disturbances, but the usual signs of tetany (spasticity, muscular twitchings, convulsions) occur only in certain circumstances which provoke in these animals attacks of acute tetany.

Factors that modify the course of tetany. The severity of acute experimental tetany is increased, and latent tetany is made manifest, in the following circumstances: (*a*) a meat diet; (*b*) severe exercise; (*c*) estrus or pregnancy; (*d*) a high external temperature; (*e*) nervous or emotional stimulation; (*f*) injection of decalcifying agents (phosphates, etc.). Factors that diminish the severity of tetany usually increase the blood-calcium level and decrease excitability; the following may be mentioned: (*a*) injection of large quantities of Ringer's solution, which contains calcium; (*b*) a milk diet, which has a high calcium content; (*c*) administration of calcium, magnesium, or strontium salts; (*d*) vitamin D or cod-liver oil, which increase blood calcium (Fig. 257); (*e*) hemorrhage; (*f*) depressants of nervous excitability. Parathyroidectomized dogs can be kept alive and free from tetany by giving them 5 gm. of calcium lactate or gluconate twice daily. After 2 or 3 months of this treatment, it can be discontinued in many of the animals, which remain in latent tetany without symptoms in spite of the low blood calcium (Frouin, Luckhardt); apparently the tissues have become adapted to this low calcium level.

The mechanism of tetany. Several theories have been put forward to explain the mechanism of tetany. The principal ones postulate (*a*) the accumulation of a toxic substance in the organism (toxic theory); (*b*) a disturbance in the acid-base equilibrium; (*c*) a disturbance in calcium metabolism.
Fig. 257. Effect of calcium and vitamin D_2 on blood calcium and tetany. Arrows from left to right: 1, thyroparathyroidectomy; 2, tetany; 3 and 4, 4 doses of calcium gluconate (5 gm. twice daily for 2 days—20 gm. in all) and 40 mg. vitamin D_2 in one dose; 5, tetany. Ordinate, calcium concentration in plasma, in milligrams per cent; abscissa, time in days.

The toxic theory was the first to be proposed, and much work was done in the search for the toxic substance. Xanthine, histamine, carbamates, guanidine, and other compounds have been considered the specific poison that accumulates after parathyroidectomy and causes tetany. These substances provoke effects that are similar to, but not identical with, those of

tetany due to parathyroid insufficiency. They do not produce hypocalcemia, and the disturbances they cause are not controlled by calcium treatment or parathyroid extracts. It was frequently maintained that the poison producing tetany was absorbed from the intestine, but Billi has demonstrated that tetany occurs after parathyroidectomy in animals in which the stomach and intestines have been completely extirpated.

Alkalosis produced by the ingestion of an excess of alkali (*e.g.*, sodium bicarbonate) or by noncompensated loss of acid (*e.g.*, repeated vomiting with loss of HCl) causes tetany. Moreover acidosis, *e.g.*, that produced by the ingestion of ammonium chloride, improves the condition of animals or patients in parathyroid tetany because it favors the ionization of calcium in the body fluids. However, there is no alkalosis in tetany of parathyroid insufficiency; on the contrary, the convulsive periods cause a slight transitory compensated acidosis due to muscular hyperactivity. There is therefore no disturbance of acid-base equilibrium in parathyroid insufficiency capable of provoking tetany.

There are marked disturbances in calcium metabolism in parathyroid insufficiency, such as hypocalcemia, hypocalciuria, and lesions in the bones and teeth due to decalcification. Ingestion of a sufficient amount of calcium prevents or cures hypocalcemia and tetany, and all measures that are efficacious in the treatment of parathyroid tetany cause a rise in blood calcium. Thus parathyroid grafts or injections of parathyroid extracts increase blood-calcium concentration and control tetany.

The intimate mechanism that is the cause of hypocalcemia in parathyroid insufficiency is not known. At one time it was attributed to loss of calcium in the urine, but hypocalcemia occurs after parathyroidectomy in nephrectomized dogs, and parathyroid extracts cause the same rise in blood calcium in these animals as in controls with intact kidneys.

The decrease in calcium ion that occurs in parathyroid insufficiency disturbs the ionic equilibrium in body fluids, *i.e.*, the ratio of monovalent ions to bivalent ions, $\frac{(Na^+) + (K^+)}{(Ca^{++}) + (Mg^{++})}$, which Loeb showed was an important factor in neuromuscular excitability. A decrease in calcium concentration causes hyperexcitability of the nervous centers, which provokes spasticity (hypertonicity), tremor, muscular twitchings, and eventually convulsions, *i.e.*, tetany.

Parathyroidectomy causes a selective appetite for calcium. Parathyroidectomized rats that are allowed to choose between tap water and calcium solution drink large amounts of the latter. If these animals are treated with dihydrotachysterol, which increases the blood calcium, the consumption of calcium solution diminishes to the preoperative level. On the other hand, if parathyroidectomized rats are offered a phosphate solution, they drink less of it than normal controls (Richter).

Several objections have been made to the calcium-disturbance theory of tetany, among which the following may be mentioned: (*a*) hypocalcemia without tetany has been observed in cases of chronic nephritis, in animals fed on diets with an insufficient amount of calcium, and in parathyroidectomized dogs in which calcium treatment is discontinued after having been given during several weeks; (*b*) tetany can be improved without increasing the blood calcium by treatment with ammonium chloride or depressants of the central nervous system. These exceptional cases are usually interpreted as due to habituation of the tissues to a low blood calcium, or to the fact that ionic calcium is kept at a normal level in spite of the decrease in total calcium; thus ammonium chloride increases calcium ionization without raising the blood-calcium concentration.

Treatment of parathyroid insufficiency. Hypoparathyroidism is treated by raising the blood calcium or administering parathyroid hormone. Calcium treatment prevents death from acute tetany in dogs and carries them over to a condition of latent tetany. Calcium therapy is also the only method of rapidly relieving an acute attack of tetany, but it should be given intravenously only in cases of extreme emergency, because unless care is taken to inject it at a very slow rate, acute hypercalcemia may be provoked. Moreover most calcium salts are irritants (calcium gluconate is one of the least caustic) and cause damage to the vein (phlebitis). Usually 20 to 30 gm. of calcium lactate or gluconate is given daily by mouth. In this way it does not act so rapidly as when it is injected intravenously, but its effects last longer. Nevertheless the total daily amount should be given in several doses to obtain a more prolonged and smooth action. Blood calcium can be main-

tained stable at a high level by treatment with vitamin D or dihydrotachysterol, and patients with hypoparathyroidism can thus be kept free from tetany. Vitamin D_2 must be given in doses of 10 to 30 mg. per day (400,000 to 1,200,000 IU) until the blood calcium has reached a normal level; afterward the dose is reduced to 3 to 5 mg. per day (120,000 to 200,000 IU). With adequate supervision this treatment can be kept up for a long time. Dihydrotachysterol, introduced by Holtz under the name of AT 10 (antitetany preparation No. 10), is given in doses of 6 mg. daily to raise the blood-calcium level; afterward 1 to 3 mg. daily is enough to maintain a normal blood calcium. Large doses are toxic, and the patients should be carefully watched for signs of hypercalcemia. The diet should always contain an adequate amount of calcium, and it is advisable to reduce the phosphorus content to 0.5 or 0.6 mg. per day.

Active parathyroid extracts were prepared for the first time by Collip in 1925, under the name of "parathormone," but so far the parathyroid hormone has not been obtained pure.[1] This extract has the following effects: (*a*) it prevents or cures tetany in the dog and man; (*b*) it raises the blood-calcium level after an interval of 4 hr., reaching a maximum in 18 hr.; (*c*) it lowers the plasma phosphate; (*d*) it increases the urinary excretion of calcium and phosphate; (*e*) it mobilizes calcium stored in the bones. The effects of parathyroid extracts diminish gradually after a time and the dose must be raised to obtain constant results. Finally very large doses must be given to counteract the results of habituation.

Parathyroid glands have been grafted successfully in the rat (Cristiani, Erdheim) and in the dog (Halsted; Rojas and Manfredi). Successful grafts have also been obtained in human cases.[2] The practical importance of this method of treatment is not great, because it is not easy to obtain fresh healthy parathyroid tissue for grafting, and large numbers of the grafts are reabsorbed.

THE REGULATION OF PARATHYROID SECRETION

The internal secretion of the parathyroid glands maintains blood calcium at a normal

[1] Ross, W. F., and R. T. Wood, *J. Biol. Chem.*, **146**, 59, 1942.

[2] Manfredi, J. T., "Injertos Paratiroideos," J. Vicenti, Buenos Aires, 1944.

level and raises it if it has fallen below this level. If blood calcium is decreased by the injection of fluoride or oxalate, it returns to the normal concentration after a time only if the parathyroids are intact; in parathyroidectomized animals blood calcium remains low.[1] On the other hand, the blood-calcium curve following intravenous injection of calcium is not modified by parathyroidectomy. Hypocalcemia stimulates parathyroid secretion; this is demonstrated by the following facts: (*a*) a parathyroid graft made by vascular anastomosis restores the normal blood-calcium level within a few hours in parathyroidectomized dogs, but the blood-calcium concentration of normal animals is not modified by a parathyroid graft;[2] (*b*) if blood from an animal in hypocalcemia is perfused through a parathyroid gland and is then injected into another animal, it provokes hypercalcemia in the latter, but this is not observed if the blood perfused through the parathyroid has a normal calcium concentration (Patt, Wallerstein, and Luckhardt, 1942). Parathyroid secretion therefore controls the concentration of calcium in the blood and maintains it at a normal level. Reciprocally the blood-calcium level controls parathyroid secretion, so that the amount of hormone secreted is sufficient to maintain a constant normal blood-calcium concentration.

HYPERPARATHYROIDISM

Acute hyperparathyroidism. This is provoked by the administration of excessive doses of parathyroid extract. It has been observed and well studied in animals, and also in a few cases of patients treated with parathyroid hormone. Blood calcium rises to 18 and even to 20 mg. per cent. Calcium is deposited in several tissues (lung, kidney, gastric and intestinal mucosa) and causes damage there. At the same time signs of calcium intoxication appear: loss of appetite, depression, muscular weakness, polyuria, vomiting, diarrhea, and dehydration. In a later stage the blood calcium falls slightly (Fig. 258), when renal lesions cause an increase in the nonprotein nitrogen of the blood. Blood phosphate is low in the first period and rises later when the kidney is damaged. In advanced calcium intoxication there are muscular relaxation (loss of tone), somnolence, coma, and eventu-

[1] Gerschman, R., *Rev. Soc. argent. de biol.*, **6**, 25, 1930.

[2] Lewis, J. T., and R. Gerschman, *Rev. Soc. argent. de biol.*, **5**, 774, 1929.

ally death. In several species a very large dose of parathormone provokes acute decalcification of bones. Prolonged treatment with large doses produces osteoporosis and osteitis fibrosa. According to Selye, the parathyroid hormone acts on the osteoblasts; a large dose converts these cells first into osteoclasts, which reabsorb bone (calcium, phosphate, and organic matrix), and later into osteoblasts which form bone.

Chronic hyperparathyroidism. In 1891 von Recklinghausen described a disease of the bones to which the name "osteitis fibrosa cystica of von Recklinghausen" was given. Later hyperplasia or tumors of the parathyroids, which were thought to be a defensive response to the disturbance in calcium metabolism, were found in these patients. Schlagenhaufer suggested that they were the cause of the disease, and Mandl (1925) performed the first extirpation of the parathyroids in these cases, observing a remarkable improvement in the patient's condition. Later this fact was confirmed in many cases and corroborated by the experimental production of osteitis fibrosa cystica in animals by prolonged treatment with large doses of parathyroid extract.

In hyperparathyroidism there is *hypertrophy or hyperplasia of the parathyroids or a tumor* (adenoma or malignant growth) in one of the glands together with disturbances in calcium and phosphorus metabolism, lesions in the bones and kidney, and general symptoms.

Disturbances in calcium and phosphorus metabolism include hypercalcemia (12 to 15, exceptionally 20, mg. per cent). Blood phosphate falls below 3 mg. per cent, frequently to 1 and 2 mg. per cent, except in the late stages when renal lesions cause retention of phosphate. Urinary excretion of calcium and phosphate is abnormally high; normal amounts of calcium and phosphate are eliminated in the feces, but the calcium balance is often negative, owing to hypercalciuria. Plasma phosphatase also increases.

Bones. Calcium is mobilized and removed from the bones, which become decalcified and painful. The bones lose consistency and are deformed by the weight of the body. Thus the vertebrae are flattened, the spine is abnormally curved (kyphosis and scoliosis), and the subject's height decreases. The bones of the limbs show abnormal curvatures, and fractures sometimes occur spontaneously. Radiographs show general decalcification of the bones, but certain areas are more intensely decalcified, especially in the cranium, spine, and pelvis. Tumors and cysts are also formed, more often in the long bones of the limbs than elsewhere. In about one-third of the cases, in which the calcium balance is not negative, there are no lesions in the bones.
FIG. 258. Effect of parathyroid overdosage on blood calcium (dark line), phosphorus (light line), and nonprotein nitrogen (dotted line). At each arrow 25 units of parathormone was injected. Abscissa, time in hours; ordinates, concentration of nonprotein nitrogen, calcium, and phosphorus in the blood, in milligrams per cent. (*Collip, J. B., Medicine, vol. 5, p. 1, 1926.*)

Kidneys. Renal lesions are seen in 92 per cent of the cases; they are secondary to the disturbances in calcium metabolism. Polyuria often occurs; sometimes it is as extreme as in patients with diabetes insipidus, and provokes intense thirst and polydipsia. Calcium is deposited in the cells of the renal tubes, and there is renal insufficiency. Frequently calcium phosphate or oxalate precipitates in the urine (urinary "sand") or stones are formed in the collecting tubes or the renal pelvis and may provoke ureteral obstruction (renal colic).

General symptoms. Calcium may precipitate in the intima of the arteries, in the gastric mucosa, bronchi, and other tissues. Hypercalcemia produces a decrease in muscle tone, muscular weakness (asthenia), neuromuscular hypoexcitability, and difficulty in performing movements. In more serious cases there is loss of appetite or vomiting, loss of weight, and anemia, and constipation occurs frequently.

Treatment of hyperparathyroidism. The diet should contain a large amount of calcium and a low phosphorus content to prevent the negative calcium balance and decalcification of the bones. Surgical removal of the hypertrophied glands or adenoma soon causes considerable improvement in the patients' condition. Removal of a functional parathyroid tumor

often causes hypocalcemia and tetany. This has been attributed to inhibition of the remaining parathyroid tissue or to the rapid removal of calcium from the circulation and its storage in the bones. Blood calcium should be carefully watched after the operation and hypocalcemia should be treated immediately in order to avoid tetany.

The mechanism of hyperparathyroidism. According to Albright, the initial disturbance in hypoparathyroidism is an excessive renal excretion of phosphorus, which would provoke mobilization of calcium and phosphorus in the bone, leading to decalcification. Parathyroid hormone, however, acts directly on the bone, as is shown by the fact that it provokes hypercalcemia and decalcification of bone in nephrectomized animals.

Secondary hyperparathyroidism. Hypertrophy of the parathyroids is found in several conditions in which there is a decrease in body calcium: (*a*) in diets with low calcium content (rats and rabbits); (*b*) in diets deficient in vitamin D (chicks); (*c*) after renal operations (rats); (*d*) in many patients with rickets and osteomalacia. In all these cases hypertrophy of the parathyroids helps to keep a normal blood-calcium level and lowers the blood phosphate. Evidently there is a close relationship between the parathyroids, the kidneys, and the bones. Hyperparathyroidism causes lesions in the bones and kidneys, and reciprocally renal lesions may cause secondary hyperparathyroidism. Albright and Ellsworth have described cases in which renal insufficiency causes first a retention of phosphate; this lowers the blood calcium, and the hypocalcemia provokes compensatory hypertrophy of the parathyroids.

CHAPTER 56

Pancreas. Thymus. Epiphysis

PANCREAS

The pancreas is an endocrine gland of great importance owing to its secretion of insulin. The physiologic significance of insulin has been studied together with carbohydrate metabolism in Chap. 41. The part it plays in fat metabolism has been studied in Chap. 42.

THYMUS

There is no final proof that the thymus is an endocrine gland; the work that has been done on this problem has so far given contradictory results.

The thymus has a typical growth cycle; it increases in size and weight up to eleven or twelve years of age, and at fifteen years begins to retrogress, the thymocytes and reticular cells being gradually replaced by fat. During pregnancy there is also a typical involution of the thymus, which recovers its size after delivery. The thymus suffers involution in many circumstances, such as inanition and infections, and by the action of x-rays or certain hormones. Autopsies performed on subjects who have died of an infectious or wasting disease, even if they are young, reveal an atrophic thymus. On the other hand, subjects who have died suddenly, *e.g.*, owing to an accident, have an apparently large thymus.

Action on growth. Extirpation of the thymus has often been performed in many species. Thymectomized birds have a tendency to lay eggs without a shell (Soli, Riddle). In the adult mammal, thymectomy produces no symptoms. In young mammals disturbances in growth have been observed after removal of the thymus. Retarded body growth and sexual maturation, decalcification of bones or rickets, mental deficiency, and cachexia have been reported in thymectomized animals. On the other hand carefully controlled experiments in rats (Chiodi) and in dogs (Park and McClure) have given negative results, *i.e.*, the animals developed without showing any abnormalities in general body growth or sexual development. In many of the experiments in which retardation of growth was observed. the diet was not adequately controlled, and the results may have been due to dietary deficiencies.

It has been said that if the thymus is removed at an early age in successive generations of white rats, after several generations there is a retardation in growth (Einhorn and Rowntree). This remarkable observation has not been confirmed by other workers (Chiodi *et al.*) who performed carefully controlled experiments. Thymus extracts that cause an acceleration in growth have been obtained (Asher). Rowntree and his associates[1] have reported that treatment with thymus extract for several successive generations of rats accelerated growth and development. The animals were born with a significantly higher weight than the controls, with well-developed teeth, and covered with hair, and the eyes opened a few hours after birth; sexual maturity was also accelerated. Later the rate of growth decreased, and the final size and aspect of the animals were normal. These results have not been confirmed by others (Chiodi *et al.*).

Action on metabolism. The thymus has been considered a factor in nucleoprotein and carbohydrate (Bomskow) metabolism, but this has not been confirmed.[2]

The Control of the Thymus by Endocrine Glands

The thymus is controlled by several endocrine glands. The gonads and the adrenal cortex inhibit it; the thyroid has a stimulating effect.

[1] Rowntree, L. G., G. A. Clark, A. M. Hanson, and A. Steinberg, *J. A. M. A.*, **103**, 1425, 1934.

[2] Castellanos, H., *Rev. Soc. argent. de biol.*, **23**, 51 and 56, 1947.

The anterior hypophysis has a direct stimulating effect on the thymus due to the growth hormone, and an indirect effect due to the secretion of thyrotrophin which stimulates thyroid secretion. The anterior hypophysis also has an indirect inhibitory effect on the thymus due to the secretion of adrenocorticotrophin, which stimulates the adrenal cortex, and of gonadotrophins, which stimulate the sexual glands.
Gonads. The growth curve of the thymus has the same shape in castrated animals as in normal ones, but at a higher level, *i.e.*, at the same age the thymus is larger in the castrates than in the controls (Fig. 259). Physiologic involution nevertheless takes place in the castrates in spite of the absence of the gonads; therefore it is not caused by the secretion of the sexual glands. The gonads exert a continuous inhibitory influence on the thymus, an influence that is removed by castration. An excess of male or female hormone causes atrophy of the thymus. Gonadotrophins also provoke involution of the thymus because they stimulate the secretion of the sexual hormones; they have no effect on the thymus of castrates.

Adrenals. Adrenalectomy is followed by hypertrophy of the thymus (Jaffe, Rapela, and others), which lasts only until the accessory adrenals have developed.[1] The condition of the thymus in cases of Addison's disease has been reported in only a few instances; sometimes early involution of the thymus was observed. It must be kept in mind that anorexia is an outstanding symptom of this disease, and that tuberculosis of the adrenals is its most frequent cause; therefore there are two nonadrenal factors (*i.e.*, undernourishment and infection) that cause atrophy of the thymus in Addison's disease. Hyperactivity of the adrenal cortex and injection of several of the corticoadrenal steroids provoke atrophy of the thymus. Adrenocorticotrophin has the same effect if the adrenals are intact, but not in adrenalectomized animals (Moon). The thymus atrophies in animals submitted to conditions of stress, such as cold, traumatisms, etc., but not if the animals have been adrenalectomized or hypophysectomized (Selye). In these cases the anterior hypophysis is stimulated and secretes an excess of adrenocorticotrophin, which causes hyperactivity of the adrenal cortex and thus involution of the thymus.

Thyroid. Thyroidectomy causes in most cases a rapid involution of the thymus (Marine, Chiodi, Pinto, and Reforzo). In cases of thyroid insufficiency in man, there are few reports on the state of the thymus. Involution of the thymus has been found (Wegelin), but it may have been due to nonthyroid causes, such as malnutrition. Thyroid treatment in adequate doses and in well-fed animals causes hypertrophy of the thymus which has been attributed to inhibition of adrenocorticotrophin secretion. Large doses of thyroid, especially if there is cachexia, cause atrophy of the thymus. Autopsies in human cases of hyperthyroidism often reveal the presence of a persistent thymus.

Hypophysis. Hypophysectomy is rapidly followed by involution of the thymus in the dog.[1] The hypophysectomized rat has a small thymus, even if it is forcibly fed by stomach tube to prevent the effects of underfeeding. Purified hypophyseal growth hormone causes hypertrophy of the thymus. A persistent thymus is often found at autopsy in cases of acromegaly.

Thymus and status lymphaticus. Paltauf described a pathologic entity, characterized by a large thymus and a highly developed lymphoid tissue, which was called "status lymphaticus." Most of the subjects in which this condition was reported had died suddenly. Hundreds of autopsies on persons who have died owing to an accident, or in war, have shown that when death occurs in healthy, well-nourished persons, the thymus and lymphoid tissues are well developed. The normal growth curve of the thymus has thus been obtained, and most, if not all, of the case histories of so-called "status lymphaticus"

[1] Houssay, B. A., and J. M Lascano-González, *Rev. Soc. argent. de biol.*, **10**, 241, 1934.

are merely descriptions of the normal condition of lymphoid tissue.

Thymus atrophy provoked by x-rays. The thymus is very sensitive to x-rays, which cause it to atrophy. X-rays act directly on the thymus and produce their effects not only in normal animals but also in hypophysectomized or adrenalectomized ones.

The thymus in myasthenia gravis. In more than half the cases of myasthenia gravis, hypertrophy or a tumor of the thymus has been reported. In some instances irradiation of the thymus with x-rays, or thymectomy, has improved the condition of the patients; in others it has had no effect.[1]

EPIPHYSIS

The epiphysis, or pineal body, develops from an area that gives rise to glandular tissue. Its histologic structure has been well studied by Del Rio-Hortega[1] and seems to be that of an organ with secretory activity. Experimental and clinical data on the epiphysis obtained up to now are contradictory, and without further evidence it cannot be considered as an endocrine gland. Precocious sexual development (early puberty) has been reported after extirpation of the epiphysis in cocks (Foà) and other animals (Sarteschi, Horrax, Martin, and Davis).[2]

(*Chiodi, H., Rev. Soc. argent. de biol., vol. 14, p. 74, 1938.*)

Careful experiments by Dandy in dogs,[1] in the rat,[2] and in birds (Bardetscher) have been completely negative. In certain cases of tumor of the epiphysis in children, accelerated growth and precocious puberty have been reported (macrogenitosomia). In women with a pineal tumor, amenorrhea is usually observed. All these disturbances may be due to compression of the nerve centers in the neighborhood of the tumor and to a secondary effect on the hypophysis.

SECTION SEVEN

Reproduction

CHAPTER 57

Sexual Characters and Their Regulation

REPRODUCTION TAKES PLACE in vertebrates when the ovum (female gamete, produced by the ovary) is fertilized by the spermatozoon (male gamete, produced by the testicle).

Sexual characters. There are many characters that differentiate the male from the female of the species. There are primary and secondary sexual characters. The primary sexual character is the organ that produces the gametes, *i.e.*, the testicle in the male and the ovary in the female (the gonads). Secondary sexual characters (the name was first used by Hunter in 1780) may be classified into morphologic, functional, and psychic. Morphologic sexual characters are divided into genital and extragenital. Genital secondary sexual characters (or accessory organs of sex) are the ducts that convey the gametes outside the body, together with the glands associated with these ducts. In the male they are the epididymis, vas deferens, urethra, and penis, with the prostate, seminal vesicles, and Cowper's glands. In the female they are the fallopian tubes, uterus, vagina, vulva, and clitoris, and the glands in the mucosae of the female genital tract. Extragenital secondary sexual characters are all those (morphologic, functional or psychic) that differentiate the sexes.

It may be useful to mention a few outstanding secondary sexual characters in species commonly employed in the experimental study of sexual physiology.

Amphibians. The male of the toad *Bufo arenarum* (Hensel) is smaller than the female, and its skin is of a more uniform color, the female being of two well-marked shades of green; the male has a callus on the thumb and croaks when it is pressed under the arms. The male of the frog *Leptodactylus ocellatus* (L.) Gir. has large forelegs and a marked clasping reflex throughout the year.

Birds. The male characters in the domestic cock are the comb and other cephalic excrescences, crowing, aggressive behavior, and searching for and treading the females. The female characters in the hen are the plumage, sexual and maternal instincts, and inhibition of the development of the spurs (Fig. 260). The plumage is not a male character in cocks; capons and castrated hens have the same plumage as cocks.[1]

Mammals. The male is usually larger and has stronger muscles than the female; in certain species the male has cephalic appendages, such as horns (stag), a mane (lion) or beard (goat), or more developed teeth (boar) or incisors (elephant). In females the mammary glands, the marsupial pouch, and the sexual cycle are prominent characters that distinguish them from the males of the species. There are also many functional and psychic differences between the sexes.

The main extragenital secondary sexual characters in the human species are the following:

Man	*Woman*
Larger corporal development	Smaller corporal development
Greater stature	Lower stature
Rudimentary mammary gland	Well-developed mammary gland
Narrow pelvis	Broad pelvis
Greatest transverse diameter at shoulders	Greatest transverse diameter at hips
Less subcutaneous fat	More subcutaneous fat

[1] Sebright bantam cocks have "henny" plumage which is conditioned by the testes; capons have "cocky" plumage.

Man	*Woman*
Thick, rough skin	Thin, soft skin
Beard, mustache, tendency to baldness	No beard or mustache, hair on head longer and without tendency to baldness
Hair on pubis extending toward the umbilicus and the anus (lozenge shape)	Hair on pubis limited by horizontal line (triangular shape)
Abundant body hair, especially on the chest and limbs	Body hair fine and scarce
Well-developed larynx and low-toned voice	Less developed larynx, high-toned voice
Higher basal metabolic rate	Lower basal metabolic rate
Higher erythrocyte count	Lower erythrocyte count
Smaller adrenals and thyroids	Larger adrenals and thyroids, which also respond more readily to stimulation
Male character ot hypophysis	Female character of hypophysis
Male psychic character and response, initiative, aggressiveness, abstract thinking, idealism, interest in social problems	Female psychic character and response, more highly developed emotivity and affections, maternal and family sentiments, practical outlook

It is absurd to discuss the superiority of one sex over the other. There are some characteristics common to both sexes and others peculiar to each sex, which complement those of the other.

Sexual characters and functions evolve in the course of life. They are incompletely developed in the child before puberty. They grow rapidly during puberty and reach a maximum which is maintained during the years of maturity. Sexual activity declines in old age. In women there is a rapid retrogression which takes place in the course of the fifth decade of lite in the majority of cases, the most notable sign being cessation of the menstrual cycle. This is known as the menopause or climacteric. In man sexual decline takes place more gradually.

Sex is determined by genetic factors in vertebrates and in the majority of invertebrates. Nevertheless the gonadal germ of vertebrates is potentially bisexual during the first stages of its development, and several external and internal factors may exert an influence that can cause the sexual germ to become differentiated in the direction of either sex. Later, sexual differentiation is controlled mainly by the sexual hormones secreted by the gonads (ovaries or testes), which provoke and maintain the development of the secondary sexual characters corresponding to each sex.

DETERMINATION OF SEX

Sex is an inherited character. The sex of the fertilized egg is determined by its genetic constitution. Sexual differentiation is the result of this genetic constitution and other factors (internal and external) which act on the sexual germ. In man there are two types of sperm and only one type of egg (male digamety or heterogamy); in birds there are two types of egg and only one type of sperm (female digamety or heterogamy). In most insects there is male digamety, but in Lepidoptera (moths and butterflies) the female is heterogamous. Fertilization by one type of sperm in the human species produces an egg that develops into a male, and fertilization by the other type of sperm results in an egg that develops into a female. Human oogonia have 48 chromosomes (24 pairs); 46 are somatic chromosomes, and the other pair is known as the X chromosomes. During the maturation division of the germ cells the number of chromosomes is reduced to one-half (meiosis), because one member of each pair of chromosomes goes into each one of the daughter cells; therefore each ovum has 23 somatic chromosomes and 1 X chromosome. Spermatogonia also have 48 chromosomes—23 pairs of somatic chromosomes, and a pair formed by the X and Y chromosomes. In the maturation division the number of chromosomes is reduced to one-half, and two types of sperm are formed (male digamety or heterogamy). Half the spermatozoa have (23 + X), and the other half (23 + Y), chromosomes. Eggs resulting from fertilization by the former develop into females; they have (46 + XX) chromosomes; eggs resulting from fertilization by the latter have (46 + XY) chromosomes and develop into males.
FIG. 260. Hormonal influence on sexual characters. The spurs have been slightly accentuated. 1, normal cock; 2. normal hen; 3, castrated cock; 4, castrated hen; 5, castrated cock with ovarian graft; 6, castrated hen with testicular graft. (*According to Zawadosky, from Martins, T., "Glandulas Sexuaes e Hypophyse Anterior," São Paulo, 1936.*)

If both types of sperm have the same fertilizing capacity and both types of egg survive in equal numbers, according to the laws of probability equal numbers of males and females will be conceived and born. In fact from 104 to 109 (average 106) boys are born for every 100 girls. In the course of life, however, the specific mortality for males is higher than for females (*i.e.*, men die at an earlier age than women). Therefore as age advances more women survive, and the sex ratio in the total population may show a predominance of women.

SEXUAL DIFFERENTIATION

Sex is determined genetically, but sexual differentiation takes place gradually in the course of development. The primitive sexual germ is potentially bisexual. In vertebrates usually the cortex of this germ has the capacity to develop into ovarian tissue, and the medulla into testic-

ular tissue. In the genetically female organism the cortex develops into ovaries and the medulla remains rudimentary or atrophies; in the genetically male organism the medulla develops into testes and the cortex atrophies.

Several internal and external factors condition the development of sexual differentiation. The most important internal factor is the sexual hormone, which stimulates the development of the gonad and sexual characters of the corresponding sex and inhibits those of the opposite sex.

Hormonal control of sexual differentiation. Three aspects of this control will be considered: (*a*) sexual differentiation of the gonads; (*b*) sexual differentiation of the genital tract, and (*c*) postnatal development of sexual characters.

Genetic and humoral factors control sexual differentiation of the gonads. According to Witschi the latter are (*a*) inductors of sexual differentiation, and (*b*) sexual hormones. The inductors are two: (*a*) medullarin, a protein which inhibits the development of the cortex (ovary) of the embryonic sexual germ, the medulla developing into a testicle; (*b*) cortecin, which inhibits the medulla, the cortex developing into an ovary. These substances have not been obtained in a pure state, and many workers (Dantchakoff, Wolff, etc.) consider that all the effects are produced by sexual hormones, which perhaps differ from those commonly used for experimental purposes (Jost). In certain species, such as cows and pigs, in cases of twin pregnancy with fetuses of different sexes, if there is placental fusion (*i.e.*, vascular communication between the placentas), the female fetus, which is called a freemartin, is masculinized and its ovaries are sterilized or converted into testes (Keller and Tandler; Lillie). This anomaly has been attributed to the secretion by the male fetus of male hormones, which pass through the communicating placentas into the female fetus. A genetic factor has also been postulated, especially as chorionic fusion may occur in other species in cases of twin pregnancy with fetuses of different sexes, without masculinization of the female (armadillo, man, etc.).

When two larvae of *Amblystoma* (axolotl) are joined in parabiosis, both always develop into individuals of the same sex (Burns), because the individual with the predominant sex modifies the gonad of the partner and causes it to differentiate into its own sex, whatever the original sex of the weaker partner may have been.

Sexual differentiation of the egg can be modified by the injection of sexual hormones into the allantoid (Dantchakoff). Male hormone converts the ovary of a female embryo into a testicle, and female hormone sometimes converts the testes of male embryos into ovariotestes. Injection of sexual hormones into the fetus or the pregnant female, in several mammalian species, causes the development of sexual characters corresponding to the hormone injected, and intersexual individuals or pseudohermaphrodites are developed.[2]

In the rabbit fetus, Jost[2] has shown that the internal secretion of the testes stabilizes or differentiates the wolffian ducts and structures developing from them and inhibits müllerian structures. The ovary, on the contrary, stimulates the development of the female genital tract, which, however, can grow even in the absence of the ovary. These facts were demonstrated by castration and grafting experiments in fetuses. Decapitation, which removes the hypophysis, did not prevent development, but the thyroid, adrenals, and testes were deficient in development and function.

Sexual reversal (*i.e.*, change of sexual characters) can be provoked in adult amphibians and birds by modifying the endocrine balance. These animals are potentially bisexual; one sex is evident, the other remains latent. The adult male toad has male characters, but it is a potential hermaphrodite, because attached to the well-developed and functioning testicle there is Bidder's organ, which is a rudimentary ovary. Removal of the testes causes the development of Bidder's organ (stimulated by the hypophysis)[3] into an adult ovary (Harms, Ponse). The opposite case, *i.e.*, conversion of a female into a male, is often seen in adult hens. If the left ovary, which is well developed, is extirpated, the remaining rudimentary right ovary is converted into a well-developed and functioning testicle in 10 per cent of the cases. The comb grows, the birds crow, female plumage is replaced by the neutral plumage of the cock at the first moulting, sexual and general behavior is that of cocks, and the birds tread hens and can fertilize them. Other cases of development of phenotypes opposite to the genotype of the animal will be considered when discussing pseudohermaphrodites and sexual hormones.

Modification of sexual characters by external factors. Tadpoles of certain amphibians, when kept

at 25 to 30°C., develop into males in a high proportion; at 10°C. females are predominant (Witschi). External temperature modifies the functions of the ovary and testes (see Chaps. 59 and 60).

HORMONAL DEVELOPMENT AND MAINTENANCE OF SEXUAL CHARACTERS

The development of sexual characters is conditioned by genetic and hormonal factors. Not only the sexual germ, but also the whole organism, is to a certain extent potentially bisexual and can respond to hormones of its own and of the opposite sex.

The development and control of sexual characters are studied by the following methods: (*a*) observation of the appearance of sexual differences in form, functions, and behavior of the male and female; (*b*) observation of the effects of prepuberal and postpuberal castration; (*c*) observation of reappearance of sexual characters in castrates by implantation or grafting of the gonads or by treatment with extracts or hormones of the sexual glands; (*d*) establishment of a state of sexual hyperactivity by overdosage with sexual hormones or extract, or observation of such states in pathologic cases.

The effects of castration. Castration produces certain effects which man has known for centuries and which have been used with the object of taming animals or modifying their flesh in order to increase its value as foodstuff. Berthold in 1849 observed that a testicular graft caused the development of male characters in capons, thus demonstrating the endocrine male function of the testes (Fig. 261).

In most invertebrates, sexual characters are apparently conditioned only by genetic factors, since castration does not modify them nor prevent their development. In vertebrates, on the contrary, sexual characters are fully developed and maintained only if the endocrine function of the ovaries or testes is normal. If the gonads fail to develop or castration is performed before puberty, sexual characters do not develop; if castration is performed in the adult when sexual differentiation is complete, some of the characters retrogress, others retain their male or female type. Pézard has distinguished prepuberal from intrapuberal and postpuberal castration; the effects are more marked the earlier castration is performed. Castration can be the result of surgical removal of the gonads, application of x-rays, injection of antagonistic hormones, nutritional deficiencies, etc.

a b c

FIG. 261. Heads of adult cocks. *a*, normal; *b*, castrated 155 days before, when 157 days old; *c*, castrated, with testicular graft made 62 days before. (*Courtesy of Dr. M. J. Copello.*)

In male toads and frogs, castration causes disappearance of the callosity on the thumb and of the clasping reflex. In the castrated cock the comb atrophies (Fig. 261), the birds no longer crow, and they lose their aggressive and specifically sexual behavior. The castrated hen changes its plumage for the neutral plumage of the cock and capon at the first moulting, and the spurs develop (Fig. 260).

Certain tissues require the continuous action of the sexual hormones to maintain their normal condition;

castration rapidly causes marked atrophy of these tissues. They are extremely sensitive to the action of sexual hormones in the normal animal, but more so in castrates, and they respond to even small doses of hormones by a rapid and marked development. For this reason this response is used for the study and assay of preparations of sexual hormones or of substances with an activity similar to that of these hormones. The capon's crest, or the seminal vesicles or prostate of rodents, are used for the assay of the male hormones, and for female hormones the vaginal epithelium or the uterus of rodents, or the vaginal epithelium or endometrium of women.

Restitution of sexual hormones. Disturbances caused by the lack of development of the sexual glands or by castration can be controlled by restitution of the sexual hormones. The principal methods used for this purpose are the following: (*a*) implantation of gonadal tissue; (*b*) injection of gonadal extract or hormones; (*c*) grafting of the gonads. Subcutaneous or intramuscular implantation of gonadal tissue produces only transitory effects, which are observed as long as the active principle in the implant is being reabsorbed. Injection of extracts of testicular or ovarian tissue was one of the first methods of restitution used; it led to the discovery of the active principles, but these extracts contain a large amount of inactive substances and others that may be harmful. Active principles that control the effects of castration have been obtained from gonadal tissue and from organic fluids. After their chemical structure was established, they were prepared by synthesis, and they are now in common use in therapeutics and for experimental purposes.

Ovarian or testicular grafts control the effects of castration after they have "taken" and as long as they function (Figs. 260 and 261). Ovarian grafts "take" with relative facility, but testicular tissue does not "take" easily, except in some species, *e.g.*, the rat, in which testicular grafting is frequently successful. Grafts "take" more frequently when the animal's own tissue is used (autografts). They "take" a little less frequently when tissue from animals of the same species is used (homologous grafts); in this case it is advisable to use, if possible, animals of the same strain. Grafts do not "take" permanently when the tissue of a different species is used (heterologous grafts).

Grafted tissues "take" more easily in castrated than in normal animals, probably because there is hypersecretion of hypophyseal gonadotrophins in the former. They also "take" more readily in adult animals than in those which have not reached the age of puberty; in this case also extragonadal factors (*e.g.*, hypophyseal gonadotrophins) stimulate the development of the grafted tissue. Gonadal grafts develop and maintain secondary sexual characters, but they do not function as actively as the normal gland. The ovaries of guinea pigs can be kept in the refrigerator for a time before being grafted (Lipschutz). Rat ovaries have been kept at low temperatures in saline with 15 per cent glycerol and then grafted successfully (Parkes).

Often the grafted tissue at first shows signs of hyperactivity and later of hypofunction before it is reabsorbed.

Experiments have been made in which gonadal tissue is grafted into an animal of the opposite sex. These experiments have shown the soma can respond to both male and female hormones (Fig. 260). In other experiments a tissue that responds to stimulation by sexual hormones (*e.g.*, the comb of a cock, or the vagina or uterus of a rat, or mammary gland or skin) has been grafted into an animal of the same or the opposite sex. These tissues develop or atrophy according to the hormonal *milieu* into which they are transplanted.

THE EFFECTS OF SEXUAL HORMONES

Sexual glands exert their influence on the body by means of hormones which they secrete into the blood stream. Male and female hormones are steroids which are built around a perhydrocyclopentenophenatrene ring. Steroids are substances of great biologic importance; not only sexual hormones belong to this group, but animal steroids (cholesterol, etc.), plant steroids (phytosterols), bile acids, the D vitamins, corticoadrenal hormones, substances with a cardiotonic effect (digitalis), genins in toad venoms, odoriferous steroids, and cancerigenic substances also form part of this vast chemical family.

Hormones that stimulate the development and maintenance of feminine sexual characters are known as *estrogenic hormones* (from *oestrus*, sexual heat). Any substance that has a similar activity is called an *estrogen.* Hormones that stimulate the development and maintenance of

male sexual characters are known as *androgenic hormones* (Greek ἀνδρός, man or male), and *androgens* are substances that have the same effect.

Sexual hormones have stimulatory and inhibitory activities. Thus female hormones stimulate the development of female plumage and inhibit the development of the spurs in birds. They do not "create" organs or behavior, but merely modify the development of preexisting physical or psychic characteristics. Sexual hormones always produce more than one effect, but one of these may be more apparent than others. The action of sexual hormones is not evident until they have reached a certain concentration (threshold) in the body fluids. Sexual hormones are either excreted or destroyed fairly rapidly. They are not stored; therefore the signs of gonadal insufficiency are seen very soon after castration. The liver is the main organ in the process of inactivation of sexual hormones.

Sexual hormones act directly on the tissues and indirectly through the hypophysis.

Specificity. The sexual hormones have a specific effect. For instance, female hormones provoke the development of female characters in females, and some female characters in males; and male hormones provoke the development of male characters in males and to a certain extent in females (Fig. 260). These facts have been clearly demonstrated by experiments in which animals of both sexes have been castrated and have been treated by grafting gonadal tissue of the same or the opposite sex, or injecting sexual hormones of the same or the opposite sex. Specificity of effect (male or female) is a well-established fact, but sexual hormones are not zoologically specific, because they produce their effects in more than one zoological species.

Gonadal or hormonal bisexuality. Specificity of action of the gonads as stated above is a well-established fact, but the gonads can produce certain amounts of the hormone of the opposite sex. Moreover sexual hormones can have effects on the secondary sexual organs corresponding to the opposite sex. These are known as the heterosexual effects of the gonads or sexual hormones, which therefore, to a certain extent, have ambisexual or bisexual effects.

Among these heterosexual effects of the gonads, the following may be mentioned:

1. Both male and female sexual hormones are found in the urine of men and women; both hormones diminish considerably after castration. The urine of stallions is one of the richest sources of estrogens, which are also found in the equine testicle; castration diminishes the urinary excretion of estrogen in these animals. It has been supposed that sexual hormonal activity persisting in the urine after castration is due in part to the excretion of adrenal "corticoids."
2. The normal ovary produces very small amounts of androgens, but ovarian grafts made in the ear (Hill, 1937) or the tail (Hernandez, 1943) of the mouse produce them in much larger quantities.
3. Certain ovarian tumors called "arrhenoblastomas" produce substances that cause virilization (Fig. 263).
4. Ovarian grafts and estrogens attenuate or delay atrophy of the seminal vesicles in castrated males. Progesterone has a slight androgenic effect.
5. Testosterone has a slight action on the endometrium, vagina, and mammary gland.
6. High doses of estrogenic hormones cause estrus in the adult castrated male dog and rat. Androgenic hormones cause estrus in females when given in large doses.[1]

Antagonism between male and female gonads. There is an apparent antagonism between the gonads of the sexes due to the hypophysogonadal relationship,[2] but there is also a direct antagonism between the effects of the male and female hormones on the secondary sexual organs.

This antagonism is evidenced by the following facts:

1. Prolonged treatment with high doses of estrogens or androgens inhibits the gonadotrophic function of the hypophysis and causes ovarian or testicular atrophy. Estrogens are more efficacious in this respect than androgens.
2. The normal endocrine secretion of the gonads has an inhibiting effect on the secretion of gonadotrophins.
3. Castration is followed by an increase in gonadotrophin secretion, which favors the development of grafted gonadal tissue; on the other hand this tissue does not "take" easily in normal animals.
4. If an ovarian graft "takes" in an intact male guinea

[1] Beach, F. A., *Physiol. Rev.*, **27**, 240, 1947; "Hormones and Behaviour," Hoeber, Inc., New York, 1948.

[2] Moore, C. R., and D. Price, *Am. J. Anat.*, **50**, 13, 1932.

pig, the mammary gland develops and secretes milk, while the testes continue to function (Sand).

Simultaneous or successive injections of male and female hormones are followed by the effects of both hormones. In some cases there is summation of the effects of the hormones of both sexes; thus injections of estrogens and testosterone in adequate proportions cause a much greater development of the seminal vesicles than can be obtained by injecting either of the hormones singly.

Antagonism between the hormones of opposite sexes can nevertheless be demonstrated in many cases. Thus testosterone diminishes or prevents several of the effects of estrogens, *e.g.*, metaplasia (cornification) of the prostatic utricle, testicular atrophy, increase in weight of the anterior hypophysis, cornification of the vaginal epithelium, etc. Reciprocally, estrone applied locally diminishes the effect of testosterone on the cock's comb. Estrogens and progesterone (the hormone of the corpus luteum) in certain proportions suppress each other's effects, but an adequate proportion of estrogen strengthens considerably the effects of progesterone on the endometrium or the mammary gland.

Effects of an excess of sexual hormones. Large quantities of hormones, secreted or injected, cause an abnormal response in the sexual organs. This is observed in some cases of ovarian or testicular tumor with hypersecretion of sexual hormones, or when the gonads are stimulated by an excess of gonadotrophin secreted by the anterior hypophysis or experimentally injected. Thus in castrates the anterior hypophysis secretes larger amounts of gonadotrophins than in normal animals, and ovarian or testicular tissue grafted into a castrate shows signs of hyperactivity for a certain length of time. For example, an ovarian graft in a castrated guinea pig secretes continuously an excess of estrogen, which causes a remarkable development of the mammary gland similar to that occurring in pregnancy, and may provoke the secretion of milk in amounts sufficient to nurse a suckling guinea pig (Steinach, Lipschütz, Giusti, etc.).

REGULATION OF GONADAL FUNCTIONS

The endocrine function of the gonads is accurately controlled, as is shown by the maintenance of the secondary sexual characters at a constant level of development and the regularity of the sexual cycles. In mammals the endocrine and reproductive functions of the sexual glands are regulated by extragonadal factors, of which the hypophysis is the principal. In normal conditions the gonads do not function at a maximum, a fact that is demonstrated by the considerable increase in sexual function following the administration of hypophyseal gonadotrophins. Constancy of gonadal activity is well demonstrated in experiments in which one ovary is removed; in the remaining ovary the number of follicles ripening at each cycle is the same as reached maturity in both ovaries before unilateral ovariectomy (Lipschütz's law of follicular constancy),[1] and the females bear the same number of offspring at each pregnancy. On the other hand, if one uterine horn is extirpated, they bear only half the normal number of offspring. A single ovary maintains the development of secondary sexual characters and the regularity of the cycles in the same way as the two ovaries of an intact female.

The onset and development of puberty are conditioned by extragonadal factors. An infantile ovary grafted into an adult organism is rapidly transformed into an adult ovary, but if it is grafted into a prepuberal castrate it will remain in the infantile condition.

The secretion of the sexual glands tends to reach a certain level and then to remain stable at that level. If subtotal gonadectomy is performed or testicular tissue is grafted into a castrate, the gonadal tissue either tends to atrophy completely, so that the animal has the characteristics of a castrate, or it grows sufficiently to maintain a full development of the male characters. There is an "all-or-nothing" effect; there are no stable states intermedaite between the castrate and the full male, as Pézard demonstrated in barnyard cocks. Nevertheless during the process of development of the gonads (or of a graft) certain secondary sexual characters appear before others; the former have a lower "threshold," *i.e.*, respond to smaller amounts of male hormone than the latter. Thus in cocks first the comb begins to develop, then the birds crow, and finally the sexual instinct appears (Pézard).

In certain cases the equilibrium between the hypophysis and the gonads is disturbed, and a stable state of hyperfunction of the ovary or testes is gradually established. Thus a condition

[1] LIPSCHÜTZ, A., *Bol. Soc. biol., Concepción*, 2, 3, 1928.

of permanent hyperfunction of the ovary can be provoked experimentally by several methods (fragmentation, grafting, ligature), in which there are continuous or prolonged and frequently recurring estrus, considerable uterine hypertrophy, etc. This state of hyperfunction is maintained by an increase in the secretion of hypophyseal gonadotrophins.

FIG. 262. Hermaphroditism. *a*, true lateral hermaphroditism, an ovary (*Ov*) with a fallopian tube (*F*) on one side, and a testis (*Ts*) with epididymis (*Ep*) and vas deferens (*V.D.*) on the other; well-developed uterine horns (*U.H.*) on both sides; *b*, unilateral hermaphroditism, an ovary on one side and an ovariotestis with vas deferens and fallopian tube on the other. (*Crew, "The Genetics of Sexuality in Animals," Cambridge, New York, 1927.*)

DISTURBANCES IN SEXUAL DIFFERENTIATION

Sex is determined by the genetic constitution of the individual at the moment of fertilization. In vertebrates the soma is, nevertheless, to a certain extent capable of developing both male and female characters if the appropriate factors come into play in the course of prenatal or postnatal development. Three types of cases must be considered:

1. Individuals in which the primary sex characters of both sexes, *i.e.*, ovarian and testicular tissues, are present and active at the same time. These are known as true hermaphrodites.[1]
2. Individuals that have either testes or ovaries, *i.e.*, are either male or female, but present secondary sexual characters corresponding to the opposite sex. These are known as pseudohermaphrodites, or intersexual individuals.[2]
3. Subjects in which there is a change from one sex to another, *i.e.*, sex reversal.

The majority of cases of disturbance in sexual differentiation are due to anomalies in development. Most of them have been reproduced experimentally by castration and injection of hormones or grafts of the gland. Thus an ovary grafted into a cock, or treatment with estrogens, causes the animal to develop female plumage (Fig. 260). If an ovary is grafted into an adult male guinea pig the animal has the aspect and behavior of a male and can fertilize females, but the mammary glands undergo hypertrophy similar to that observed in pregnant females; they secrete milk, and the males can suckle young guinea pigs (Sand). Castration, homosexual and heterosexual gonadal grafts, and implantation of sexual hormones have been successfully performed in fetuses.

True or biglandular hermaphroditism. The simultaneous presence of functioning testes and ovaries is the normal condition in certain animals, *e.g.*, some of the worms, but in mammals it is seldom observed, except in pigs (Fig. 262). Amphibians and hens can be considered as potential hermaphrodites, because the rudimentary ovary (Bidder's organ in the toad) or testes can develop and function in certain circumstances, as was explained in the paragraph on sexual differentiation. In man, according to Young,[1] only 20 out of all the cases published can be considered as adequately proved cases of true hermaphroditism, in which an ovary was found on one side and a testis or

[1] From the Greek myth of Hermaphroditus, the son of Hermes and Aphrodite, who when bathing became joined in one body with the fountain nymph Salmacis.

[2] "Intersexuality" is a term that has often been given different meanings. It is applied most frequently to the appearance of characters corresponding to one sex in individuals of the opposite sex. A female intersex shows secondary sexual characters intermediate between those of male and female type.

[1] YOUNG, H. H., "Genital Anomalies, Hermaphroditism and Related Adrenal Diseases," Williams & Wilkins, Baltimore, 1937.

an ovariotestis on the other. Cases published after the appearance of Young's work bring the total of well-authenticated hermaphrodites up to 38 (Selye). The testicle on one side is usually joined to a vas deferens, a prostate, and a rudimentary penis. The ovary on the other side is connected with a fallopian tube and uterus. There is definite proof that the testis in these subjects produces male and female hormones. In certain hermaphrodites (pigs, goats, and a few human cases) a hereditary factor seems to play a part in the causation of the anomaly.

According to Young, hermaphrodites can be classified into (*a*) true lateral hermaphrodites, with an ovary on one side and a testis on the other (Fig. 262*a*); (*b*) unilateral hermaphrodites, with an ovary on one side and an ovariotestis on the other (Fig. 262*b*); (*c*) true bilateral hermaphrodites with an ovary and testis on each side.

Pseudohermaphroditism. Certain individuals are either male or female, because they have either testes or ovaries, but they have secondary sexual characters of both sexes. This pseudohermaphroditism may be due to causes that act before birth (congenital pseudohermaphroditism) or after birth, even in adult life (acquired pseudohermaphroditism). If ovarian tissue is present, the individual is a female pseudohermaphrodite; if testicular tissue is present, the individual is a male pseudohermaphrodite.

The congenital female pseudohermaphrodite has an ovary but the organs that develop from the müllerian duct (fallopian tubes, uterus) are usually rudimentary. There is no testicular tissue, but the clitoris is hypertrophied and in some cases has the size of a penis. The labia take on the aspect of a scrotum, and anomalies in the vaginal canal are frequently observed. The organs arising in the wolffian duct (vas deferens, etc.), do not develop. The mammary glands are frequently underdeveloped, there is hirsutism in most cases, and usually these individuals do not menstruate. These anomalies are probably due to the production of androgens by the ovary or the adrenal cortex in the course of fetal development (Jost).

The congenital male pseudohermaphrodite has a testicle (sometimes ectopic) with a vas deferens and prostate. The external genitalia have the appearance of the vulva. In some cases there is a uterus with fallopian tubes and a vagina, and other female characteristics, such as the shape of the body, mammary development, treble voice, and feminine behavior. The testicle apparently secretes female hormone; in some reported cases, the female characters have been observed to retrogress after the testicle has been extirpated. Jost suggests that these disturbances are probably due to prenatal deficiency in testicular hormone, and the secretion of feminizing factors.

Male acquired pseudohermaphroditism may be due to (*a*) feminizing tumors, such as chorioepitheliomas of the testes and exceptional cases of feminizing corticoadrenal tumors; (*b*) prolonged administration of high doses of estrogens. The external genitalia retrogress. There is testicular atrophy and abnormal development of the mammary gland (gynecomastia), occasionally with a pigmented areola.

Female acquired pseudohermaphroditism is usually due to hyperplasia or tumors of the adrenal cortex which

a b c

FIG. 263. Masculinization due to arrhenoblastoma in a twenty-nine-year-old woman. *a* and *b*, before operation, hirsutism and atrophy of the breasts; *c*, 6 months after the tumor was removed, abnormal hair has disappeared and the breasts have developed. Later the patient gave birth to two normal children. (*Althabe, A., D. Colillas, and G. Di Paola, Bol. Soc. de obst. y ginec. de Buenos Aires, vol. 18, p. 739, 1939.*)

secrete androgenic steroids, or to arrhenoblastomas. The latter are ovarian tumors, probably developed from the medulla of the ovary. They secrete a substance that exerts a powerful masculinizing influence resulting in hypertrichosis (abnormal development of the beard and body hair), masculine shape of the body, bass voice, etc. (Fig. 263). Male characters usually retrogress after the tumor has been removed.

Masculinization has been reported in a few cases of tumors developed from the ovarian theca cells (Fraenkel).

Hyperplasia and certain tumors of the adrenal cortex can produce pseudohermaphroditism in women, causing virilization with hypertrichosis (adrenogenital syndrome; see Fig. 252 and discussion in Chap. 54). Extirpation of the tumor is usually followed by retrogression of the male characters.

Sex reversal. Change of sex in the adult has been observed in certain fishes which at some times produce spermatozoa and at others produce ova. In some old hens the ovary atrophies, the rudimentary wolffian structures develop, and the hen is converted into a fertile cock (Crewe).

Gynandromorphism. In birds and insects individuals have been found that are a mosaic of male and female characters, *i.e.*, certain parts of the body are male, while others clearly distinguishable from the former are female; *e.g.*, one half of the body has a testicle and male characters, the other half an ovary and female characters. No cases of this anomaly have been observed in mammals.

CHAPTER 58

Endocrine Regulation of Sexual Functions

The endocrine sexual system. The sex glands have a double function: (*a*) *gametogenic, i.e.*, they produce and release the gametes of the corresponding sex, *i.e.*, sperm or eggs; (*b*) *hormonal, i.e.*, they secrete hormones that contribute to develop and maintain the secondary sexual characters, *i.e.*, the morphologic (genital and extragenital), functional, and psychic characteristics that differentiate one sex from the other. Among the psychic characteristics one of the most important is the libido, or sexual impulse toward the opposite sex.

The gametogenic and hormonal functions of the sex glands are governed by the pars distalis of the hypophysis, which secretes the gonadotrophins needed for the development and maintenance of the functions of the sex glands (see diagram). The hypophysis is therefore an organ of primary importance for reproduction.

Pars distalis of the hypophysis

+ − + − + −

Adrenal cortex Gonads Thyroid

SEX CHARACTERS
Reciprocally the hormones secreted by the gonads regulate the secretion of gonadotrophins, in some cases stimulating this secretion, but usually inhibiting it.

The adrenals have direct and indirect effects on the sex organs. The direct effects are due to the virilizing or feminizing activity of the corticoadrenal hormones. The indirect effects are exerted through the anterior hypophysis.

The thyroid also has direct and indirect effects on the sex organs. The indirect are due to the effect produced by thyroid secretion on gonadotrophin secretion.

Gonadotrophin secretion is regulated by the hormones of the gonads, adrenals, and thyroid, and in some cases by the activity of the nervous system.

Certain organs which exist only for a short period, such as the corpus luteum and the placenta, also secrete hormones of great importance in the process of reproduction.

In summary: (*a*) the pars distalis of the hypophysis regulates the development and functions of the sex glands; (*b*) five endocrine glands, *i.e.*, the testicle, ovary, placenta, and in a lesser degree the adrenal cortex and thyroid, secrete hormones acting directly on the secondary sex characters; (*c*) these five glands regulate the activity of the pars distalis. The gonads control not only the hypophyseal secretion of gonadotrophins, but also the secretion of adrenotrophin, thyrotrophin, and mammotrophin; thus indirectly they control the development and functions of these glands.

Several nutritive factors (*e.g.*, dietary deficiencies, avitaminoses, etc.), metabolic disturbances (*e.g.*, diabetes), and infectious diseases

can disturb the endocrine regulation of sexual functions by their effects on the hypophysis or by a direct action on the sexual organs.

HYPOPHYSIS AND SEXUAL FUNCTIONS

The pars distalis of the hypophysis is the fundamental factor in the reproductive functions of both sexes. It has a direct effect on the sex glands, which consists in (*a*) stimulation of the maturation of the gametes (spermatozoa and ova) and their release (formation of sperm and ovulation); (*b*) development of the gonads and maintenance of their structure and internal secretion. It has an indirect effect on secondary sex characters, mainly through the control of the secretion of sex hormones by the ovaries and testes, and to a slight degree through the control of corticoadrenal secretion of sex hormones. The latter are of little importance in normal individuals, but in certain abnormal conditions (adrenogenital syndrome) they exert a considerable influence on sex characters.

Hypophyseal gonadotrophins do not act directly on the external genitalia, vagina, uterus, and tubes, or on the penis, prostate, and seminal vesicles. They exert their influence on these organs exclusively by controlling the secretion of sex hormones by the gonads; therefore hypophyseal gonadotrophins have no effect in castrates.[1]

In mammals the anterior hypophysis is a necessary factor for the continuance of pregnancy; it exerts its influence on the processes of ovulation, implantation of the embryo, and maintenance of the embryo in the uterus. It is also a necessary factor in lactation; it contributes directly and indirectly to the development of the mammary glands and provokes and maintains the secretion of milk.

a *b* *c*
FIG. 264. Action of the hypophysis on the uterus and the ovary. *a*, hypophysectomized bitch weighing 9 kg.; the ovaries weighed 243 mg.; *b*, normal bitch, weighing 5.6 kg.; the ovaries weighed 395 mg.; *c*, bitch weighing 4.7 kg. after injection of anterior hypophyseal lobe extract; the ovaries weighed 1,192 mg. (The ovaries and the uterus have not been photographed with the same enlargement.)

The reciprocal influence of the hypophysis and the gonads has been demonstrated by the results of hypophysectomy, castration, and the injection of hypophyseal and sex hormones.

The effects of hypophysectomy on the sex glands. Hypophysectomy is rapidly followed by marked atrophy of the sex glands and consequently of the secondary sex characters, which

[1] There are a few exceptions to this general rule. Thus the anterior hypophysis stimulates the secretion of the oviduct in the toad *Bufo arenarum* (Hensel), even in castrated animals (Inés L. C. de Allende, 1938). Prolactin, secreted by the anterohypophysis, has a direct effect on the mammary gland.

are controlled by the internal secretion of the gonads[1] (Fig. 264). The primary follicles of the ovary start to develop, but when they reach a certain size they retrogress, and the ovary gradually loses its power to respond to hypophyseal hormones. The interstitial cells also retrogress in those species which possess this type of cell. The existing corpora lutea undergo involution, and new ones are not formed.[2]

Hypophysectomy prevents nidation of the egg and provokes abortion in many species (see "The hypophysis during pregnancy," page 661). Hypophysectomized animals do not secrete milk, and its secretion is suppressed by hypophysectomy in lactating females.

In males, hypophysectomy causes marked atrophy of the gametogenic and interstitial tissues of the testes. Spermatogonia continue to divide for some time after hypophysectomy, but spermatozoa are not formed; eventually all spermatogenetic activity ceases.

The effects of castration on the hypophysis. Castration suppresses the inhibitory effect of the sexual hormones on the anterior hypophysis; therefore gonadotrophins contained in, and secreted by, the pars distalis increase gradually in the course of several months and reach a considerable amount (see diagram).
a, normal reciprocal relationship between the anterior lobe of the hypophysis (AHL) and the ovary (O); *b*, hypophysectomy, ovarian atrophy and insufficiency; *c*, excess gonadotrophin, ovarian hypertrophy and hyperfunction; *d*, castration, excess secretion of gonadotrophin.

The gland increases in weight, and cytologic changes, which vary in different species, are observed. In the castrated rat the most typical change is the formation of vacuoles in the basophil cells, which gradually merge into a single large vacuole surrounded by a thin layer of protoplasm. The whole cell, with a prominent nucleus, has the aspect of a seal ring.

[1] Crowe, Cushing, and Homans, 1910; Aschner, 1913; Ascoli and Legnani, 1912; Houssay, 1916; Smith, 1927 to 1930.

[2] In the hypophysectomized rat, involution of the corpora lutea proceeds at a slower rate than in normal rats, but this is not seen in other species.

The increase in gonadotrophins can be demonstrated in several ways. Thus injection of extract of or implantation of the anterior hypophysis of castrates causes much greater effects than the same amount of normal anterior hypophyseal tissue. The increase in gonadotrophins in the blood is very clearly demonstrated by experiments of parabiosis (Martins). A male or female castrated rat is joined to a normal rat of the opposite sex. The abnormally large amount of gonadotrophins secreted by the castrate passes into the normal partner and stimulates the development of its sexual glands. If the normal partner is a female, whether adult or prepuberal, the ovaries are considerably enlarged by the ripening of numerous follicles and the formation of corpora lutea (Fig. 265).[1] The ovaries thus stimulated secrete large quantities of estrogenic hormone which cause hypertrophy of the uterus and cornification of the vaginal epithelium (permanent or continuous estrus). If the normal partner is a male, the testes are stimulated and there is hypersecretion of male hormone which provokes hypertrophy of the male organs, especially of the prostate and seminal vesicles (Fig. 265). Hypersecretion of gonadotrophins by the castrate hypophysis can be prevented or inhibited by grafting gonadal tissue or by injecting sexual hormone. Parabiosis of normal females does not cause any disturbance in the estral cycle of the partners. Parabiosis of normal males does not modify the sexual organs of the partners.

The effects of sexual hormones on the hypophysis. Injection of male or female hormone prevents the appearance of the cytologic changes in the anterior hypophysis and hypersecretion of gonadotrophins caused by castration, and it suppresses these effects if they have already appeared.

Female hormones stimulate the secretion of the luteinizing hormone and luteotrophin (prolactin) of the pars distalis, and corpora lutea are formed.[2] Adrenocorticotrophin secretion is also stimulated. Prolonged treatment with large doses of estrogens inhibits the secretion of all the anterohypophyseal hormones. Inhibition of the hypophysis is also obtained by the injection of male hormone, but estrogens have a more

[1] Matsuyama, 1921; Martins, 1929; Kallas, 1929; Fels, 1929.

[2] This effect of estrogens is, of course, not observed in hypophysectomized animals.

constant and powerful inhibitory effect than androgens.

The anterior hypophysis of these animals (rats) increases considerably in size; the blood vessels are dilated and give the gland a cavernous aspect. Only chromophobe cells are found; all the chromophil cells disappear. All the functions of the anterior hypophysis (gonadotrophic, thyrotrophic, adrenotrophic, etc.) are diminished. Sometimes a complete syndrome of anterior hypophyseal insufficiency is observed, *i.e.*, growth ceases and the gonads, thyroid, and adrenals atrophy as in hypophysectomized animals.

FIG. 265. Hypophysogonadal equilibrium. Parabiosis in rats. There is hypersecretion of gonadotrophin in the castrates of both sexes. 1, normal females; no change in estrus cycle or ovaries; 2, female castrate with normal female partner; in the latter there is hypertrophy of the ovaries and continuous estrus; 3, male castrate with normal female partner; in the latter there is hypertrophy of the ovaries and continuous estrus; 4, normal males; no change in seminal vesicles and prostate; 5, male castrate with normal male partner; in the latter there is hypertrophy of the seminal vesicles and prostate; 6, female castrate with normal male; in the latter there is hypertrophy of the seminal vesicles and prostate.

The male hypophysis differs from the female in its weight, cytologic aspect, and gonadotrophic and adrenotrophic activity. Thus the female anterior hypophysis secretes more adrenotrophin than the male, because estrogens stimulate this secretion and androgens inhibit it. These sexual differences in the hypophysis are produced by sexual hormones, therefore they must be considered secondary sexual characters.

The female anterior hypophysis shows periodic changes in activity and in its cytologic aspect, which coincide with the sexual cycle. The male hypophysis is more stable and secretes continuously. If testicular tissue is grafted into a newborn female mouse or rat, the hypophysis takes on a male aspect, which persists after the graft is removed. The masculinized hypophysis secretes gonadotrophins continuously, and the animals show endometrial changes typical of an excess of estrogen (Pfeiffer).[1]

The action of the nervous system on the hypophyseal-gonadal complex. Certain lesions in the hypothalamus provoke atrophy of the gonads and consequently retrogression of the secondary sexual characters.[2] In some cases there is also considerable accumulation of fat and a typical adiposogenital syndrome (Fröhlich syndrome) is observed. In these animals

[1] Lipschütz has observed that an ovary grafted into a male castrate guinea pig provokes greater development of the mammary gland and more abundant milk secretion than an ovary grafted into a female castrate. This is due to the secretion of estrogen provoked by continuous secretion of the hypophysis in the male; in the female periodically corpora lutea are formed and estrogen secretion diminishes.

[2] Aschner, 1912; Camus and Roussy, 1913; Houssay and Hug, 1921; Bailey and Bremer, 1921; Smith, 1930.

either all gonadotrophin secretion, or only the luteinizing gonadotrophin secretion, is inhibited (Dey).

Intense electrical stimulation of the hypothalamus (or of all the head) provokes a release of gonadotrophins which causes ovulation and luteinization in the rabbit and rat. This effect is not observed in hypophysectomized animals.

Intense and continuous illumination provokes the development of the gonads and secondary sexual characters in ferrets and birds in winter, when normally the animals are in a condition of sexual rest. This effect of light is not observed if the animals have the head or eyes covered or if they have been hypophysectomized.

In some species (rabbit, cat, ferret) ovulation does not occur spontaneously but is provoked by copulation. The female rabbit ovulates 10 to 18 hr. after copulation, but she does not ovulate if the hypophysis is removed before or up to ½ hr. after copulation (Fee and Parkes) or if the pituitary stalk has been cut (Brooks). In the female toad *Bufo arenarum* (Hensel) ovulation is provoked by the sexual clasp of the male (amplexus), but not if the pars distalis has been extirpated (Houssay). Pigeons ovulate when in the presence of another pigeon; a visual reflex must play a part in this process, because sometimes the bird ovulates if she sees her own image in a mirror.

The hypothalamus seems to exert some control on gonadotrophin secretion. In certain species its action can be suppressed by drugs (pentobarbital, atropine, dibenamine).

Section of the pituitary stalk suppresses some of the reflex effects on the hypophysis, such as ovulation in rabbits and the inhibition of estral cycles by cold in rats. However, most of the sexual functions of the hypophysis are not disturbed by this operation and the sexual cycle, estrus, copulation, ovulation, pregnancy, and lactation take place normally if vascular connections between the median eminence of the hypothalamus and the pars distalis are re-established (Harris and Jacobsohn). In these cases gonadotrophins are released and act without the hypothalamus taking part in the different processes. Gonadotrophins do not act through the hypothalamus in the process of ovulation, as is demonstrated by the fact that the gonadotrophins provoke ovulation in female toads in which the hypothalamus has been destroyed (Houssay and Giusti).

The effect of anterior hypophysis. Implantation[1] or grafts of the pars distalis prevent atrophy of the ovary or testicle after hypophysectomy, or restore the normal condition of the gonads if they are already atrophied. The gametogenic tissue and the interstitial cells are stimulated, and retrogression of the secondary sexual characters is prevented, or their normal condition is restored if they have already retrogressed.

Implantation of anterior hypophyseal lobe in infantile rats or mice causes precocious sexual development (precocious puberty). In adults it provokes intense sexual stimulation, and in old animals sexual activity is restored. These effects are obtained by implantation of the anterior hypophysis of the same or the opposite sex, and of the same or another species; *i.e.*, there is no specificity in this action of the hormones produced by the pars distalis.

Implantation of the pars distalis provokes the following effects in females: (*a*) abnormally abundant ovulation (superovulation), with the production of an abnormally large number of offspring; (*b*) increase in ovarian weight due to ripening and luteinization of a large number of follicles; (*c*) sometimes, pseudopregnancy, caused by the ovarian hypersecretion and luteinization; (*d*) congestion and hypertrophy of the uterus, and continuous estrus.

In the male, anterior hypophyseal implantation has the following effects: (*a*) development of the testes in prepuberal animals, but no increase in weight of the testes in adults; (*b*) hypersecretion of male hormone, which causes hypertrophy of the prostate, seminal vesicles, and other secondary sexual organs.

All these facts demonstrate that hypophyseal gonadotrophin secretion is controlled by nervous impulses only to a very limited extent. The hypophyseal-gonadal relationship is the most important factor in the regulation of gonadotrophin secretion; the thyroid and the adrenal cortex also play a part, and nutritive factors (*i.e.*, undernourishment, avitaminosis E, etc.) exert a certain influence on the functioning of the anterior hypophysis.

GONADOTROPHINS

Gonadotrophins are substances that stimulate the sex glands. Gonadotrophins are produced by the hypophysis and by the chorion. Hy-

[1] Ascheim and Zondek, 1926; Smith, 1926; Smith and Engle, 1927.

pophyseal gonadotrophins have been obtained from (*a*) hypophyseal extracts; (*b*) urine of women in menopause or after castration; (*c*) blood and urine of normal men and women. Chorionic gonadotrophins, *i.e.*, those produced by the placenta, have been obtained from (*a*) urine and blood of pregnant women; (*b*) blood of pregnant mares.

Hypophyseal gonadotrophins. Three gonadotrophins have been extracted from the pars distalis of the hypophysis: (*a*) the follicle-stimulating hormone; (*b*) the interstitial-cell-stimulating or luteinizing hormone;[1] (*c*) luteotrophin or prolactin. These substances are glycoproteins; the luteinizing hormone and luteotrophin have been obtained in a pure and crystalline form. They produce the following effects in mammals:

The follicle-stimulating hormone (FSH, or follicular maturation factor, or gametogenic hormone, or Van Dyke's thylakentrin) has a gametogenic action, *i.e.*, it provokes the formation of ova and spermatozoa.[2] The activity of this hormone is clearly demonstrated by its effect on hypophysectomized rodents (rats or mice). In the male it maintains or restores the normal condition of the seminiferous epithelium and the formation of spermatozoa, but it has no effect on the interstitial cells and does not stimulate the secretion of male hormone; therefore it has no effect on the secondary sexual characters. In the female it stimulates growth of the follicles but not of the interstitial cells, and does not stimulate the secretion of estrogens. In the normal female it provokes ripening and dilatation of the follicles.

The interstitial-cell-stimulating or luteinizing hormone[3] stimulates the interstitial tissue (Leydig's cells) in the normal and hypophysectomized male. It also stimulates the secretion of male hormone, with considerable development of the secondary sexual organs (prostate, seminal vesicles, etc.). Testosterone thus secreted stimulates the germinal epithelium and spermatogenesis. In the female this hormone converts the ripe follicles into corpora lutea; it stimulates the development of theca cells and the secretion of estrogenic hormones, but it does not prevent atrophy of the corpora lutea, nor does it stimulate their internal secretion. In the hypophysectomized rat it provokes growth of the involuted interstitial cells.

Luteotrophin (prolactin) maintains the structure and functions of the corpora lutea, even after hypophysectomy, and stimulates their internal secretion in the rat.

The association of follicle-stimulating hormone and luteinizing hormone in adequate proportions usually reinforces their effects (hormonal synergy). On the other hand, if the proportions of the hormones are not adequate they may inhibit each other's effects (hormonal antagonism). Hormonal synergy can be well demonstrated in normal and hypophysectomized animals by the development and ripening of the follicles, ovulation, and luteinization, with a great increase in ovarian weight. The greatest effects are obtained by injecting first FSH and then LH. The secretion of estrogens is increased, but the internal secretion of the corpora lutea is not stimulated.

Hormonal synergy is also observed in the male; the testes of infantile animals increase in weight, although this does not occur in adults; spermatogenesis is stimulated in both young and adult animals, and secondary sexual organs are considerably hypertrophied.

The follicle-stimulating hormone never produces luteinization in hypophysectomized females; but in females with a normal hypophysis FSH produces luteinization because it increases the secretion of LH by the anterior hypophysis and hormonal synergy comes into action.

The urine of normal women sometimes contains gonadotrophins (0 to 25 rat units per day); there are larger amounts (5 to 360 rat units daily) in the urine of women at the menopause.[1] The hypophysis undergoes cytologic changes at the menopause, and FSH (but not LH) is found in the blood and urine. Urinary and blood gonadotrophins, found in normal adult women

[1] These two hormones were first separated by Fevold, Hisaw, and Leonard (1931) and obtained in pure form by Li (1949).

[2] Highly purified FSH has only a small effect on the germinal epithelium; apparently it must be slightly contaminated with luteinizing hormone to produce its maximum effect.

[3] LH (luteinizing hormone, Fevold); ICSH (interstitial-cell-stimulating hormone, Evans *et al.*); or metakentrin (Van Dyke).

[1] Determination of urinary gonadotrophins gives valuable information in many clinical conditions (Klinefelter, F. H., F. Albright, and J. C. Griswold, *J. Clin. Endocrinol.*, **3**, 529, 1943) They can be concentrated by precipitation with alcohol or by ultrafiltration (Gorbman, Jungck, etc.).

and at the menopause, are supposed to be produced by the hypophysis.

Placental or chorionic gonadotrophins. Gonadotrophins of placental origin have been found in (*a*) the urine and blood of pregnant women; (*b*) the serum of pregnant mares.
Fig. 266. Gonadotrophins in pregnant woman's urine. Comparison between the concentration of gonadotrophin in the urine of pregnant women (data from Evans *et al.*) and in the serum of pregnant mares (data from Cole *et al.*). *a*, duration of human pregnancy in days; *b*, percentage duration of pregnancy. Solid line, concentration of gonadotrophin in pregnant woman's urine; broken line, concentration of gonadotrophin in pregnant mare's serum. (*According to Evans, Kohls, and Wonder, 1937.*)

Pregnant women eliminate in the urine gonadotrophin produced by the placenta.[1] This gonadotrophin can be extracted from the placenta, and it is produced *in vitro* in cultures of placental tissue.[2] It is found in the urine of women who have aborted while the placenta is retained in the uterus, and it is eliminated in large quantities when there is a tumor of placental origin (hydatiform mole or chorioepithelioma) and in certain cases of tumor of the testicle.

Chorionic gonadotrophin has been purified and crystallized.[3] The crystalline substance has an activity equivalent to 6,000 or 8,000 units per milligram. It has a follicle-stimulating effect and a very strong luteinizing effect. It is found in blood and urine of pregnant women shortly after the nidation of the embryo. Its maximum concentration in the urine occurs around the thirtieth day of pregnancy (Evans), or 50 to 60 days after the last menstruation (Browne) (Fig. 266). Aschheim and Zondek utilized urinary elimination of gonadotrophin for the diagnosis of pregnancy (Aschheim-Zondek pregnancy test).

The serum of pregnant mares has a very active gonadotrophin (Cole and Hart, 1930), which is produced by special glandular structures of the placenta, the endometrial cups. It is a protein of great molecular weight; therefore it does not pass into the urine. It reaches its highest concentration between the fiftieth and eightieth day of pregnancy, then gradually diminishes, so that around the one hundred-eightieth day it has disappeared and is not found again for the rest of the 330 to 350 days of pregnancy. It produces effects even in hypophysectomized females, and in this respect differs from the gonadotrophin of pregnant women. It provokes follicular growth and luteinization.

The international unit of chorionic gonadotrophin is the specific activity of 0.1 mg. of the international standard gonadotrophin. The international unit of pregnant-mare gonadotrophin is the specific activity of 0.25 mg. of the international standard. The international unit of luteotrophin (prolactin) is the specific activity of 0.1 mg. of the international standard.

Tests for the diagnosis of pregnancy. Tests used in the diagnosis of pregnancy are based on the fact that the placenta produces chorionic gonadotrophin which is excreted in the urine, where it can be easily detected.

The Aschheim-Zondek test is performed as follows: Mice, 3 to 4 weeks old, weighing 6 to 8 gm., are treated

[1] This gonadotrophin has been found in the urine of pregnant orangutans, chimpanzees, and macaques, during certain stages of pregnancy. So far it has not been found in the urine of pregnant females of other species.

during the course of 3 days with 6 injections of 0.3 to 0.4 cc. of the urine voided in the morning by the patient. It is useful to acidify the urine and wash it with ether. The animals are killed 100 hr. after, and the genital tract is examined. The following results may be observed in sections of the ovary (Fig. 267): (*a*) follicular dilatation; (*b*) hemorrhagic points (intrafollicular hemorrhage); (*c*) luteinization. Hemorrhage and luteinization indicate pregnancy; simple follicular dilatation does not. This test gives accurate results in 98.5 to 99 per cent of the cases.

Hypophysectomized rodents do not respond, or give only a rudimentary response (slight luteinization of the granulosa without ripening of the follicles), to the injection of urine from pregnant women. The results observed are usually due to the synergic effects of the chorionic gonadotrophins injected and gonadotrophins secreted by the animal's own hypophysis. There are several modifications of the Aschheim-Zondek test.

Friedman's test (Fig. 268) is the one of these modifications that is most commonly used, because it is completed in a shorter time and gives results that can be appreciated macroscopically. Mature female rabbits which have already had offspring or which weigh 1.8 to 2 kg. are used, after having been kept isolated for 4 weeks. If further precaution is desired the ovaries are examined before performing the test in order to be sure there are no hemorrhagic follicles. The urine to be tested (10 cc.) is injected slowly into the marginal veins of two rabbits. One animal is examined 24 hr. later and the other 48 hr. later. The test is positive (*i.e.*, there is pregnancy) if hemorrhagic follicles are found.

Other tests are based on the early appearance of congestion in the ovary, which can be detected by the naked eye under an intense illumination. These tests are not so reliable as the Aschheim-Zondek and Friedman tests; thus, 2 hr. after the injection the readings give 15 per cent of errors; 3.7 per cent when the

observations are made 6 hr. after the injection, and 1 per cent when they are made 24 hr. after.[1]

Galli-Mainini's test[2] is performed as follows: A male toad (*Bufo arenarum*) weighing 100 gm. or more is injected subcutaneously with 10 cc. of the first urine voided in the morning. If the urine is that of a preg-
FIG. 268. Friedman's pregnancy test. Rabbits' ovaries. Above: mature follicles, no hemorrhage, negative. Below: ovulation and hemorrhage in follicles, positive of pregnancy.

nant woman, the Sertoli cells swell and release the spermatozoa attached to them. The spermatozoa are carried through the kidneys and ureters to the cloaca and are accumulated in the bladder. One to three hours after, the urine is collected from the cloaca by means of a pipet, and if the test is positive, numerous motile spermatozoa will be seen microscopically. Normally spermatozoa are never found in the cloaca except during amplexus (sexual clasping). The test is easily performed, the results are obtained within a very short time, and its cost is low. More accurate and rapid results can be obtained by injecting three animals and observing the cloacal contents of each one at alternate hours after the injection; sometimes there is a positive response at the first hour, but occasionally a response is not obtained for several hours. With urine from women in the first 5 months of pregnancy, 99.5 to 100 per cent positive tests have been obtained; with urine from women in the second half of pregnancy, only 92 per cent positive results have been observed. Other species of batrachians have also been employed successfully for the performance of this test.

The urine of pregnant women provokes ovulation in the South African toad *Xenopus laevis*. Zwarenstein and Duncan[3] have described a pregnancy test using this species. They have obtained 98.6 per cent accurate results in 1,407 tests.

Gonadotrophins in cases of malignant tumors.[1] Certain patients suffering from testicular tumors, especially chorioepitheliomas, eliminate large quantities of chorionic gonadotrophin (and sometimes of estrogens) in the urine. Other types of testicular tumor (seminomas) provoke the urinary excretion of gonadotrophin with the activity of the hypophyseal follicle-stimulating hormone. In some cases both types of gonadotrophin are excreted alternately or, more seldom, simultaneously.

The effects of gonadotrophins on women. The effects of hypophyseal gonadotrophins on women are not well known. Results obtained with gonadotrophins extracted from pregnant women's urine or pregnant mare's serum have not been encouraging; no effects, or no physiologic effects, were observed. It has not been possible to maintain the menstrual cycle permanently or to keep up a constant hormonal level. Prolonged treatment causes a decrease in sensitiveness to the preparation used, and sometimes the formation of antibodies occurs, especially when pregnant-mare-serum gonadotrophin is used.[2] Moreover, cases of allergic reaction have been reported.

Large doses of gonadotrophins provoke a transitory increase in the secretion of estrogens and the effects of hyperfunction of the corpus luteum.[3] By means of injections of large doses of pregnant-mare-serum gonadotrophin, followed by the injection of chorionic gonadotrophin, it has been possible to provoke menstruation in many cases of amenorrhea, ovulation has been obtained, and in a few cases pregnancy has resulted.

Large doses of crystallized chorionic gonadotrophin (36,000 units injected intravenously during the course of 3 days) provoke follicular stimulation without ovulation or luteinization. If this is combined with small doses (3,000 units) of pregnant-mare gonadotrophin, the follicles ripen and do not regress into atresia, but are converted into corpora lutea.

The effects of gonadotrophins on males. In some cases of ectopic testicle, injections of luteinizing or chorionic gonadotrophin cause the

migration of the testes into the scrotum. Injections of chorionic gonadotrophin (750 units, twice daily during 3 weeks) in cases of hypogonadism have been followed by stimulation of the Leydig cells, secretion of male hormone, and growth of the penis and sexual hairs; estrogens are excreted in the urine. The subsequent injection of FSH has provoked spermatogenesis in these cases.[1]

The hypophysis during pregnancy. The anterior hypophysis increases in size during pregnancy.[2] The so-called "pregnancy cells" appear in the pars distalis. These cells are seen not only in pregnancy but also after treatment with sexual hormones. According to Severinghaus, they are degranulated acidophil and basophil cells, loaded with mitochondria. The anterior hypophysis of pregnant women contains little gonadotrophin between the second and ninth months of pregnancy; the gonadotrophin content returns to normal after the delivery.

Hypophysectomy is followed by abortion in several species (dog, cat, and rabbit). In these species the secretion of the corpora lutea is indispensable for the persistence of pregnancy. Abortion can be prevented in hypophysectomized animals by treatment with progesterone, estrone, or gonadotrophins (Robson). In the rat nidation does not take place if the hypophysis is removed during the first days of pregnancy. If it is removed between the seventh and tenth day, the fetuses are reabsorbed. If it is removed from the eleventh to the twentieth day, the delivery is prolonged, the mother dies, and the fetuses are born dead.[3]

THE SEXUAL FUNCTIONS OF THE THYROID

The thyroid has an influence on sexual functions by means of a double mechanism: (*a*) it controls the secretion of gonadotrophin by the pars distalis, an adequate amount of thyroid secretion stimulating the secretion of gonadotrophin, while excessive amounts have as unfavorable an effect as thyroid insufficiency; (*b*) it acts directly on the ovaries.[4]

[1] Maddock, W. O., and W. O. Nelson, *J. Clin. Endocrinol.*, **12**, 985, 1952.

[2] Comte, 1898; Erdheim and Stumme, 1909.

[3] When considering the functions of the neurohypophysis facts were discussed which showed that it perhaps plays a part in delivery. The fundamental importance of the hypophysis in lactation will be discussed in Chap. 62.

[4] A direct action of the thyroid on the secondary sexual organs has not been demonstrated.

In the female the thyroid has a slightly greater weight than in males, and it varies in size and cytologic aspect in the different stages of sexual activity (puberty, pregnancy, menopause, and sometimes the menstrual cycle). Diseases of the thyroid are more frequently observed in women than in men, and the course of the disease varies with the stage of sexual activity of the patient.

Thyroid insufficiency prolongs the duration of diestrus and diminishes hypophyseal gonadotrophin in rats. In several species severe thyroid insufficiency at an early age causes hypoplasia of the sex glands and sexual insufficiency.[1] In women during the early stages of thyroid insufficiency there is an increase in menstrual flow; uterine hemorrhage and abortion frequently occur. During the later stages the menstrual flow diminishes; then amenorrhea and sterility are observed. In the male, severe thyroid insufficiency is sometimes accompanied by genital hypoplasia and loss of libido.

Mild hyperthyroidism provokes early puberty and a slight increase in the frequency of estrus in the rat. Severe hyperthyroidism causes retardation or suppression of the estrous cycle. Gonadotrophins in the hypophysis increase during the first stages (Reforzo) and diminish in advanced hyperthyroidism (Arrighi). The ovaries and sexual organs retrogress in severe hyperthyroidism and their response to gonadotrophins and sexual hormones is diminished.

In women suffering from hyperthyroidism, disturbances in the menstrual cycle are not always observed; usually as the condition increases in severity, menstruation and fertility diminish. Subtotal thyroidectomy improves the condition of the sexual functions together with the general improvement experienced by the patients.

Thyroid treatment often improves cases of hypomenorrhea, probably by its action on the anterior hypophysis; however, an excess of thyroid may cause amenorrhea.

THE SEXUAL FUNCTIONS OF THE ADRENALS

The adrenal cortex secretes hormones that exert a direct influence on the sexual characters. Probably corticoadrenal hormones also act on

[1] In the rabbit the follicles ripen, but ovulation is difficult to provoke; the anterior hypophysis contains FSH but does not have LH; injection of extract of such a hypophysis does not provoke ovulation (Chu).

the anterior hypophyseal secretion of gonadotrophins, but this has not been clearly demonstrated.

The adrenal cortex and the gonads arise from the epithelium of the celoma. The gonads have a definite effect on the adrenal cortex, as is shown by the differences between the cortex of the male and female. Thus in females the cortex is stimulated and has a greater development than in the male, in which androgenic hormones have a slight inhibitory influence. Castration is followed by moderate atrophy of the adrenal cortex in the female and slight hypertrophy in the male (Pinto, 1943). The adrenal of the female shows certain changes coinciding with estrus, sexual activity, and pregnancy.

The following substances with sexual activity have been extracted from the adrenal cortex: (*a*) female hormones (including estrone); (*b*) male hormones, such as adrenosterone and other steroids related to androsterone; (*c*) progestational hormones which act on the endometrium, such as progesterone.[1] Normally these adrenal steroids have little effect, and they are unable to prevent retrogression of the sexual organs following castration.[2] Estrogens and androgens found in the urine of castrates are supposed to be produced mainly by the adrenal cortex.

The masculinizing and feminizing effects of tumors or hyperplasia of the adrenal cortex have been considered in Chaps. 55 and 57.

[1] Survival after total adrenalectomy is more prolonged if the operation is performed during the animal's estrus or pregnancy, because in these states there are active corpora lutea.

[2] In young rodents atrophy of the prostate takes place more rapidly if adrenalectomy is performed at the same time as castration.

CHAPTER 59

The Endocrine Functions of the Ovary

Physiologic Anatomy. The surface of the ovary is covered by the germinal epithelium, formed by a layer of cells which are cuboidal in girls but become flat in adult women. In the course of fetal development the genital cords of Pflüger are formed by invagination of the germinal epithelium, later being divided into cell nests from which the primordial follicles arise (Fig. 269). In the newborn girl there is a large number of these primordial follicles (400,000), but with age they diminish, and they disappear completely after the menopause. Each primordial follicle consists of an oocyte surrounded by a single layer of follicular cells. The oocyte is converted by a process of ripening into the mature ovum; the other cells of the primordial follicle multiply and form the membrana granulosa, which is made up of several layers. Later, fluid appears between the cells of the granulosa (liquor folliculi), and a cavity, filled by this liquid,

gradually appears. At one end of the follicle, a mass of cells surrounds the ovum; this is the discus proligerus, which forms a salient into the follicular cavity. The follicle is surrounded by a capsule formed by cells derived from the neighboring stroma. This capsule has two layers. The inner layer, called the theca interna, is made up of large polyhedral cells with an oval nucleus; it has many blood vessels, whence the name "tunica vasculosa" that is sometimes given it. The outer layer, or theca externa, is made up of fusiform cells and thick connective fibers, closely packed in concentric order; it is sometimes called the "tunica fibrosa" (Fig. 270).

FIG. 271. Human ovary. Two follicles and a corpus luteum. (*Courtesy of Professor R. Sammartino.*)

The mature graafian follicle is ruptured at the moment of ovulation, and the ovum, surrounded by cells of the discus proligerus and follicular fluid, is expelled into the peritoneal cavity and conveyed along the fallopian tube. Only one follicle ripens and expels an ovum at each monthly cycle (exceptionally, two); therefore only 300 or 400 follicles reach full maturity throughout the whole sexual life of a woman. The remaining hundreds of thousands of follicles disappear by a process of degenerative involution called "atresia," which can occur at any stage in the process of maturation.

The ruptured follicle is converted into the corpus luteum (Fig. 271). The follicular cavity is at first filled by erythrocytes, which have migrated by diapedesis from the blood capillaries, or as the result of a

minute hemorrhage. The cells of the granulosa rapidly multiply and form folds which fill the whole follicular cavity. These cells are filled with a lipoid pigment, which is either yellow or orange or white according to the species. The pigment is called "lutein" and the cells containing it are known as "luteal" cells. Connective tissue and numerous blood capillaries are found between the large luteal cells (Fig. 272). The cells of the theca interna take on the same aspect as the luteal cells in some species (theca-luteal cells). Later the corpus luteum undergoes a process of involution. As this process advances, neutral fats in the luteal cells increase, the organ takes on a bright yellow color, and a hyaline substance appears between the luteal cells, which are finally replaced by connective-tissue cells. The whole organ atrophies (corpus albicans) and eventually is reduced to the fibrous tissue of a residual scar. All corpora lutea pass through the following stages: (*a*) proliferation; (*b*) vascularization; (*c*) full development; (*d*) involution.

There are several types of corpora lutea, according to the circumstances of their development. In the following types the corpora lutea are of short duration: (*a*) the *periodic* or *cyclical* corpus luteum follows ovulation at each cycle; (*b*) the *atretic* corpus luteum is the result of the luteinization of the cells of a follicle that has not ripened completely and retains the ovum.[1] The corpus luteum has a longer period of activity in the following circumstances: (*a*) in *pregnancy*, throughout which the corpus luteum can be found, although from the fifth month onward it shows signs of involution; (*b*) in *lactation, i.e.*, as long as the mother nurses the child; (*c*) in *pseudopregnancy;* (*d*) after *hysterectomy* in certain species.
FIG. 272. Corpus luteum recently formed, surrounded by internal theca cells. (*Courtesy of Professor R. Sammartino.*)

The interstitial cells of the ovary form nests or columns; they have the aspect of epithelial cells, with granules of lipids and other substances. They are derived from the fusiform stroma cells and from the cells of the membrane of atretic follicles. They reach maximum development in girlhood; in adult women they are reduced to a few irregular columns of epithelioid cells in the midst of the stroma, or may even be completely missing. In the rabbit and other rodents, a considerable number of interstitial cells are found at all ages.

FUNCTIONS OF THE OVARY

The following are the principal functions of the ovary: (*a*) *reproduction* or *gametogenesis*, *i.e.*, the production of ova; (*b*) *endocrine activity*, *i.e.*, the secretion of female hormones which develop and maintain the secondary sexual characters; (*c*) the *formation of the corpus luteum*, which also secretes hormones; (*d*) the *preparation of the uterus for pregnancy* and the continuance of pregnancy;

[1] This type of corpus luteum is produced by the luteinizing hormone of the hypophysis and by chorionic gonadotrophins.

(*e*) the *development of the mammary gland* in preparation for lactation.[1]

REGULATION OF THE ENDOCRINE FUNCTIONS OF THE OVARY

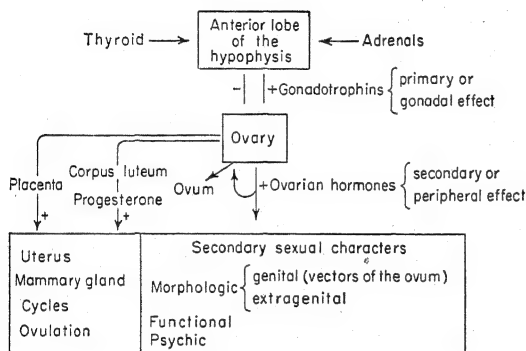
The development and functions of the ovary depend on several factors. The principal factor is the secretion of gonadotrophins by the pars distalis of the hypophysis, which controls the development, structure, and activity of the ovary (see diagram).

Thyroid → Anterior lobe of the hypophysis ← Adrenals

− | +Gonadotrophins { primary or gonadal effect

Ovary

Placenta | Corpus luteum | Progesterone | Ovum | +Ovarian hormones { secondary or peripheral effect

Uterus Mammary gland Cycles Ovulation	Secondary sexual characters Morphologic { genital (vectors of the ovum), extragenital Functional Psychic


The sexual function of the anterior lobe of the hypophysis is controlled by (*a*) *hormones* of the ovary, thyroid, and adrenal cortex; (*b*) *reflexes* stimulated by copulation, light, etc.; (*c*) *nutritive factors*, such as vitamin E, undernourishment, etc.

Hormones secreted by the ovary not only have a feminizing effect, they also act on the anterior hypophysis: (*a*) they moderate the secretion of gonadotrophins; (*b*) in certain concentrations they provoke the release of luteinizing hormone, which produces the rupture of the mature follicles (ovulation) with subsequent luteinization of these follicles and sometimes of other immature follicles (atretic luteinization).

Ovarian hormones act on the ovary itself, mainly indirectly through the hypophysis, but also directly on the follicles (see "Hormonal factors in the menstrual cycle").[2]

Factors that modify ovarian functions. The greater part of the factors that modify ovarian functions act through the anterior hypophysis, but some of them act directly on the ovary. The activity of the ovary is modified by extraovarian factors in the following circumstances:

1. In certain species ovulation is provoked by a reflex (copulation in the cat and rabbit, amplexus in the toad, visual reflexes in the pigeon) or by electrical stimulation of the hypothalamus or the whole brain (rat and rabbit).
2. Excessive illumination provokes sexual activity during hibernation in certain species.
3. Cold inhibits ovarian activity and suppresses the sexual cycle.
4. Infections and other diseases (*e.g.*, tuberculosis) may suppress the menstrual cycle.
5. Chronic undernourishment diminishes and eventually suppresses the sexual cycle and ovulation.
6. Thyroidectomy or thyroid insufficiency prevents sexual development and diminishes the frequency of the cycles. Moderate hyperthyroidism increases the frequency of the cycles, but severe hyperthyroidism suppresses the cycle.
7. Adrenal insufficiency and corticoadrenal hyperfunction disturb ovarian functions in women.

There is an optimum level of thyroid and of adrenal secretion necessary for the normal functioning of the ovary; insufficiency or excess of these hormones disturbs the activity of the ovary.

THE SEXUAL CYCLE

Comparative biology of the sexual cycle. Cyclic activity is an outstanding feature of feminine sexual functions. The sexual cycles begin at puberty and end at the menopause. In some species there are only one or two periods of sexual activity in the year, *i.e.*, one cycle at each breeding season. These periods during which the female accepts the male are called *estrus* or "heat"; outside estrus, *i.e.*, during *anestrus*, the female does not accept the male. Animals with this type of cycle are called *monoestrous*. At the beginning of the cycle, in the stage known as *proestrus*, there are congestion and secretion in the uterus and vagina, the vaginal epithelium proliferates, and the vulva is swollen. During estrus the changes in the genital tract are at a maximum, ovulation takes place, the vaginal epithelium desquamates cornified cells, and the female accepts the male. The stage following

[1] The part played by the ovary in the development and maintenance of female secondary sexual characters has already been considered in previous chapters.

[2] The role of the thyroid and adrenals in the regulation of anterior hypophyseal sexual functions, of ovarian functions, and of secondary sexual characters has been discussed in preceding chapters.

estrus, during which the corpus luteum is formed and secretes, is called *metaestrus*. In some species (*e.g.*, the rabbit and ferret), even when the female has not been fertilized, estrus is followed by changes similar to those of pregnancy, which last as long or nearly as long as pregnancy. There is considerable development of the mammary glands and sexual organs and changes in the uterine mucosa which resemble those seen just before nidation of the embryo (progestational changes). This condition is called "pseudopregnancy."

In *polyestrous* animals the cycles occur with greater frequency throughout the sexual life of the female. Each cycle has the proestrus, estrus, and metaestrus phases and is separated from the following cycle by a short period of quiescence called *diestrus*. Rats and mice are polyestrous animals. Their sexual cycle has been the subject of considerable work, on which a great part of the knowledge of female sexual functions is based. There are changes in the ovary, fallopian tube, uterus, and vagina. The vaginal response is typical and can be easily followed by microscopic examination of smears of the vaginal content.[1] During proestrus large nucleated epithelial cells are found; during estrus there are only squamous cornified cells; during metaestrus leukocytes appear among the cornified cells; during diestrus there are only leukocytes, a few epithelial cells, and mucus. The corpus luteum has a very short time of activity in polyestrous animals, such as the rat and mouse; luteal activity is much more intense and prolonged in species in which estrus is followed by pseudopregnancy.

The average duration of the cycle in different species is as follows: rat and mouse, 4 to 6 days; guinea pig, 14 days; sheep, 16 days; cow, 20 days; sow, 21 days; macaque, 27 days; woman, 28 days; chimpanzee, 36 days. The bitch has two cycles a year, the bat and marmot one cycle a year. In the cat, rabbit, and ferret the follicle ripens but ovulation does not take place unless there is copulation or intense sexual excitement. The rabbit ovulates 12 to 16 hr. after copulation and the cat 26 hr. after.

The Sexual Cycle in Women

Puberty. The most typical sign of female puberty is the onset of menstruation. In temperate climates this usually occurs between the ages of eleven and fifteen (average, thirteen and one-half); if it takes place outside these ages, puberty is considered as precocious or retarded.[1] Other signs of puberty are the development of the ovaries, uterus, and mammary glands, the appearance of hair on the pubis and in the axillae, etc.
Fig. 273. Diagram of sexual cycle. Above, in species with estrus; below, in primates.

Menstruation. The two outstanding events in the female cycle are menstruation and ovulation, the latter occurring toward the middle of the period between two menstruations (Fig. 273). Ovulation does not always occur at each cycle. In early puberty there are many anovulatory cycles. In some women they also occur from time to time, with greater or lesser frequency. These anovulatory cycles are sterile, because there is no ovum to be fertilized.

Menstruation consists in a hemorrhagic flow from the vagina (20 to 200 cc.), which comes from the endometrium. Menstrual blood usually does not clot. This flow lasts 3 to 7 days in 95 per cent of women (3 to 5 days in 66 per cent). It appears every 27 or 28 days, but there is considerable variation in the duration of the menstrual cycle of different women (Fig. 274), and even in the same woman the duration of the cycle may change from time to time. In the course of the 30 or 40 years of sexual life, a woman menstruates from 300 to 500 times.

Ovulation. Ovulation takes place toward the middle of the cycle. Ova have been collected by washing out the fallopian tubes in women be-

[1] Stockhard, C., and C. Papanicolau, *J. Anat.*, 22, 225, 1917.

[1] In well-nourished girls menstruation begins earlier than in the undernourished.

tween the twelfth and twenty-first day after the beginning of menstruation; the largest number have been found on the fifteenth day (Allen). The postovulatory stage, *i.e.*, the interval between ovulation and the following menstruation, is less variable in duration (10 to 16 days) than the preovulatory stage, *i.e.*, the interval between the beginning of menstruation and ovulation. Since the ova do not live long, fertilization can occur only during a short period following ovulation; this is the fertile period of the cycle. According to Ogino, Knaus, and others, ovulation occurs 12 to 16 days before the following menstruation. The situation of the fertile period in the cycle varies, therefore, with the length of the cycle. It can fall from the eighth to the twenty-first day (Hartman); the days before and after this period are sterile in the sense that fertilization cannot take place during them. In female monkeys the existence of fertile and sterile periods has been clearly demonstrated (Hartman). Observations in women have shown increased fertility in the middle of the cycle, but fertilization has been seen to take place even during the so-called "sterile" period.

FIG. 274. Frequency distribution of duration of menstrual cycle. Abscissa, days of cycle; ordinate, percentage of incidence in 154 women. (*After Haman.*)

Diagnosis of ovulation. Ovulation has been observed in women by inspection of the ovaries in the course of abdominal operations. Definite proof of ovulation has been obtained by washing out the fallopian tubes and observing the ovum. There are, however, more simple and practical methods of establishing the moment of ovulation. Basal temperature (rectal or sublingual), taken in the morning, varies between 36.3°C. and 36.8°C. during the preovulatory phase and rises to 37 to 37.3°C. in the postovulatory phase. This difference of 0.3 to 0.5°C. is observed only in ovulatory cycles, not in anovulatory ones (Fig. 275).

At the moment of ovulation there is an increase in the cornified acidophil cells of the vaginal smear (Allende and Orías) (Fig. 276). There is also an increase in urinary gonado trophin just before ovulation occurs,[1] which has been used for diagnostic purposes. Two rats, 21 to 25 days old, are injected subcutaneously with 2 cc. of urine, and 2 hr. later congestion of the ovaries is observed if the gonadotrophin content of the urine is high. The test is repeated for four days, and if it is consistently positive, ovulation will take place on the fourth day, this being the most favorable moment for fertilization. It usually occurs 11 to 14 days after the

FIG. 275. Temperature changes during menstrual cycle. Abscissa, days of cycle; ordinate, temperature in degrees centigrade; stippled area, menstruation.

first day of the last menstruation, or at the half of the cycle minus 2 days (Farris).

In an ovulatory cycle a corpus luteum is formed, and its activity can be established by (*a*) glandular proliferation and secretion of the endometrium, established by histological examination of a small fragment of uterine mucosa excised with a curet; (*b*) a sudden increase in the urinary excretion of pregnandiol (a metabolic product of progesterone) for 4 to 5 days following ovulation; (*c*) an increase of 0.3 to 0.5°C. (0.6 to 0.9°F.) in basal temperature.

Hormonal factors in the menstrual cycle. When the follicle begins to ripen, the oocyte and the cells of the granulosa stimulate growth and activity of the cells of the theca interna. In some of the follicles the theca secretes estrogens, which provoke secretion of follicular fluid by the cells of the granulosa and sensitize the follicle to FSH secreted by the hypophysis. In women FSH provokes the maturation of only one follicle (in rare cases, two) at each cycle, *i.e.*, the follicle sensitized by estrogens. This follicle develops up to a diameter of 2 cm., while the other follicles that were in the process of ripening cease to grow, and some become atretic. The mass of maturing follicles is nevertheless necessary for the development of the single follicle that ovulates.[1]

Secretion of estrogens increases gradually, reaching a maximum at the moment of ovulation. During the preovulatory phase estrogens predominate and stimulate the development of the uterus, especially the proliferation of the endometrium. When estrogens are at a high level, secretion of FSH is inhibited and secretion of LH, and probably of luteotrophin (prolactin), increases. LH acting on the mature and sensitized follicle causes its rupture and the release of the ovum, *i.e.*, ovulation. LH then provokes the development of the corpus luteum in the ruptured follicle, and luteotrophin stimulates the secretion and maintains the structure of the newly formed corpus luteum.

Progesterone, secreted by the corpus luteum, stimulates secretion of the endometrial glands and causes progestational changes which prepare the endometrium for the implantation of the fertilized ovum. During the postovulatory phase progesterone activity is predominant. Three to four days after ovulation pregnandiol appears in the urine; from 40 to 60 mg. of this metabolic product of progesterone are excreted during each cycle (Venning and Browne, 1936). The high level of progesterone in the circulation inhibits the secretion of LH and luteotrophin, and this causes involution of the corpus luteum. Progesterone then diminishes, the endometrium breaks down, and menstruation occurs.
FIG. 276. Cornification of vaginal epithelium in the course of a cycle in which ovulation occurs. 1, menstrual; 2, postmenstrual; 3, preovulatory, 4, ovulatory; 5, postovulatory; 6, progestational; 7, premenstrual. (*I. C. de Allende and O. Orías, 1947.*)

Apparently normal menstruation with typical changes in the endometrium can be provoked in cases of amenorrhea and in castrated women by injecting estrogens followed by progesterone; when progesterone is withdrawn, uterine bleeding commences. Uterine hemorrhage has also been provoked in castrated female monkeys and in castrated women by withdrawal of treatment when estrogens only are injected (Corner), or even by reducing the dose of estrogen (Zuckerman). These facts led Corner to formulate the hormone-withdrawal hypothesis of menstruation. According to this hypothesis, menstruation is caused by the sudden fall in progesterone secretion due to involution of the corpus luteum in the final stages of the cycle.

Anovulatory cycles, *i.e.*, menstrual cycles without ovulation, have been observed in monkeys and in women. These cycles are sterile; fertilization cannot take place because no ovum has been released. No corpus luteum develops in this type of cycle; therefore the endometrium does not show progestational changes or the secretory phase. According to Corner's hypothesis, menstruation in these cycles is caused by a decrease in estrogens.

The uterine cycle. Typical changes take place in the endometrium in the course of the

[1] The factors conditioning the favored follicle so that "it is lifted on the shoulders of its contemporaries" are not yet well understood (Hohlweg and Westman, 1934; Laqueur *et al.*, 1945–1946; etc.).

menstrual cycle (Fig. 277). These have been studied by simultaneous microscopic observation of small fragments of vaginal mucosa and endometrium, correlating the changes seen with those observed in the ovary in women submitted to abdominal operations. Simple macroscopic examination of the ovaries *in situ* may be the cause of serious errors (Hartman); therefore histological examination should always be performed. The following changes occur in the course of a complete cycle:

1. *Proliferative stage* (sixth to fourteenth day after the beginning of menstruation). The endometrium increases in thickness, and the glands lengthen. At first they are straight, but later they become folded and tortuous (Figs. 277*a* and 278). This stage is sometimes called the "estrogenic phase" because estrogens stimulate the growth of the endometrium.
2. *Secretory or progestational stage* (fifteenth to twenty-seventh day of cycle). The endo-

a
b
c

FIG. 277. Cyclical changes in human endometrium. *a*, proliferation; *b*, secretion; *c*, menstrual desquamation.

metrium increases in thickness even more. The cells of the stroma proliferate. The uterine glands attain a considerable development and are distended by mucus. On section the endometrium has a serrated aspect owing to the epithelial folds. The spiral arteries in-

Venning, Royal Victoria Hospital, Montreal.*)

crease in size and number, and there are numerous wide capillaries (Figs. 277*b* and 278). Changes in this stage are produced by the hormone of the corpus luteum (progesterone). They are a preparation for the reception and implantation of the fertilized ovum; hence the name "progestational stage."

3. *Destructive stage.* The superficial spongelike layers of the endometrium diminish in thickness, the circulation becomes slow, and stasis occurs. Later there is vasoconstriction in the mucosa which lasts 4 to 24 hr., a fact that has been directly observed in transplants of endometrium placed in the eye behind the cornea.[1] The arteries again dilate, and hemorrhage begins. Blood is lost through the capillaries, arterioles, and veins of the stroma and glands. Small blood lakes are formed

[1] MARKEE, J. E., "Progress in Gynecology," Grune & Stratton, New York, 1946; REYNOLDS, S. R. M., *J. A. M. A.*, **135**, 552, 1947.

under the superficial epithelium, which becomes necrosed and is sloughed into the uterine cavity together with unclotted blood, leukocytes, and mucus (Figs. 277*c* and 278). If there is abundant hemorrhage, thrombin and blood clots are formed; if there is a slow hemorrhage, the blood is gradually defibrinated and contains antithrombin. Fibrin in intrauterine clots is usually dissolved fairly rapidly (fibrinolysis).

In approximately three days the endometrium loses half its thickness. The process of repair then begins (second to fifth day) and merges into the proliferative stage.

A menstrual toxin (menotoxin) has been described,[1] which seems to be an atypical euglobulin produced by the endometrium, similar to necrosin, found by Menkin in inflammatory exudations. This substance has been found not only in menstrual blood but also in the blood of the general circulation. It is believed to cause vascular lesions. Release of this toxin seems to be due to the involution of the corpus luteum and to the decrease in estrogen and progesterone.

The significance of menstruation has been the subject of much discussion. It is not the equivalent of estrus, to which the preovulatory stage could be more appropriately compared (Fig. 273). Sometimes there is a small hemorrhage and pain (*Mittelschmerz*) toward the end of the proliferative stage which corresponds, to a certain extent, to the phenomenon of estrus. In women there is no typical estrus and the male is accepted at any stage of the cycle. Menstruation provokes renewal of the endometrium when the progestational changes brought about in preparation for the implantation of the fertilized ovum are not followed by pregnancy.

"Amenorrhea" means the cessation of menstruation. "Hypomenorrhea" means a scanty menstrual flow, and "hypermenorrhea" an abundant flow. "Oligomenorrhea" is the term used for the appearance of menstruation at long intervals, and "polymenorrhea" for abnormally frequent menstruation. "Dysmenorrhea" means painful menstruation.

The vaginal cycle. (Figs. 276 and 279.) In childhood, in old age, and in genital aplasia, *i.e.*, whenever there is estrogen deficiency, the vaginal epithelium is thin. Estrogens provoke an increase in the thickness of the epithelium and cornification of the superficial cells. The aspect of the vaginal smear changes with the level of estrogenic activity: (*a*) estrogenic activity is revealed by the preponderance of superficial karyopycnotic and cornified acidophile cells; (*b*) when there is slight or moderate estrogen deficiency, the majority of the cells are small deep-layer cells and intermediate cells, and a few superficial cells, with mucus, leukocytes, and bacteria; (*c*) in marked estrogen deficiency, there are only small deep-layer cells, mucus, leukocytes, and bacteria. Cornified cells increase as the cycle proceeds, remaining separated from each other. They are at a maximum (peak of cornification) at the moment of ovulation. During the progestational stage there is a preponderance of intermediate cells; cornified cells are seen in clumps with folded margins.

Cytological examination of the urethral smear or the urinary sediment shows changes similar to those of the vaginal smear.[1]

The vaginal pH is lower during the first half of the cycle than during the second half.

Changes in other organs. Cyclic changes are also observed in other epithelia, such as the mucosae of the fallopian tubes, the mouth, the nose, and perhaps the mammary gland. In several species cyclic changes in the adrenals have been reported.

General symptoms. Just before menstruation, several disturbances, known as "premenstrual symptoms," are frequently observed. These include headache; tension in the pelvis, which is sometimes intensely painful; and slight or even marked congestion of the nasal, laryngeal, and buccal mucosae. This congestion sometimes causes slight hemorrhage, which has been mistakenly called "vicarious menstruation." Occasionally tension and tenderness of breasts are noted. In some women water is retained and there is a transitory increase in weight. In the female monkey estrogens (secreted by the ovary or injected) provoke congestion and edema of the sexual skin, and the body weight may increase by 25 per cent. When estrogenic activity ceases (ovulation, or withdrawal of estrogen treatment), congestion and edema of the sexual skin disappear, and there is polyuria and loss of weight, before menstruation begins. During menstruation the BMR and temperature diminish. (Deep rectal or vaginal temperature is

low during the first half of the cycle; there is a further sharp decrease at the moment of ovulation and then a rise, and the temperature is high during the activity of the corpus luteum.)

upper part of the chest, together with a sensation of suffocation and sweating. Frequently a tendency to obesity appears and sometimes there are signs of virilization (hair growth on the upper lip and on the body, and lowering of the voice register).[1] Personality changes often occur at the menopause; there are emotional instability, psychic tension, and irritability. Some women complain of headache and of diffuse pain in the trunk and limbs.
FIG. 279. Diagram of vaginal cycle in women. (*After Murray.*)

Menopause. The menopause, or climacteric, consists in the cessation of the menstrual cycle.[1] It occurs most frequently between forty-five and fifty years of age. If it takes place before the age of thirty-five it is considered premature, and retarded if the cycles are prolonged beyond the fifty-fifth year. It is known as "artificial menopause" when it is due to castration by surgical procedures or by the application of x-rays, or to hysterectomy. Natural menopause is accompanied by a decrease of, and finally the disappearance of, estrogens in the urine and by an increase in gonadotrophins.[2] Ovarian activity diminishes and finally ovulation ceases. The genital organs and mammary glands undergo gradual involution. There are many general symptoms, including crises of vasodilatation (hot flashes) in the skin of the head, neck, and

[1] MARAÑON, G., "La Edad Crítica," 2d ed., Ruiz, Madrid, 1925.

[2] Many of the unpleasant symptoms suffered by women at the menopause have been attributed to the increase in gonadotrophin.

Castration. The removal of one ovary does not provoke the appearance of symptoms of ovarian insufficiency or disturbances in the cycle, nor does it diminish the number of offspring if the remaining ovary is in normal condition. Extirpation of both ovaries is followed by symptoms of ovarian insufficiency. If castration is performed before puberty the genital organs and the secondary sexual characters do not develop. There are few reported cases of prepuberal castration in women, and most of these have not been the object of a thorough and complete study. The genital tract and mammary gland remain in an infantile condition. There is no menstruation. Axillary

[1] This has been attributed to androgenic corticoadrenal hyperfunction.

and pubic hair does not grow. Feminine and genital instincts do not appear. The subjects are usually tall owing to retarded closure of the epiphyseal cartilages. The condition is called "sexual infantilism" ("feminine eunuchoidism" is not a correct term), and it has been observed in different degrees of severity.

Postpuberal castration is performed for therapeutic reasons in adult women suffering from certain diseases of the ovaries or uterus. In this case the disturbances observed differ from those of sexual infantilism because secondary sexual characters are already developed. The disturbances are similar to those seen in the menopause, but they are more severe than in the natural menopause and take place more rapidly.[1] There is a more or less intense and progressive atrophy of the uterus and the epithelia of the vagina and vulva. Menstruation ceases, but in some cases castration is followed by one menstrual flow. The mammary gland atrophies, although in some cases this is not apparent because of the increase in adipose tissue, due to a tendency to obesity. The libido frequently suffers no change after castration in women, because it is strongly conditioned by psychic factors, but in animals estrus ceases completely. Growth of hair on the face and limbs often occurs, and sometimes hypertrichosis is seen. This has been attributed to an increase in corticoadrenal androgenic secretion, but it might also be due to the suppression of an inhibitory effect of estrogens on hair growth, similar to the inhibitory effect on the spurs of the hen. Castration is often followed by psychic disturbances such as emotional instability, irritability, or depression; the subjects become very susceptible to emotional stimulation and are easily angered or subject to fits of uncontrolled laughter. They also suffer from vasomotor disturbances (hot flashes) accompanied by sweating; these flashes can be provoked by the injection of adrenaline. They often complain of palpitations (tacnycardia is observed), cold hands and feet, headache, diffuse pains in the limbs, and other abnormal sensations. Urinary elimination of estrogen diminishes and the excretion of gonadotrophins increases, especially during the vasomotor crises.

[1] The examination of vaginal smears shows that at the menopause the ovary continues to secrete estrogens at a progressively decreasing level during several years. Castration causes a sudden cessation of estrogen secretion.

Restitution of ovarian functions. The effects of castration can be prevented or controlled by several methods (see Chap. 57): (*a*) ovarian grafts; (*b*) implantation of ovarian tissue; (*c*) injection of ovarian extract; (*d*) injection or implantation (pellets) of ovarian hormones. The most commonly used method is the administration of ovarian hormones (natural estrogens) or of substances that have estrogenic activity. This treatment stimulates the development of the genital tract and maintains it as long as the treatment lasts. In young castrated women, if the uterus remains intact, menstrual cycles can be provoked by the injection of 15 to 20 mg. of estradiol during 20 days, followed by 5 to 25 mg. progesterone during 5 days; when the treatment is suspended the menstrual flow begins. Biopsies of the endometrium show the histologic changes corresponding to the three stages of the cycle.

Estrogens.[1] The knowledge of the cyclic changes occurring in the vaginal epithelium of rodents provided a simple method for the study of substances with estrogenic activity. At first the natural estrogens, *i.e.*, those obtained from animal tissues and fluids, were studied.[2] Later artificial estrogens were prepared. Dozens of estrogenic substances are now known. They have been obtained from animal and plant tissues and from minerals such as tar and asphalt.

Natural estrogens are steroids that have a perhydrocyclopentenephenantrene ring. They are derivatives of the unsaturated Δ, 1, 3, 5-estratriene ring. The principal estrogenic substances[3] are: (*a*) *estradiol;*[4] (*b*) *estrone;*[5] (*c*) *estriol.*[6] These three substances have an OH group on C^3; estradiol also has OH on C^{17}, estrone O on C^{17}, and estriol OH on C^{16} and C^{17}. Estradiol has been obtained from the ovaries of sows, from human urine, and from the testes of stallions. It is six times as active as estrone and seems to be the main, if not the true, ovarian hormone. In therapeutics the benzoate, propionate, or dipropionate of estradiol is used.

[1] Doisy, E. A., *J. A. M. A.*, **116**, 501, 1941; *Endocrinology*, **30**, 933, 1942.

[2] Mainly by Doisy, Butenandt, and Laqueur and their associates in 1929 and 1930.

[3] The names "folliculin" and "estrin" are no longer used.

[4] Dihydroxyestrin.

[5] Ketohydroxyestrin or theelin.

[6] Trihydroxyestrin or theelol; it is found in the placenta forming part of a complex (emmenin).

Natural estrogens have been found in the ovary, liquor folliculi, placenta, adrenals, and the human corpus luteum during the first third of pregnancy. There are large quantities in the urine of pregnant women and mares and in stallion's urine[1] (Table 78).

Estrane

Estratriene

Estradiol

Estrone

Estriol

Equilin
Castration diminishes the urinary output of estrogens in the horse. The urine of normal women contains little estrogen; there is an increase about the time of ovulation and another just before menstruation (Fig. 278).

Ovariectomy performed during the first weeks of pregnancy does not prevent the increase in the urinary excretion of estrogens, which occurs later and is maintained at the usual high level in spite of castration. This is due to the fact that estrogens in pregnant women's urine are produced not by the ovaries but by the placenta.

The cells of the granulosa, the theca interna, and the corpus luteum all seem to produce estrogens, and when a large number of follicles ripen there is hypersecretion of estrogen. The follicles, however, are not the only structures that can produce estrogens, because normal cycles have been observed in rodents in which the follicles were destroyed by x-rays without damaging the interstitial cells. The latter therefore can also produce estrogens.

[1] Large quantities of estrogens are found in the urine of pregnant women, pregnant mares and stallions. In women most of the estrogen is estriol.

Table 78. Estrogen Content of Tissues and Organic Fluids

Estrogen	*Sow's ovary, mg. per kg.*	*Pregnant woman's urine, mg. in 24 hr.*	*Human placenta, mg. per kg.*	*Bovine adrenal*	*Stallion's urine*
Estradiol. . .	0.14	0–0.06	0.038		
Estrone. . . .	0.10	1–3	0.033	+	+
Estriol.	. . . .	10–30	0.140		

Estrogens produced by the organism are rapidly converted into inactive substances; only small amounts are eliminated without change. The most important site of estrogen inactivation is the liver. It is for this reason that, to obtain the effects of a certain amount of estrogen injected subcutaneously, fifty to one hundred times that amount must be given by mouth.[1]

Diethylstilbestrol

Hexestrol

Dienestrol

The most commonly used artificial estrogens are diethylstilbestrol, hexestrol, dienestrol, bencestrol, ethylnilestradiol, doysinolic and dehydrodoysinolic acids, allenolic and dimethylallenolic acids. The first three are derivatives of dihydroxystilbene (stilbestrol) and they differ from each other by their side chains. They have the same estrogenic properties as natural estrogens but differ from them in other respects. They are in common use in therapeutics because they are active by mouth and can be prepared at low cost.

The action of estrogens. The main effect of estrogens is stimulation of the development of the genital organs and mammary glands, an effect that is observed in intact and in castrated animals. In hens they stimulate the development of female plumage and inhibit the growth of the spurs.

In women and female monkeys, estrogens provoke proliferation of the endometrium, with an increase in the length of the uterine glands but with very little secretion; there are also vasodilatation and edema. If estrogen administration is discontinued, uterine hemorrhage occurs. This effect is seen in the infantile uterus and in women who have been castrated or have entered the menopause. In monkeys there is also reddening and swelling of the sexual skin around the vulva and anus, and water is retained. The tonus of the uterus increases, and it becomes more sensitive to the oxytocic effect of neurohypophyseal extracts.

The vaginal epithelium increases in thickness, it desquamates cornified cells, and its secretions increase. The motility of the fallopian tube increases, the cilia are more active, and the secretory activity of the mucosa is greater. The ducts of the mammary gland proliferate in all species, but there is proliferation of the alveoli only in some, *e.g.*, in the guinea pig, in which estrogen provokes the secretion of milk.[1]

Estrogens in moderate doses stimulate the secretion of the luteinizing, luteotrophic (prolactin), and adrenotrophic hormones of the anterior hypophysis; in large doses they have an inhibitory effect. In adequate doses they prevent the appearance of or control the cytologic changes in the anterior hypophysis produced by castration. Large doses given repeatedly cause an increase in the size of the anterior hypophysis, accompanied by deficiency in all the functions of the gland.

In the male, estrogens cause testicular atrophy due to inhibition of the hypophysis. They also provoke dilatation and keratinization of the prostatic utricle in rodents and monkeys. The prostate is considerably enlarged and causes urinary retention in the bladder and hydronephrosis. In man, estrogens have been used in the treatment of cancer of the prostate, in order to inhibit the growth of the epithelial cancerous cells (see Chap. 60).

Estrogens produce metabolic effects such as

[1] Ethylnilestradiol and the so-called "artificial estrogens" are more resistant to the inactivating action of the liver than natural estrogens and are therefore effective by mouth.

[1] Diethylstilbestrol stimulates the development of the mammary glands in cows and goats, even after castration.

(*a*) retention of Na, Cl, and water; (*b*) decrease in blood phosphate; (*c*) diminished excretion of Ca and P in some cases in which it is increased, and establishment of positive Ca and P balances.

Estrogenic activity is usually expressed in international units. An international unit is the specific activity of 0.1 μg of estrone (this corresponds to approximately ⅓ rat unit). The international unit of estradiol benzoate is the specific activity of 0.1 μg of a standard preparation of the substance. The activity of estrogens is measured by injecting the substance into castrated rats or mice and determining the minimum amount necessary to provoke a vaginal cycle or an increase in uterine weight.

FUNCTIONS OF THE CORPUS LUTEUM

The corpus luteum is formed and functions at each cycle, but its most important activity takes place during pregnancy and is prolonged during lactation. The main functions of the corpus luteum are the following:

1. It inhibits ovulation and the sexual cycle, which do not occur if there is an active corpus luteum.
2. It diminishes the tonus of the uterus and decreases its sensitiveness to oxytocic substances.
3. It stimulates proliferation of the endometrium and its glandular secretion, and prepares it for the implantation of the fertilized egg (progestational activity).
4. It maintains the nutrition of the embryo and fetus.
5. It stimulates complete development of the mammary glands.

Progestational and gestational changes in the endometrium. Toward the middle of the cycle, after the ovum has been expelled, the follicle is converted into the corpus luteum, which secretes a hormone called progesterone. The uterine glands, which have grown during the proliferative stage of the cycle, owing to the action of estrogens, are stimulated by progesterone to a maximum development, and they enter into a secretory phase. This premenstrual secretory activity is a preparation of the uterine mucosa for the nidation and nourishment of the fertilized egg. If the ovum is not fertilized it is not implanted in the uterus and the corpus luteum retrogresses. Involution of the corpus luteum is the cause of the menstrual breakdown of the endometrium and the commencement of the maturation of a new follicle (or set of follicles) and of another cycle.

In species in which ovulation is followed by pseudopregnancy, the progestational changes in the endometrium are more marked. Thus Ancel and Bouin observed endometrial changes in the female rabbit after copulation with a vasectomized male. The ovum could not, of course, be fertilized in these conditions, but a corpus luteum was formed. The endometrium proliferated (Fig. 280), and the mammary glands were considerably enlarged, due to growth of the ducts and alveoli. If the corpora lutea are removed this development ceases, and it may be prevented if the extirpation is performed sufficiently early.

If, during the luteal phase of the cycle, a thread is passed through the uterus so as to include the endometrium, or simply an incision is made in the endometrium, a tumoral mass grows in the damaged area. This tumor has a structure similar to the decidual membrane of the pregnant uterus, and it is known as a deciduoma. This effect does not occur unless there is an active corpus luteum, *i.e.*, it is not observed during the proliferative stage or after removal of the corpus luteum (Leo Loeb). A deciduomatal response can be obtained from the uterus of a castrated animal by the injection of progesterone after having provoked the development of the endometrium by treating it with estrogens.

The effect of progesterone on the endometrium and mammary gland is considerably enhanced by giving adequate doses of estrogen before and during treatment with progesterone. Larger doses of estrogen inhibit the activity of progesterone.

The continuance of pregnancy. Toward the end of the last century, Born remarked that animals in which a placenta was not formed did not have corpora lutea. Fraenkel showed that extirpation of the corpora lutea prevented nidation or provoked abortion in the rabbit. This fact has been observed in many other species (rat, dog, etc.) in which the corpus luteum persists throughout pregnancy. In other animals (*e.g.*, guinea pigs and monkeys) it is not indispensable after the first stages of pregnancy, and normally it is seen to retrogress before the end of pregnancy. In women the corpus luteum can be removed after the fourth or fifth month of preg-

nancy without provoking abortion. There is some proof that at this stage the placenta begins to produce luteal hormone.

Progesterone treatment carries pregnancy to term, preventing abortion, after castration in pregnant rabbits (Corner). In the absence of progesterone the uterine tone increases and by compression kills the fetus. Extrauterine pregnancy can proceed normally after castration in the rabbit.[1]

Pregnancy can be prolonged by the injection of progesterone or of pregnant women's urine, which contains luteinizing hormone and causes the development of new corpora lutea (Snyder). An abundant secretion of estrogen seems to be necessary to maintain the development of the corpus luteum during pregnancy and to cooperate with its action on the uterus.

Development of the mammary gland. After the development of the mammary gland has been stimulated by estrogens, the hormone of the corpus luteum completes this development by provoking the growth of the acini and preparing the gland for the secretion of milk.

Action on the sexual cycles. An active corpus luteum, or the injection of progesterone, prevents ovulation. At each cycle ovulation is retarded by the action of the corpus luteum; if it is removed, ovulation occurs earlier. During pregnancy the corpus luteum prevents ovulation and the possibility of another fertilization (superfetation) when the uterus is already occupied. This effect is produced by the inhibition of hypophyseal gonadotrophin secretion.

Action on the uterine muscle. The secretion of the corpus luteum stimulates the growth of the uterine muscle during pregnancy (trophic effect). It also decreases the tonus of the uterus and renders it less sensitive to the oxytocic effect of posterior hypophyseal extract (Knaus). Adrenaline relaxes the virgin uterus and provokes contraction of the gravid uterus in several

[1] COURRIER, R., and R. M. A. COLONGE, *Compt. rend. Acad. sc.*, Paris, **230**, 1438, 1950.

species. This is due to the secretion of the corpus luteum, because progesterone treatment in a virgin guinea pig will cause the uterus to respond to adrenaline with contraction.

Action on the pubic symphysis. In certain species, *e.g.*, the guinea pig, the ligaments of the pubic symphysis and sacroiliac joints soften and relax during pregnancy. Three hormones can provoke this effect: (*a*) estrogen, when treatment is prolonged; (*b*) progesterone, after treatment with estrogen; (*c*) relaxin, extracted from the ovary, corpus luteum, and uterus, which has a much more rapid and intense effect than other hormones (Hisaw, 1926).

The hormone of the corpus luteum. Several active substances have been obtained from the corpus luteum.[1] The most active of these is progesterone (the names "progestin" and "luteosterone" are not now commonly used). It is a steroid related to the estrogenic, androgenic, and corticoadrenal hormones.[2]

[1] Mainly by Corner and Allen, 1929, Allen and Wintersteiner, 1934, Butenandt and Westphal, 1934, and Slotta, Ruschig, and Fels, 1934.

[2] Testosterone, desoxycorticosterone, and other steroids have a slight progestational activity. Ethylniltestosterone (pregneninolone) has a marked progestational effect, and it is active by mouth (Inhoffen and Hohlweg, 1938).

Progesterone

Pregnandiol

Pregneninolone

Progesterone has been synthesized by Butenandt from stigmasterol (a plant steroid found in soya beans) and from pregnandiol.

Pregnandiol is a waste product of progesterone which is excreted in the urine (Marrian) combined with glycuronic acid, forming sodium pregnandiol glycuronidate. This substance appears in the urine of normal women 12 days before the menses, *i.e.*, 1 or 2 days after ovulation, when the corpus luteum begins to secrete. Urinary excretion of this substance increases and reaches a maximum in about a week and then ceases suddenly one or two days before menstruation. During pregnancy large quantities of pregnandiol are eliminated in the urine, maximum amounts are found toward the eighth or ninth month. Ovariectomy does not suppress urinary elimination of pregnandiol in pregnancy, because the placenta continues to produce it. Women excrete in the urine as pregnandiol 10 to 20 per cent of progesterone injected into them. During pregnancy this rises to 30 to 35 per cent. The uterus is not indispensable for the conversion of progesterone to pregnandiol, but during the menopause it can contribute to this process.[1]

[1] SOMMERVILLE, I. F., and G. F. MARRIAN, *Biochem. J.*, **46,** 290, 1950.

The activity of progesterone and of extracts of the corpus luteum is expressed in international units; 1 IU is the specific activity of 1 mg. of standard progesterone. Activity is measured by the effect on the endometrium of adult rabbits, which have been submitted to sterile copulation (with a vasectomized male) and castrated immediately afterward; progestational proliferation is observed (Corner). Immature virgin rabbits can also be used, but the endometrium must first be sensitized by the injection of estrogens (Clauberg).

Progesterone has the following effects: (*a*) it causes nidation of the fertilized egg, and it prevents abortion after castration in rabbits; (*b*) it prevents abortion after hypophysectomy; (*c*) it produces progestational development of the endometrium, previously sensitized by estrogens, and pseudopregnancy in castrated animals; (*d*) it diminishes the tonus of the uterus and sensitiveness to the oxytocic effect of posterior hypophyseal extracts; (*e*) it reverses the response of the virgin uterus to adrenaline, causing contraction instead of relaxation; (*f*) it prolongs or suppresses the sexual cycle; (*g*) in certain species it prolongs pregnancy when given in large doses.

Progesterone has no effect on the endometrium unless the latter has been previously sensitized by estrogens.

Disturbances in ovarian functions. Ovarian insufficiency, sexual infantilism, and menstrual disorders have already been mentioned. Certain tumors of the granulosa have feminizing activity and provoke precocious puberty in girls or cause development of the uterus and the reappearance of the menstrual cycle in women after the menopause. Thecomas (tumors made up of theca cells) can also have a feminizing effect. Exceptionally thecomas and thecosis, *i.e.*, diffuse hyperplasia of the theca cells (Fraenkel, 1941), have a masculinizing effect, similar to that of arrhenoblastomas (see Chap. 57).

Therapeutic application of female hormones. Estrogenic hormones are given to obtain the development of the genital organs and mammary glands in cases of sexual infantilism. Large and repeated doses may inhibit the hypophysis. Estrogens are also used in cases of infantile vaginitis due to gonorrhea, in order to provoke thickening of the vaginal epithelium and an acid secretion, thus creating unfavorable conditions for the development of the germs. They are also used in cases of senile vulvar pruritis in order to modify the mucosa and secretions of the vulva. Estrogens have been used in the treatment of atrophic rhinitis. The main use of estrogens is the treatment of the symptoms of natural or artificial menopause (castration, x-rays, etc.) (see page 673). Examination of vaginal smears and biopsies of endometrium, at the appropriate times, after treatment show the changes characteristic of the various phases of the cycle. Estrogens are used to inhibit growth of cancerous cells in cases of cancer of the prostate.

Progesterone is used in the preventive treatment of abortion and to produce progestational development of the endometrium.

In cases of amenorrhea if the endometrium has undergone estrogenic development, treatment with progesterone (5 mg. daily for 5 to 6 days) will provoke menstruation within 4 days after the end of the treatment. If the endometrium is atrophic, gonadotrophins are given in order to stimulate the ovaries.

Androgens have been used in the treatment of hypermenorrhea and painful mastitis, but they should be used with caution as they have a masculinizing effect (growth of beard and body hair, acne, development of the clitoris, etc.).

Cancerigenic effects of estrogens. Estrogens are growth factors, therefore they can provoke the development of tumors in tissues that are sensitive to their morphogenic effect if hereditary factors and acquired conditions necessary for tumoral growth are also present.

Certain strains of mice have a high incidence of breast tumors. Castration prevents the development of these tumors (Loeb). In other especially bred strains, castration provokes the development of estrogenic corticoadrenal tumors, and in some cases tumors in the mammary gland. Certain strains have a high incidence of mammary tumors in the females, but not in males; tumors can be developed in the males of these strains by treatment with estrogens (Lacassagne). Large doses of estrogens given continuously for long periods to mice and guinea pigs cause the appearance of cancer in the uterus (Riesco). Prolonged administration of small doses of estrogens provokes the formation of fibrous tumors and subperitoneal fibromyomas in guinea pigs (Lipschütz *et al.*). Reports have been published of cases in which prolonged treatment with large doses of estrogens has been considered as an accessory factor in the development of tumors of the uterus and breast. On the other hand, it is worthy of note that some cancerigenic substances have estrogenic activity.

CHAPTER 60

The Endocrine Function of the Testes

The TESTES HAVE two functions: they produce the male gametes, *i.e.*, spermatozoa, and they secrete a hormone that develops and maintains the genital and extragenital male secondary sexual characters. Male genital secondary sexual characters or organs are (*a*) the vectors of the gamete, *i.e.*, vas deferens and penis; (*b*) glands such as the prostate, seminal vesicles, and Cowper's and urethral glands, which add their secretions to the sperm. Extragenital male secondary sexual characters are all those morphologic, functional, and psychic traits which differentiate the male from the female. The most typical psychic male character is the libido, *i.e.*, the sexual impulse toward the female. The relation between the testes and virility and the consequences of castration have been known for many centuries.

Physiologic histology. The testes are made up of seminiferous tubules, in which the spermatozoa are formed, and of interstitial epithelial cells (Leydig cells), which secrete the male hormone (Fig. 281).

The seminiferous tubules are formed by several layers of cells surrounded by a thin connective-tissue membrane. The cells of the deeper layers (spermatogonia) divide and produce the more superficially placed spermatocytes of the first order. These on dividing produce spermatocytes of the second order, which by division give rise to spermatids. The latter do not divide but are converted into spermatozoa. Between the spermatogonia there are long columnar cells which emerge into the lumen of the seminiferous tubules. These are the Sertoli cells, on which the spermatozoa are inserted until they are ready to be released and ejaculated. Spermatogenesis (*i.e.*, the formation of spermatozoa) begins at puberty; it is provoked and maintained by the gametogenic (follicle-stimulating) hormone of the anterior hypophysis.

The interstitial, or Leydig, cells originate in the mesoderm. There are large numbers of these cells in the fourth month of fetal life. At birth they are less numerous, and they continue to decrease throughout childhood. At puberty they increase, and there is a more or less constant number during adult life, until they diminish in old age. These cells are typical epithelial cells with mitochondria, granules, rods, and pseudocrystals in the protoplasm and with a well-developed nucleus. They are situated around the blood vessels. In mammals development of the Leydig cells is stimulated by the interstitial-cell-stimulating (luteinizing) hormone of the anterior hypophysis.

ENDOCRINE REGULATION OF TESTICULAR FUNCTIONS

In man, the rat, and other animals the testes are in permanent activity and spermatogenesis is continuous. In other species there are seasonal changes; periods of sexual activity alternate with others of sexual rest, during which spermatogenesis ceases and the sexual characters retrogress. In man spermatogenesis diminishes gradually between the ages of fifty and seventy and may cease completely, but spermatogenetic activity has been reported even in extreme old age (ninety years).

The internal secretion of the testes is produced by the interstitial cells (Ancel and Bouin, 1903). If the vas deferens is tied, the seminal tubes de-

generate and only the Sertoli cells remain; the interstitial cells, on the contrary, are hypertrophied (Fig. 281*b*). The secondary sexual characters are not disturbed by this operation. The same result can be obtained by irradiating the testicles with a moderate dose of x-rays; however, large doses can cause atrophy of the interstitial cells and signs of castration appear. In certain individuals the testes do not descend into the scrotum, but remain in the abdomen or inguinal canal (cryptorchism). The seminal tubes of the undescended testicles are more or less atrophied, but usually the interstitial cells are well developed and the secondary sexual characters, including the sexual impulse, are normal. In some of these cases, however, the secretion of testicular hormone is deficient and castration cells are found in the anterior hypophysis. In man the relationship between the state of the Leydig cells and the development of secondary sexual characters has been well established.

a *b*

FIG. 281. Sections of rabbit's testes. *a*, normal adult, active spermatogenesis, few interstitial cells; *b*, several months after vasectomy, no spermatogenesis, only Sertoli cells, hypertrophy of interstitial cells.

Androgenic hormones stimulate spermatogenesis, and in hypophysectomized animals they prevent atrophy of the seminal ducts and maintain the production of sperm. Certain nonandrogenic hormones produce this same effect. These hormones should not be used for this purpose in human therapeutics, because they inhibit gonadotrophin secretion by the anterior hypophysis (as is shown by the decrease in the urinary excretion of gonadotrophin) and may thus eventually depress spermatogenesis.[1]

The development and maintenance of sexual functions depend principally on the continuous action of gonadotrophins secreted by the pars distalis of the hypophysis. In mammals the gametogenic (follicle-stimulating) hormone provokes the development of the seminal tubes and spermatogenesis even in immature or hypophysectomized animals, but it does not stimulate the interstitial cells or the development of secondary sexual characters. The interstitial-cell-stimulating (ICSH) or luteinizing (LH) hormone stimulates the development and secretion of the Leydig cells and therefore the development of secondary sexual characters, but it has no direct effect on the seminal tubes of immature animals. In hypophysectomized animals

[1] HELLER, C. G., and W. O. MADDOCK, *Vitamins & Hormones*, 5, 393, 1947; HELLER, C. G., *et al.*, *J. Clin. Investigation*, 30, 648, 1951.

this hormone acts indirectly on spermatogenesis by stimulating the secretion of androgenic hormones by the Leydig cells.

Simultaneous administration of gametogenic (FSH) and interstitial-cell-stimulating or luteinizing (ICSH or LH) hormones provokes intense spermatogenesis and stimulates the Leydig cells not only in normal animals but also in hypophysectomized ones. Luteotrophin (prolactin) has no appreciable effect on the testes of mammals, but in birds it causes involution of the testicles.

Functional
Psychic: Virility; Libido

Hypophysectomy provokes testicular atrophy. Spermatogenesis ceases in the seminal tubes owing to the lack of FSH, and no more spermatozoa are ejaculated (azoospermia). The interstitial cells also atrophy, owing to the lack of ICSH, and the secondary sexual characters retrogress. An excess of ICSH or of chorionic gonadotrophin stimulates the testes in immature animals, causing them to grow and, when undescended, to migrate into the scrotum (Engle). The prostate and seminal vesicles increase in size. In the adult the testicle does not increase in size, having reached the fullest possible development, but the Leydig cells are stimulated, and the hypersecretion of androgenic hormones thus provoked causes the prostate, seminal vesicles, and other secondary sexual characters to grow.

The testes control and moderate the sexual function of the anterior hypophysis. Castration is followed by an increase in the gonadotrophin content of the hypophysis; there is also an increase in its secretion. The injection of androgens prevents hyperfunction of the anterior hypophysis and the appearance of the castration cells in the pars distalis. Prolonged treatment with large doses of androgens may inhibit gonadotrophin secretion sufficiently to provoke testicular or ovarian atrophy. Estrogens are much more efficacious than androgens as inhibitors of the anterior hypophysis.

A normal rate of thyroid secretion is necessary for the normal gonadotrophin secretion. Thyroidectomy is followed by a decrease in this secretion and subsequently by testicular atrophy. Severe hyperthyroidism also disturbs gonadotrophin secretion and indirectly the functions of the testes.

Several factors modify the structure and functions of the testes by acting on the hypophysis. Darkness and confinement cause testicular atrophy in some species. Intense illumination, on the contrary, provokes growth of the testes and secondary sexual characters in hibernating animals such as the ferret and in ducks.[1]

Deficiency of vitamin E and, sometimes, of other vitamins (A, B_1) provokes atrophy of the seminal tubes and Leydig cells, which becomes irreversible if the deficiency is severe. Prolonged undernourishment depresses testicular functions, and the same effect is produced by alcoholic excess. Testicular atrophy has been observed in animals fed on diets deficient in manganese. Hepatic lesions and the loss of bile through a fistula also cause testicular atrophy.

If the testes remain in the abdominal cavity without descending into the scrotum (cryptorchism) or if they are experimentally transplanted into the abdomen, the seminal tubes degenerate and spermatogenesis ceases. This has been attributed to the high temperature in the abdominal cavity. Sensitiveness of the testes to heat has been demonstrated by warming the scrotum, a procedure which causes degenerative changes in the seminal tubes. Patients with high and prolonged fever also show disturbances in spermatogenesis. These facts indicate that the

[1] In ducks irritation of the eyes has the same effect.

lodging of the testes in the scrotum outside the abdomen assures a lower and more suitable temperature for normal spermatogenesis than the higher intra-abdominal temperature.

The removal of one testicle and a large part of the other is not followed by signs of castration if a sufficient amount of interstitial cells remains. In animal experiments a residue of only 2 per cent of the whole testicular weight has been found to be sufficient. The Leydig cells of the remaining tissue undergo compensatory hypertrophy if the hypophysis functions normally, but not if there is hypophyseal insufficiency, unless gonadotrophins are injected.

Castration. The removal of the testes (castration) has been practiced since prehistoric times in order to tame animals or to improve their meat by softening and fattening. In man castration has been practiced by certain religious sects and to obtain eunuchs to serve as custodians of harems or male singers with treble voices. Castration is sometimes the consequence of trauma, and it has been performed in cases of testicular tumors and in order to retard the evolution of cancer of the prostate.[1] In some countries castration has also been legally performed with the object of preventing procreation by persons with hereditary diseases.

Prepuberal castration causes much more severe disturbances than castration in adults. Most of the secondary sexual characters do not develop, while in adults some of the sexual characters do not retrogress after castration and others undergo only an incomplete retrogression. Total castration produces a condition called eunuchism; the condition caused by testicular insufficiency is known as eunuchoidism. Persistence of prepuberal forms in adults who have been castrated in childhood is called sexual infantilism.

Persons castrated in adult life are of normal height. Prepuberal castrates[2] are usually tall; their height is definitely above the average (Fig. 282). They have long limbs and therefore a remarkably wide span. The width at the shoulders is less than normal. They have a narrow chest; on the other hand, the pelvis is wider than in females, and they have broad hips. The cranium is small, the face is broad, and the nose is usually not prominent. The abnormal height and length of limbs are due to persistence of activity in the epiphyseal cartilages beyond the age at which it usually has ceased.

The genital organs do not develop after prepuberal castration, and there is no libido. Castration in adults is seldom followed by a decrease in the size of the penis; the prostate and seminal vesicles are atrophied. The libido and erections persist in many subjects, especially if castration has taken place late in life. Copulation, with orgasm and ejaculation of fluid from the seminal vesicles and prostate but without spermatozoa, has been reported in men 10 to 25 years after castration.

Prepuberal castrates have no beard or mustache. Hair does not grow in the axilla, and the pubic hairs are scarce and have a feminine distribution. The hair on the head is usually abundant, fine, and straight. In adult castrates, the beard and mustache frequently continue to grow.

The skin of young castrates is at first fine and soft like the skin of children. Later it becomes sallow (an effect of carotenoids) and finely wrinkled and takes on a senile aspect. Seborrhea and acne do not occur in castrates. In many cases fat is deposited, especially on the hips and buttocks and in the mammary region.

The muscles are poorly developed and soft, and the subjects are easily fatigued. The larynx does not develop after prepuberal castration, and castrates retain all their life the treble voice of childhood, with something of falsetto. The voice does not change after castration in adults.

The urine of normal men contains androgenic substances (17 to 122 IU per day, with an average of 70 IU); in women the urinary elimination of androgens is approximately 70 per cent that of men.[1] There is also urinary elimination of 17-ketosteroids. The amount excreted by normal young men and women varies over a wide range and there is considerable overlapping in the values found in the two sexes. In men the majority of mean values reported lie between 12.5 and 16.7 mg. per 24 hr., with a lower limit of 6 mg. and an upper limit of about 25 mg. The range of mean values for women is approximately 7 to 12 mg. per 24 hr., with a lower

[2] Tandler, J., and S. Grosz, "Die biologischen Grundlagen der sekundären Geschlechtscharacter," Springer, Berlin, 1913; Pittard, E., "La Castration chez l'homme," Masson et Cie, Paris, 1934; Hamilton, J. B., *J. A. M A.*, **146**, 1903, 1941.

[1] Hamburger, C., *et al.*, *Acta pharmacol. et toxicol.*, **1**, 129, 1945; Heller and Maddock, *loc. cit.*; Schon, H. I., *Acta endocrinol.*, **8**, 149, 1951.

limit of 3 mg. and an upper limit of about 22 mg.[1] In childhood smaller amounts are excreted; at the age of puberty there is a sudden increase, and a maximum is reached between the twentieth and twenty-fifth year; in old age excretion of these substances diminishes. Approximately five-eighths of the 17-ketosteroids excreted is produced by the adrenal cortex and the rest in the gonads. Androgen and 17-ketosteroid excretion diminishes after castration or adrenalectomy, but these substances are found in the urine of castrated adrenalectomized monkeys; therefore there must be some other source besides the adrenal cortex and the gonads. In cases of corticoadrenal and testicular hyperfunction (tumors with endocrine activity), large quantities of these substances are excreted in the urine. Injection of gonadotrophins, adrenocorticotrophin, androgens, or corticoadrenal hormones is also followed by increased elimination of these substances (see Chap. 54).

Creatine is sometimes found in the urine of castrates, and if creatine is given to them, they retain less than normal subjects.

a b c
FIG. 282. Eunuchism. *a*, eunuch, twenty-four years old, castrated when five years old; height, 1.84 m.; long limbs, broad hips, no beard, feminine distribution of pubic hair. *b*, eunuchoid, twenty-six years old, no beard, fat on chest and hips. *c*, skeleton of eunuchoid, long limbs, epiphyseal cartilages not calcified.

The BMR is often subnormal in castrates, and the arterial blood pressure is low. In a few individuals vasomotor crises with sweating (hot flashes) have been observed. The thymus is usually enlarged.

The life span is apparently not shortened by castration, and in spite of the wrinkled aspect of the skin, there are no definite proofs that castrates suffer from premature senility.

Castration may provoke psychic disturbances owing to difficulties in social adjustment. Castrates are frequently timid and pacific, sober,

[1] MASON, H. L., and W. W. ENGSTROM, *Physiol. Rev.*, 30, 321, 1950.

honest, and hard-working, a fact that has been observed in the Skopzy, a religious sect in southern Russia and Rumania which practiced castration.[1] Intellectual development is not disturbed by castration, and some castrates are remarkably intelligent and of outstanding intellectual achievement.

Stimulation of the development of sexual characters. Deficiency in male secondary sexual characters can be corrected by (*a*) administration of interstitial-cell-stimulating (ICSH), or chorionic, gonadotrophin if there are Leydig cells capable of response (in castrates these substances have no effect); (*b*) administration of androgenic extracts or substances that have a direct peripheral action.

Symptoms of castration can be prevented from appearing, or they can be controlled, by (*a*) implantation of testicular tissue; (*b*) testicular grafts; (*c*) injection of testicular extracts; (*d*) injection of androgens. Subcutaneous or intramuscular implantation of testicular tissue or androgens produces effects during the time the active substances are being reabsorbed. Testicular grafts[2] do not take as easily as ovarian grafts. Successful grafting is followed by complete restitution of male characters in the castrated cock, rat, guinea pig, and other animals; in man usually only transitory effects have been observed. The method most frequently used in man is the administration of androgens, *e.g.*, testosterone and methyltestosterone.

Male hormones. Masculinizing or virilizing hormones are called androgens. The following are the principal androgens extracted from animal tissues or fluids: (*a*) *androsterone*, extracted from urine by Butenandt (1931–1932) and prepared synthetically by Ruzicka (1934); (*b*) *testosterone*, extracted from the testicle by David and Laqueur (1934), which is 7 to 10 times as active as androsterone; (*c*) *dehydroisoandrosterone*, found in the urine. The testes also contain Δ^5 pregneninolone, which is not androgenic but acts on spermatogenesis. Virilizing substances are also produced by (*a*) the adrenal cortex, from which *adrenosterone* and other androgenic steroids have been extracted (Fig. 252); (*b*) arrhenoblastomas of the ovary (Fig. 263). The nature of the active substances secreted by the ovarian tumors is not yet known. Several derivatives of natural androgens have been prepared by synthesis; one of the most frequently used in therapeutics is methyltestosterone, which is active by mouth. Natural androgens are rapidly inactivated mainly in the liver when given by mouth.

Testosterone

Androsterone

Dehydroisoandrosterone

Adrenosterone

[1] Koch, W., "Ueber die Russisch-Rumanische Kastraten Sekte der Skopzen," Carl Fischer, Jena, 1921.

[2] Berthold, 1849; Pézard, 1911; Steinach, 1912; Harms, 1914; Thorek, 1922; Lipschütz, 1924; etc.

Testosterone and other steroids (Δ_4 androstene-3,17-dione, 17-ketocholesterol) have been found in the blood of the testicular vein of the dog.[1]

The potency of androgens is expressed in international units; 1 IU is the specific activity of 0.1 mg. standard androsterone. This activity is measured by (*a*) the growth of the capon's comb; (*b*) prevention or control of atrophy of the prostate and seminal vesicles in rodents, estimated by the weight or the histologic aspect of these organs; (*c*) in guinea pigs, restoration of the capacity to ejaculate upon electrical stimulation of the nerve centers (in normal males, such stimulation provokes ejaculation of about 2 cc. of sperm which forms a clot; in castrates there is little or no secretion and it does not clot); (*d*) survival of spermatozoa in the testes of hypophysectomized rats or in the epididymis of castrated ones. There are other methods of estimating androgenic activity, but the most frequently used are (*a*) and (*b*).

Testicular hormones have sexual and general effects. The sexual effect consists in the development and maintenance of male genital and extragenital secondary sexual characters. In several species these hormones stimulate spermatogenesis even after hypophysectomy, but in man testosterone treatment diminishes spermatogenesis. The action of androgens secreted by the testes in this respect is not well known.

Male hormones produce important general metabolic effects. Nitrogen retention is increased and a positive nitrogen balance is established.[2] Phosphorus, potassium, sodium, sulfur, and other elements utilized for the formation of tissue are also retained. Muscular development is stimulated by male hormones, especially by testosterone propionate. The latter is used in cases in which nitrogen retention and the formation of cellular proteins are desired, or in which there is excessive nitrogen catabolism. Thus creatinuria is diminished or suppressed by testosterone.[3]

The sexual effect of androgens can be demonstrated (*a*) in the fetus, by stimulation of the development of male characters in male and female fetuses, in some cases provoking intersexuality (Chap. 57); (*b*) in infantile animals, in which precocious puberty is provoked; (*c*) in women, in whom male characters develop, such as growth of hair on face (beard) and body, lowering of the voice pitch, growth of the clitoris, suppression of menstruation,[1] decrease in milk secretion, acne, etc. (when the treatment is discontinued some of these changes retrogress); (*d*) in male castrates, in which the symptoms of testicular insufficiency are controlled; (*e*) in men, by general metabolic effects and stimulation of male characters.

Androgens given in adolescence at first increase growth in height, but ossification of the epiphyseal cartilages is completed prematurely and the subjects are not above normal height. Treatment at this age causes the penis, prostate, and seminal vesicles to develop more rapidly. If the testes were undescended they migrate into the scrotum, which grows and becomes pigmented. The beard, axillary, pubic, and body hair grow and have the aspect of the adult male. The skin thickens, seborrhea and acne occur, and frequently there is loss of hair on the head. The larynx grows and the register of the voice is lowered. The muscles develop and increase in strength and in resistance to fatigue. Libido, erection, and copulatory reflexes are established. The effects of castration on the anterior hypophysis are prevented or suppressed by androgens, which also virilize the adrenal cortex and diminish the size of the thymus. In the urine, androgens and 17-ketosteroids increase and gonadotrophins diminish if they had been previously increased by castration. (See Chap. 57 for the bisexual effects of androgens, and their antagonistic and synergic action with female hormones.)

Estrogens have been extracted from the testes of horses, pigs, and men. Estrone and estradiol are excreted in the urine of horses and men; they diminish after castration.

McCullagh, Martins, and Rocha postulated the existence of a testicular hormone that inhibited gonadotrophin secretion and prevented the appearance of the histologic changes in the anterior hypophysis following castration. This hypothetical hormone, called "inhibin," has never been identified. On the other hand, the prevention of castration changes in the hypophysis by testosterone has been demonstrated. There is experimental evidence which shows that the small amount of estrogen found in the testicle may be

[1] West, C. D., *et al.*, *Endocrinology*, **12**, 915, 1952.

[3] Methyltestosterone increases creatinuria.

[1] Hens cease laying eggs.

responsible for the prevention of the changes in the hypophysis following castration. Observations on pathologic conditions in man and animals suggest that the Sertoli cells may secrete estrogens. These cells are homologous to the granulosa cells of the ovary. Sertoli-cell tumors with feminizing activity have been found in dogs. Sertoli cells do not usually inhibit the hypophysis (Heller), but occasionally they may have an inhibitory effect (del Castillo *et al.*). The Leydig cells, however, seem to be the main source of estrogens in males (Maddock and Nelson).

Functional exploration of the testes. The functional condition of the testes can be determined by the following procedures: (*a*) examination of the development of male secondary sexual characters; (*b*) examination of the sperm, counting the spermatozoa and noting their motility; (*c*) biopsy and histological examination of small fragments of testis; (*d*) estimation of the gonadotrophin and 17-ketosteroids excreted in the urine.

TESTICULAR INSUFFICIENCY

Testicular insufficiency can be due to (*a*) primary disturbances or lesions in the testes; (*b*) disturbances in the anterior hypophysis which cause secondary testicular insufficiency. In both types of cases the age of onset is of importance, and the effects differ according to whether the disturbance began in childhood (prepuberal) or in the adult (postpuberal).

Primary testicular insufficiency. This may be either total or partial.

Total primary insufficiency is caused by traumatic or surgical castration (eunuchism), congenital absence of the testes (anorchism), the destruction of the testes by tumors or infections, etc. It is also observed in cases of so-called "male climacteric." In all these conditions the endocrine and spermatogenetic functions are diminished or absent. Urinary excretion of follicle-stimulating (gametogenic) gonadotrophin is increased; that of 17-ketosteroids is slightly diminished and does not increase after gonadotrophin injection.

Partial primary testicular insufficiency may involve either the seminal tubes or the interstitial cells.

Seminal insufficiency occurs in several forms:

1. Klinefelter's syndrome,[1] which begins at puberty. There is hyalinization of the seminiferous tubules; therefore spermatozoa are not formed (azoospermia). The Leydig cells are normal, and the secondary sexual characters may develop normally, but in some cases they are definitely subnormal. Gynecomastia, due mainly to proliferation of periductal connective tissue but also to growth of the ducts, occurs. The urinary excretion of gonadotrophin is increased as in castrates.
2. Seminal insufficiency in which spermatogenesis is not completed; there is therefore azoospermia. The secondary sexual characters are normal.
3. Cryptorchism, *i.e.*, undescended testes, in which the interstitial cells are well developed but there is no seminal tissue.
4. Sertoli-cell syndrome (del Castillo *et al.*),[1] in which the testes are slightly smaller than normal and there are no seminiferous cells, but the Sertoli cells are normal. The Leydig cells, the secondary sexual characters, and urinary excretion of 17-ketosteroids are normal. Urinary excretion of gonadotrophin may be normal, but it is usually increased (Nelson).

No cases have been reported of Leydig-cell atrophy with normal seminiferous tubules.

Secondary testicular insufficiency. Several forms due to hypophyseal insufficiency have been described; in all of them the Leydig cells and seminiferous tubules are atrophied: (*a*) total anterior hypophyseal insufficiency due to destruction of the anterior hypophysis by tumors such as craniopharyngiomas, by suprachiasmatic arachnoiditis, by trauma, etc.; (*b*) eunuchoidism, due to selective insufficiency of gonadotrophin secretion; (*c*) inhibition of the hypophysis by estrogens, in which case the testes are atrophied and the urinary excretion of gonadotrophins diminishes. In all these cases the urinary excretion of gonadotrophin and 17-ketosteroids is below normal. The administration of gonadotrophins increases excretion of 17-ketosteroids.

Testosterone treatment is given in cases of primary insufficiency due to castration. In man the most commonly used methods of administering this treatment are (*a*) subcutaneous injection of testosterone propionate (25 mg. two to five times per week); (*b*) oral administration of methyltestosterone (25 to 100 mg. per

[1] Klinefelter, H. F., E. C. Reifenstein, and F. Albright, *J. Clin. Endocrinol.*, **2**, 615, 1942.

[1] Del Castillo, E. B., A. Trabucco, and F. A. de la Balze, *J. Clin. Endocrinol.*, **7**, 493, 1947.

day). Other methods are used less frequently: (*a*) subcutaneous implantation of testosterone pellets (five pellets of 200 mg. produce effects that last several months); (*b*) sublingual absorption of testosterone (5 mg. dissolved in 0.2 cc. propylene glycol); (*c*) cutaneous absorption of testosterone applied in ointments.

Testosterone rapidly inhibits spermatogenesis. Prolonged treatment (25 mg. daily for 24 to 100 days) in normal men provoked first a decrease of spermatozoa, then azoospermia, with marked histologic lesions in the testes. There was no urinary excretion of gonadotrophins. When the treatment was discontinued, there was some improvement after 6 months and complete recovery in 17 months (Heller *et al.*). In some cases of hypogonadism, after the initial depression produced by testosterone, an increase in spermatogenesis above the primitive level has been observed (Heckel, Heller, *et al.*).

TESTICULAR HYPERFUNCTION

Injection of androgens, or of gonadotrophin if the testes are in condition to respond, provokes abnormally large development of some of the secondary sexual characters, *e.g.*, the prostate and seminal vesicles in rodents and the comb in cocks. These effects are not always sustained, and in some cases the organs retrogress after having been stimulated.

Several types of precocious puberty have been described in man.

1. Precocious puberty with premature hyperfunction of the Leydig cells.
2. Hyperplasia or tumors of Leydig cells (adenoma or carcinoma), with precocious puberty. The first case, described by Sacchi (1895), was that of a child of nine years with a tumor in the left testicle. The patient's growth was accelerated and he rapidly reached a height of 1.43 cm. The beard grew, the voice became low, and there were erections and ejaculations. After the tumor was removed the erections ceased, the beard was lost, and the voice regained the infantile treble. Eight similar cases have been reported.[1]
3. Constitutional syndrome of hypermasculinization, so called when the cause of the symptoms is unknown.
4. Tumors or lesions of the hypothalamus, hydrocephalus of the third ventricle, and tumors of the epiphysis and the neighboring structures.

[1] Sandblom, P., *Acta endocrinol.*, **1**, 107, 1948.

Rejuvenation. Methods for increasing sexual vigor, muscular strength, and intellectual alertness in old age are announced from time to time. After critical consideration of the results obtained, it is seen that they consist in transitory sexual stimulation, due largely to psychic causes (suggestion). The following methods of rejuvenation or sexual reactivation have been proposed: (*a*) injection of testicular extract (Brown-Séquard, 1889); (*b*) ligature of the vas deferens (Steinach, 1920), which produces atrophy of the seminiferous tubules and proliferation of the interstitial cells; (*c*) testicular grafts;[1] (*d*) testicular denervation (Dopler); (*e*) injection of blood taken from the testicular veins or of blood from young subjects; (*f*) implantation of monkey's testicle (Voronoff), which acts transitorily while active substances in the tissues are being reabsorbed.

CHAPTER 61

Fertilization. Pregnancy. The Physiology of the Fetus. Parturition

FERTILIZATION

Fertilization consists in the union of the spermatozoon and ovum. The optimum period for fertilization occurs in women around the middle of the menstrual cycle, when ovulation takes place. Normally sperm is deposited in the vagina by the erect penis, but artificial insemination, depositing the sperm in the uterine cavity by means of a catheter, has been performed successfully.

Erection. In mammals fertilization occurs within the body of the female (internal fertilization). Copulation is preceded by erection. The penis lengthens and hardens and from a flaccid, pendant structure is converted to a rigid and erect organ. These changes are due to the accumulation of blood in the erectile tissues of the penis, *i.e.*, the two corpora cavernosa penis and the corpus cavernosum urethrae, which expands into the glans. If an erect penis is tied at the base it remains erect until the ligature is removed; when the blood can flow out the penis becomes flaccid. Distention of the erectile tissue is due to dilatation of the afferent arteries; it is not produced by ligature of the veins of the penis. Vasodilatation during erection is demonstrated as follows: (*a*) if the corpora cavernosa are cut in the dog and the nervus erigens (formed by the first two or three sacral rami) is stimulated, blood flows from the wound in large quantities while the nerve is stimulated, and the flow diminishes considerably when stimulation ceases; (*b*) venous blood flow increases 10 to 15 times when stimulation of the nervus erigens is discontinued, *i.e.*, when erection retrogresses; (*c*) the blood pressure falls in the arteries and rises in the veins of the penis during erection; (*d*) plethysmography of the penis shows dilatation.

Erection is therefore primarily due to vasodilatation reflexly stimulated by cholinergic fibers of the parasympathetic. The most frequent stimuli that cause erection are cutaneous stimuli, especially those applied to the genital region and, more particularly, on the mucosa of the glans. Friction of the penis produces first erection and then ejaculation. Other cutaneous stimuli and visual and olfactory stimuli can also produce erection if they have been associated with the sexual impulse; psychic representation of appropriate stimuli is sufficient to provoke erection. Certain stimuli inhibit erection. A frequent cause of this inhibition is emotional stress, and many cases of impotence in young persons are exclusively due to psychic inhibition.

The centripetal path of reflex erection initiated in the penis goes along the dorsal nerve of the penis, a branch of the internal pudendal nerve. Section of this nerve prevents erection in some animals, *e.g.*, the horse, even when there is intense sexual excitement. The centrifugal path lies in the nervus erigens; the fibers afterward travel in the internal pudendal nerve. Stimulation of these fibers provokes erection, but not in castrates. In man fibers from the second to fourth sacral nerves conduct impulses which provoke erection. Extirpation of the thoracic sympathetic produces disturbances in erection in 57 per cent of the cases (Whitelaw *et al.*).

Ejaculation. Spermatozoa are being formed continuously. They are carried along the genital ducts by the cilia of the epithelia lining the

epididymis and the vas deferens and by their own motility. Thus they advance 5 to 7 m. and are deposited in the ampulla of the vas deferens. The seminal vesicles are not reservoirs for spermatozoa, although in some species spermatozoa may be found in them; they are glands which, together with the prostate, Cowper's glands, and the epithelia of the genital ducts, secrete a fluid that forms a substantial part of the ejaculate.

In the process of ejaculation, contractions of the vas deferens empty the sperm through the ejaculatory ducts into the urethra by two orifices situated on each side of the verumontanum. Simultaneously the seminal vesicles, Cowper's glands, and the prostate pour out their secretions into the urethra. The verumontanum becomes turgid and the sphincter vesicae contracts, preventing the flow of sperm into the bladder. Seminal fluid is not immediately expelled from the urethra, but accumulates in the membranous segment of the urethra between the verumontanum and the sphincter urethrae, which is contracted, damming up the fluid coming into the urethra under pressure, due to the contraction of the smooth-muscle fibers of the vas deferens, seminal vesicles, and prostate. The sphincter urethrae suddenly relaxes and the bulbocavernosus and ischiocavernosus muscles and the levator ani contract rhythmically, alternating with the contraction and relaxation of the sphincter urethrae. Thus seminal fluid is ejected intermittently into the vagina.

Ejaculation is a reflex phenomenon. The main impulses arise in the glans and in the urethral mucosa. The ejaculatory center is situated in the spinal cord at the level of the fourth and fifth lumbar segments in the rabbit, slightly cephalic to the center for erection. Efferent fibers leave the upper lumbar segments and form part of the adrenergic lumbar sympathetic; these fibers provoke contraction of the vas deferens and the seminal vesicles. Other fibers, arising in the third and fourth sacral segments, travel along the internal pudendal nerves to the ischiocavernosus and bulbocavernosus muscles and the sphincter urethrae. Ejaculation does not take place if the parasympathetic (sacral) fibers are destroyed. Emission of sperm is suppressed by destruction of sympathetic (lumbar) fibers; sometimes the sperm is sent into the bladder instead of being evacuated through the meatus. Removal of the lumbar sympathetic below the twelfth dorsal segment produces disturbances in ejaculation (Whitelaw).

Erection normally precedes ejaculation, but emission of seminal fluid occasionally takes place without erection. In the guinea pig ejaculation can be provoked by stimulation of the hypogastric plexus or the inferior mesenteric ganglion, which causes contraction of the vas deferens and seminal vesicles; also by electrical stimulation of the brain. Asphyxia provokes ejaculation in several species, particularly in rodents.

Ejaculation is accompanied by sensations and motor phenomena which constitute the orgasm. It is followed by muscular relaxation; the erectile organs become flaccid, and often there is a sensation of fatigue.

The amount of seminal fluid emitted at each ejaculation varies from 2 to 5 (average 3.2 cc.), with 40 to 300 million spermatozoa per cubic centimeter (average 90 million).[1] The quantity of seminal fluid ejaculated is closely related to frequency of copulation, diminishing as frequency increases.

Normal forms are found in 60 to 100 per cent of spermatozoa (average 82 per cent in 100 fertile men). Motility is seen in 40 to 90 per cent (average 61 per cent). Minimum conditions for fertility are: 2 cc. of sperm with 20,000,000 spermatozoa per cubic centimeter; 40 per cent with motility 3 of the Hotchkiss-MacLeod scale; normal forms in 60 per cent (MacLeod and Gold). Motility is the characteristic most closely related to fertility.

Chemical analysis of sperm[2] has shown it contains relatively large amounts of fructose (200 to 800 mg. per 100 cc.); choline, phosphocholine, citric acid, and acid phosphatase have also been found. Fructose and choline come from the seminal vesicles; acid phosphatase and citric acid come from the prostate. These substances diminish after castration, and increase during treatment with androgens.

Ejaculated seminal fluid clots in many animals, especially in rodents. The semen of guinea pigs and rats clots and forms the vaginal plug. This plug is supposed to prevent the escape of sperm from the

[1] MacLeod, J., *Ann. Rev. Physiol.*, **5**, 399, 1943; "Proceedings of the Conference on Diagnosis of Sterility," Charles C Thomas, Springfield, Ill., 1946.

[2] Mann, T., and C. Lutvak-Mann, *Physiol. Rev.*, **31**, 27, 1951; Lunquist, F., *Acta physiol. Scandinav.*, **19**, Suppl. 66, 1949.

vagina, or to stimulate the cervix and retard the involution of the corpora lutea (pseudopregnancy). It is formed by clotting of the fluid of the seminal vesicles brought about by the secretion of the prostate (guinea pig) or the coagulating glands (rat). A drop of this secretion can coagulate a large amount of the fluid of the seminal vesicles. Later the clot retracts and a clear serum separates. The coagulating ferment has been called vesiculase (Camus and Gley, 1896).

Accessory genital glands. The seminal vesicles add their fluid to the sperm in the process of ejaculation. Extirpation of these organs does not prevent normal copulation, but it diminishes fertility. Removal of the abdominal sympathetic nerve chains prevents evacuation of the seminal vesicles and prostate and in some species causes sterility.

The prostate also adds its secretion to the sperm.[1] After the age of forty it frequently increases in size, and it has been found hypertrophied in 30 to 50 per cent of men above the age of fifty-five. Hypertrophy involves not only the prostate but also other structures such as the periurethral glands. The enlarged prostate is usually an obstacle to the normal evacuation of the bladder and in some cases has to be removed in order to prevent urinary retention.

The prostate has been supposed to have endocrine functions essential for reproduction or to maintain the vitality of the sperm. This internal secretion has never been satisfactorily demonstrated. Moreover the prostate has been removed in animals and man without diminishing *potentia coeundi* (*i.e.*, copulatory capacity) or causing any disturbance in the sexual characters. *Potentia generandi* (*i.e.*, fertility) is sometimes impaired, probably owing to mechanical obstacles to the emission of sperm created by prostatectomy, but it is doubtful whether the absence of prostatic secretion plays a part in this. Prostatic fluid or extracts have several properties such as producing a fall in blood pressure when injected, or provoking contraction in the isolated intestine or uterus.[2] There is no proof that the substances that have these effects are secreted into the blood or have any importance in physiologic processes.

The development of the prostate is governed by testicular hormones. Prepuberal castration

[1] Huggins, C., *Physiol. Rev.*, **25**, 281, 1945; *Harvey Lect.*, **42**, 148, 1947.
[2] Euler, U. S. von, *Skandinav. Arch. f. Physiol.*, **81**, 65, 1935.

causes atrophy of the prostate. The hypertrophied prostate of older subjects also diminishes in size after castration. Testosterone treatment causes prostatic growth and hypertrophy, especially if administered before puberty. Cancer of the prostate is stimulated by androgens; on the other hand its development is retarded, and the tumor may decrease in size, after castration or injection of estrogens.[1] Castration and estrogen treatment have been applied successfully in order to alleviate pain and prolong life in cases of cancer of the prostate. Adrenalectomy has also been performed in some cases in order to suppress an additional source of androgens.

Pilocarpine stimulates and atropine inhibits the secretion of prostatic fluid. Stimulation of the hypogastric nerves provokes secretion of prostatic fluid and contraction of the muscle fibers of the prostate. Stimulation of the pelvic nerves contracts prostatic muscles but has little effect on the emission of prostatic fluid.[2] The secretory innervation of the prostate seems to be provided by sympathetic cholinergic fibers similar to those which stimulate the sweat glands. The prostate contains acid phosphatase, which increases in the blood of patients with cancer of the prostate.

Excitability and contractility of the smooth muscles of the vas deferens, seminal vesicles, and prostate are diminished by testosterone and increased by estrogens (Martins, Valle, and Porto).

Copulation in the female. The erect penis is introduced into the vagina, and there it ejaculates the seminal fluid. Sexual excitement during copulation causes erection of the corpora cavernosa of the clitoris and the bulbus vaginae, which are distended with blood. The clitoris does not rise in the process of erection; its extremity curves downward and is applied on the dorsal aspect of the penis. The bulbus vaginae is in part surrounded by the constrictor muscle of the vagina; rhythmic contractions of this muscle and turgescence of the bulbus vaginae tend to narrow the vulvar orifice of the vagina and close it on the penis. The bulbocavernous muscle and the levator ani also take part in producing this effect. Rhythmic movements of the pelvis frequently occur. In some animals the uterus and the os contract and relax

[1] Huggins, C., *Cancer Research*, **1**, 293, 1941; *Ann. Surg.* **115**, 1192, 1942.
[2] Farrel, J., *J. Urol.*, **39**, 171, 1938.

rhythmically during copulation. Orgasm is usually more prolonged in the female than in the male; it is accompanied by generalized motor activity and is followed by relaxation as in the male.

Erection of the clitoris does not always occur, or it may occur late in copulation. The female can be fertilized without having experienced erection or orgasm, as is demonstrated by the facts that an unconscious woman can be fertilized and that fertilization by artificial insemination can occur.

In the female, as in the male, the nervi erigentes are constituted by cholinergic parasympathetic fibers which arise in the first, second, and third sacral segments (in the dog).

The ducts of the glands of Bartholin open on each side of the vagina. During copulation these glands secrete a fluid that apparently serves to lubricate the penis and facilitate penetration.

PREGNANCY

Fertilization and nidation. Fertilization usually takes place in the fallopian tube. The head of one spermatozoon penetrates into the ovum, and there is fusion of the nuclei of the two gametes. The fertilized egg then divides, and the embryo is formed by the successive divisions of the egg. The ovum survives only 6 to 20 hr. after ovulation, and spermatozoa 30 to 48 hr. after ejaculation. The egg migrates down the fallopian tube and normally becomes implanted in the endometrium 6 or 7 days after fertilization.[1] The earliest human embryos that have been observed are one 4 days old, which had not yet been implanted, and one 7½ days old, already implanted (Rock and Hertig). In the process of nidation the embryo penetrates into the uterine mucosa (interstitial implantation). The trophoblast (the membrane covering the embryo) apparently releases a proteolytic enzyme that facilitates this process by destroying the adjacent mucosa.

Parthenogenetic division of the ovum has been provoked *in vitro* in the rabbit. If the ovum thus activated is placed in the uterus it can become implanted and develop into rabbits which are normally delivered (Pincus and Shapiro, 1940).

[1] Nidation occasionally occurs in the fallopian tubes, on the surface of the ovary, or in the abdominal cavity (ectopic pregnancy).

Fertilized eggs of one female have been transplanted into the uterus of another which had been prepared by hormonal treatment. The embryos developed to full term, in some cases even after several hours intervened between extraction and implantation of the egg. The fertilized ovum of man and the first stages of its development have been observed *in vitro* (Rock *et al.*, 1944).

It has been claimed that sperm must have a sufficient amount of hyaluronidase for the spermatozoa to penetrate into the ovum.

The duration of pregnancy. Pregnancy in women has a duration of approximately 280 days (40 weeks, *i.e.*, 9 months and 10 days) counting from the first day of the last menstruation.[1] Cases of normal babies born after a pregnancy of only 250 days or as long as 330 days have been reported. A pregnancy is considered abnormally prolonged, and the life of the fetus is in danger, when it lasts more than 300 days. In many species the duration of pregnancy is a multiple of the duration of the estral cycle.[2]

Changes in the uterus. The uterus grows considerably during pregnancy. The lumen of the virgin uterus has a capacity of 2 to 5 cc.; at full term this has increased to 5,000 or even 7,000 cc. The virgin uterus weighs 50 gm.; at the end of gestation it weighs approximately 1,000 gm. Uterine hypertrophy extends to all its parts and is especially marked in the myometrium. Each uterine muscle fiber increases to between 7 and 11 times its original length and 3 to 5 times its original transverse diameter. The number of uterine muscle fibers also increases (hyperplasia). Uterine hypertrophy is due to the action of estrogen[3] and to distention.[4]

Uterine contractility in the pregnant woman has been studied by registering pressure changes

[1] The average duration of pregnancy (in days) in different species is as follows: rat, 22; rabbit, 29 to 30; dog, 59 to 63; guinea pig, 60 to 66; cat, 63; sheep, 147 to 154; chimpanzee, 236; cow, 285; mare, 340; elephant, 660.

[2] Snyder, F. F., *Physiol. Rev.*, **180**, 578, 1938; Kenneth, J. H., "Gestation Periods," Oliver & Boyd, Edinburgh, 1943; Asdell, S. A., "Patterns of Mammalian Reproduction," Comstock Publishing Company, Inc., Ithaca, 1946.

[3] The stimulating action of estrogens is also seen during estrus in many animals and in female castrates treated with estrogens.

[4] Reynolds, S., *Physiol. Rev.*, **17**, 304, 1937; "Physiology of the Uterus," Hamilton, London, 1939.

in the amniotic fluid with a water manometer[1] (Fig. 283). During the first half of pregnancy there are continuous, small, rhythmic, regular, painless contractions which have been recorded from the second month. These contractions increase amniotic pressure by 1 to 7 cm. H_2O from a basal pressure of 4 to 11 cm. H_2O; their frequency is one to two per minute (Fig. 283*A*). Basal tonus has slow oscillations. Contractions of greater amplitude appear occasionally during the first months; they increase in frequency as pregnancy advances (Fig. 283*B*). During the last two weeks contractions increase in amplitude (Fig. 283*C*) and there is a gradual transition from the weak contractions of pregnancy to the strong contractions of labor.

The uterus becomes gradually more sensitive to the oxytocic effect of posterohypophyseal extracts. The increase in the excitability of the uterus toward the end of pregnancy can be demonstrated, not only in the uterus *in situ*, but also in the isolated surviving uterus.[2]

Three factors cause the increase in uterine excitability as pregnancy advances: (*a*) gradual increase in estrogens, which are uterine stimulants; (*b*) gradual decrease of progesterone, which inhibits the uterus; (*c*) distention of the uterus, which stimulates it. Adrenaline causes relaxation in the virgin uterus of certain animals, but on the contrary it provokes the contraction of the pregnant uterus. This inversion of the effect of adrenaline is due to the sensitizing effect of progesterone.
FIG. 283. Records of uterine contractions in pregnant women. *A*, 9 weeks; *B*, 7 months; *C*, 2 days before labor. (*Alvarez and Caldeyro-Barcia.*)

The uterine mucosa increases in thickness and vascularization during pregnancy. On the fifteenth day of pregnancy it is 0.5 cm. thick, and 0.7 cm. on the sixtieth day. The stroma cells are converted into large epithelioid cells, known as "decidual cells" because the uterine mucosa is shed after parturition and for this reason is called the *decidua*.

When the embryo penetrates into the endometrium a chamber lined by mucosa is formed. The mucosa that lines the uterine cavity outside the embryo is called the *parietal decidua* (*decidua vera*). The mucosa that covers the embryonic chamber and separates it from the lumen of the uterus is the *reflex decidua* (*decidua reflexa*). The embryo is separated from the uterine wall by the *basal decidua* (*decidua serotina* or *basalis*) (Fig. 284).

The parietal decidua is thick and well vascularized at the beginning of pregnancy, but

[1] ALVAREZ, H., and R. CALDEYRO-BARCIA, *Arch. urug. de ginecol. obst.*, **7**, 79, 1948; *Surg., Gynec. & Obst.*, **91**, 1, 1950.

[2] The human uterus is more sensitive to vasopressin than to oxytocin; the guinea pig uterus, on the contrary, is more sensitive to oxytocin (Scott, 1943).

from the fourth month on, it diminishes in thickness and at full term it is only 1 to 2 mm. thick. The reflex decidua also diminishes in thickness and by the sixth week only traces of it can be found; in the course of the fifth month its fusion with the parietal decidua is complete. The basal decidua takes part in the formation of the placenta.

The placenta. The placenta is the organ by means of which the fetus is nourished. It is formed of a maternal part (the basal decidua) and a fetal part (the chorionic villi). The fetal part of the placenta arises from the trophoblast, *i.e.*, the primitive membrane that surrounds the embryo. As the embryo develops, processes appear on the surface of the trophoblast which penetrate like fingers into the basal decidua. These processes are invaded by blood vessels and mesodermal tissue, and eventually they develop considerably, forming the chorionic villi. The villi grow into the vascular spaces of the basal decidua, and here again the cytolytic activity of the embryonic structures facilitates penetration into the maternal tissues. Fetal blood circulates through the villi, separated from the maternal blood by a double layer of epithelium—one layer of maternal, the other of fetal, origin. Later the two layers are fused into a single layer.[1] This epithelium is the barrier between the fetal and maternal circulations and the site of metabolic exchange between the mother and fetus. It is endowed with selective permeability.[2] Crystalloids pass through the membrane; colloids and small particles (bacteria, etc.) are retained. Oxygen, water, salts, foodstuffs, vitamins, and certain hormones pass into the fetus. CO_2 and waste products pass out from the fetus. Certain antibodies can also pass through the placenta into the fetus. The permeability of the placenta to radioactive sodium increases as pregnancy advances.[3]

The placenta is not only the site of exchange between the mother and fetus; it is also an endocrine gland, which produces hormones necessary for the continuance of pregnancy.

[1] The chorionic villi are lined by two layers; one layer is formed by the cells of Langhans, the other is a syncytium. The former gradually diminishes and in parts disappears completely.

MATERNAL CHANGES IN PREGNANCY

In the course of pregnancy many important changes take place in the maternal organism in order to adjust it to the needs created by the development of the fetus.[1] The fallopian tubes, uterus, and vagina hypertrophy under the influence of estrogens and progesterone; the mammary gland and the nipple also develop. Pigmentation appears on the skin of the face, the abdomen, and the areola around the nipple. The abdominal viscera are displaced, and the diaphragm is pushed upward. The veins of the lower limbs and pelvis dilate and, in some cases, become varicose (hemorrhoids).
FIG. 284. [1] HARDING, V. J., *Physiol. Rev.*, 5, 279, 1925; SEITZ, L., and R. T. JASCHKE, in Bethe's "Handbuch der normalen und pathologischen Physiologie," 14, 436 and 579, Springer, Berlin, 1926; VIGNES, H., in G. H. Roger and L. Binet, "Traité de physiologie normale et pathologique," vol. 11, Masson & Cie, Paris, 1934, p. 271.

An outstanding character of metabolism during pregnancy is the predominance of anabolic processes. Nitrogen, calcium, phosphorus, iron, water, and many other substances are retained by the maternal organism in order to provide the fetus with materials for building up its tissues. When considering the nutritional requirements of the human organism (Chap. 50), the increased needs of the pregnant and lactating woman were emphasized. Wherever there is the risk of nutritional deficiency, such as that of iodine in goitrous districts or that of vitamin D in northern industrial towns, care should be taken to provide sufficient amounts of the potentially deficient factor. It is necessary to bear in mind that intrauterine nutritive deficiency may produce irreversible unfavorable effects on the development of the fetus (*e.g.*, cretinism).

In the course of the last three months of pregnancy the maternal organism is submitted to considerable metabolic strain. During this period the fetus makes up 75 per cent of its protein, 93 per cent of its fat, 65 per cent of its Ca, 68 per cent of its P, 80 per cent of its iron, and 70 per cent of its weight at birth (Hugget, 1942).

The BMR of the mother increases toward the end of pregnancy. This increase is not due to an increase in maternal metabolic rate, but to the metabolism of the fetus. If the metabolisms of the mother and child are determined shortly after birth, it will be seen that the sum of both adds up to the figure found in the mother just before birth.

The alkali reserve diminishes in pregnancy. Blood and alveolar CO_2 tensions are below the normal, and there is marked hyperventilation. It is still unknown whether hyperventilation precedes or follows the decrease in the alkali reserve. This phenomenon has been called the "physiologic compensated acidosis of pregnancy," but the hydrogen ion concentration is always normal.

Liver glycogen falls more rapidly during fasting in pregnant animals than in nonpregnant ones. Blood fat is high, and total blood cholesterol (especially free cholesterol in plasma) rises, although in the erythrocytes it may fall. Creatinuria is often observed.

The minute output of the heart increases rapidly from the tenth week, reaching a maximum at the twenty-sixth to twenty-ninth week (30 per cent above the basal nonpregnant level); later it diminishes.[1] Extracellular fluids (blood plasma and tissue fluid) increase; therefore the circulating volume is also increased, and erythrocyte concentration diminished, especially toward the end of pregnancy. Neutrophil leukocytosis is often seen. The suspension stability of the red blood cells is considerably diminished; the erythrosedimentation rate is therefore increased (Fåhraeus). This is due to the increase in plasma globulins (see Chap. 3).

Toward the end of pregnancy, 35 to 60 per cent of women have slight glycosuria or lactosuria, which ceases soon after delivery.

Pregnant women retain water easily. Toward the end of pregnancy the urine should be periodically examined for the presence of albumin, the blood pressure should be determined, and the appearance of edema or a sudden increase in weight should be watched. These are premonitory symptoms of eclampsia, a convulsive condition with a serious prognosis, which can usually be avoided by an adequate diet and by restricting the intake of salt and water. Plasma clearance tests show that there is frequently some impairment of renal function during the last stages of pregnancy.

There is a considerable increase of histaminase in blood; apparently this enzyme is produced by the decidua. Oxytocinase also increases.

Hormonal changes in pregnancy. The anterior lobe of the hypophysis hypertrophies, and typical cells (pregnancy cells) appear. The gonadotrophin content of the gland diminishes considerably in pregnant women. The thyroid and the adrenal cortex increase in weight, and the thymus undergoes involution. The urine of pregnant women contains large quantities of estrogens, chorionic gonadotrophin, and pregnandiol.

These estrogens are mainly estriol and smaller amounts of estrone and estradiol bound to glycuronic acid. They play an important part in the processes of pregnancy by (*a*) stimulating the growth of the uterus and the rest of the genital tract; (*b*) sensitizing the myometrium to the effects of oxytocic agents; (*c*) prolonging the life of the corpus luteum and stimulating its secretion; (*d*) acting synergically with progesterone in the development of the endo-

[1] HAMILTON, H. F., *Edinburgh M. J.*, **57**, 1, 1950; "Toxemias of Pregnancy," Ciba Foundation Symposium, J. & A. Churchill, London, 1950, p. 135.

metrium; (*e*) stimulating growth of the mammary gland in preparation for lactation.

Chorionic gonadotrophin found in the urine of pregnant women is produced by the placenta. It increases considerably between the fortieth and eightieth day of pregnancy and then falls to a lower level, where it remains (Fig. 285). The part it plays in the adjustments of pregnancy is still unknown. Pregnandiol is a metabolic product of progesterone secreted by the corpus luteum of pregnancy and in part by the placenta.

The activity of the corpus luteum persists up to the fourth or fifth month of pregnancy, the corpus luteum then gradually undergoing involution. It secretes progesterone, which fulfills the following functions: (*a*) progestational development of the endometrium in the second half of the menstrual cycle, characterized by glandular development and secretion; (*b*) continuance of pregnancy by acting on the placenta; (*c*) inhibition of ovulation and menstrual cycles during pregnancy; (*d*) inhibition of the tonus of the uterus; (*e*) stimulation of alveolar development in the mammary gland after estrogens have stimulated mammary growth; (*f*) softening and relaxation of pelvic ligaments (see "Functions of the corpus luteum," Chap. 59).

Urinary excretion of corticosteroids increases during pregnancy. It shows two peaks, one around the eightieth day, the other around the two hundred twentieth day (Venning, 1946).

The placental hormones. The placenta produces estrogens, chorionic gonadotrophin, adrenocorticotrophin, and small amounts of progesterone.[1] It is the main source of estrogens in pregnancy, as shown by the fact that these substances continue to be produced at an increasing rate in pregnant women who have been castrated during the second or third month of pregnancy.
Fig. 285. Urinary excretion of hormones and chorionic gonadotrophin in blood during pregnancy. The peak of each curve corresponds approximately to the following figures: *G*, chorionic gonadotrophin, 500 IU/cc. of serum; *C*, corticosteroids, 200 glycogenic units; *P*, pregnandiol, 40 to 100 mg./day; *E*, estrogens, 15 to 45 mg./day (mostly estriol, 1 to 3 mg. of estrone). (*Data from Venning, Albert, etc.*)

The chorionic gonadotrophin in the urine of pregnant women differs from chorionic gonadotrophin found in the blood serum of pregnant mares. It differs also from anterior hypophyseal gonadotrophins; it is produced by the placenta, where it is found in large quantities, and it continues to be excreted in the urine after expulsion of the fetus if the placenta has been retained. In cases of placental tumors (hydatiform mole and chorioepithelioma) large amounts of gonadotrophins are eliminated in the urine. The gonadotrophin content of the hypophysis diminishes considerably in pregnant women, possibly owing to the great amount of estrogens poured into the circulation by the placenta.

Placental hormones maintain the activity of the corpus luteum. Collip, Selye, and Thomson showed that the corpora lutea persisted in rats after the fetuses were removed between the ninth and thirteenth day of pregnancy, if the placentas were left in the uterus. If the placentas were also removed, the corpora lutea retrogressed rapidly.

Progesterone has been extracted from the

[1] Newton, W. H., *Physiol. Rev.*, **18**, 419, 1938; Newton, W. H., in Allen, "Sex and Internal Secretions," Baillière, London, 1939, p. 720.

placenta, which seems to produce small amounts of this hormone. Ovariectomy causes abortion in rats owing to the suppression of the corpora lutea. If toward the middle of pregnancy the ovaries are extirpated and all the fetuses except one are removed, leaving all the placentas, the single remaining fetus is carried on to full term and is born normally, as if the placentas secreted progesterone (Haterius). In that case, the placentas are expelled from the uterus at the end of parturition, and after delivery milk is secreted normally.

THE PHYSIOLOGY OF THE FETUS[1]

Prenatal growth. The fertilized egg is approximately 0.2 mm. in diameter. It soon divides and the organism grows very rapidly during its embryonic and fetal life. The rate of growth is highest in the early stages and diminishes progressively up to the end of prenatal life.

The newborn child usually weighs from 3 to 3.5 kg. (6.6 to 7.7 lb.), smaller infants weighing as little as 2.4 kg. (5 lb.) and larger ones as much as 4.5 kg. (10 lb.); rarely even smaller or larger infants are born and survive. Males are on an average heavier (3.4 kg. = 7.4 lb.) than females (3.3 kg. = 7.2 lb.). The infant at birth measures 48 to 52 cm. (18 to 20 in.).

The fetal circulation. The circulation of blood in the fetus differs considerably from the circulation after birth. The differences are due mainly to the existence of the placental circuit and the absence of pulmonary respiration. Gaseous interchange in the fetus takes place through the placenta. The circulatory system of the fetus is a closed circuit, completely independent of the maternal circuit, and in no place or stage of development is there any mixture of maternal and fetal blood.

The fetal circulation has been studied *in vivo* in the lamb[2] by means of roentgencinematography after the injection of opaque substances. Oxygenated blood goes from the placenta to the fetus in the umbilical vein. On reaching the liver the greater part passes through the ductus venosus into the inferior vena cava; the rest is distributed in blood vessels of two-thirds of the liver (the other third receives blood from the portal vein). The blood leaving the liver passes through the suprahepatic veins into the inferior vena cava. The arterial blood from the placenta is therefore mixed with venous blood brought from the abdomen and lower limbs by the portal vein and the vena cava.

The blood from the inferior vena cava enters the right auricle, where it impinges on the eustachian valve (crista dividens) and is divided into two currents. The main current is directed through the foramen ovale of the interauricular septum into the left auricle. Here it is mixed with the small amount of blood coming from the pulmonary veins and passes into the left ventricle, from which it is pumped into the aorta. The aorta gives out the coronary arteries to the heart and the arteries going to the head, which thus receive blood with the highest oxygen partial pressure circulating in the fetus. This pressure is, however, lower than the oxygen pressure in arterial blood after birth. The aorta also gives out branches for the different viscera and ends in two large umbilical arteries which carry blood from the fetus to the placenta.

The smaller of the two currents in the right auricle is mixed with venous blood from the head and upper limbs brought by the superior vena cava and blood from the coronary sinus. It passes into the right ventricle and is driven into the pulmonary artery. The greater part of this blood passes through the ductus arteriosus into the aorta; a small part goes to the lungs in the branches of the pulmonary arteries.

Radiographic examination has shown that on tying the umbilical cord considerable changes rapidly take place. First the umbilical veins are closed in the placenta, and the opening into the ductus venosus is occluded by the contraction of a sphincter. The eustachian valve closes the foramen ovale, and the ductus arteriosus is closed by the contraction of its own muscle fibers, which takes place a few minutes after the umbilical cord has been tied. All the blood from the right ventricle now passes into the lungs, and the pulmonary circuit is established.

Patten[1] maintains that the change from the prenatal to the postnatal type of circulation does not occur suddenly; he bases his conclusions

on anatomical studies. Pereira,[1] however, having made comparative studies of the duration of the different phases of the cardiac cycle in fetuses immediately before and after birth, found significant evidence that the change takes place suddenly or within a very short time.

Fetal respiration. The newly implanted embryo, in its initial stages, breathes in the same way as other cells of the organism, *i.e.*, by absorbing oxygen from, and eliminating CO_2 into, the interstitial fluid of the uterine mucosa. Differences in the respective partial pressures within and without the cells are the cause of this gaseous exchange. At a later stage of development the fetus performs its gaseous interchange (external respiration) through the placenta, which receives fetal venous blood through the umbilical artery and sends arterial blood through the umbilical vein.

Blood gases have been studied in the human fetus immediately after birth and in the fetuses of sheep and goats during the course of pregnancy.

The blood flow through the uterus increases throughout pregnancy, but at a certain moment the fetus grows at a quicker pace than the placenta; therefore, in spite of the increase in placental circulation, during the second half of pregnancy, maternal blood leaving the placenta is increasingly less saturated with oxygen. The oxygen saturation of venous blood from the nonpregnant uterus is about 65 per cent; this figure is reduced to 20 per cent in advanced pregnancy.[2]

There is a significant difference between the oxygen partial pressures of arterial and venous maternal and fetal blood, as is seen in the following figures given by Barcroft:

	O_2 Saturation, Per Cent
Maternal circulation:	
Arterial blood to the uterus	95
Venous blood from the uterus	60
Fetal circulation:	
Venous blood in umbilical artery to the placenta	15 to 45
Arterial blood in umbilical vein from the placenta	70 to 80

[2] BARCROFT, J., *Physiol. Rev.*, **16**, 103, 1936; NEWTON, W. H., in Evans, "Recent Advances in Physiology," 7th ed., J. & A. Churchill, London, 1949.

The gaseous interchange of O_2 and CO_2 through the placenta can therefore be explained by the differences in partial pressures alone.

Nevertheless in fetuses of goats some paradoxical facts have been observed; *e.g.*, 80 per cent HbO_2 can be found in fetal arterial blood, while maternal blood in the placental sinuses is only 66 per cent saturated. Active secretion of oxygen from the mother to the fetus has been postulated, but this is an unnecessary hypothesis. The oxygen dissociation curve of fetal hemoglobin differs from that of adult hemoglobin; the affinity for O_2 of fetal hemoglobin is greater than that of adult hemoglobin, especially at HbO_2 percentages below 70. The difference is sufficient to explain the paradoxical results observed. Physicochemical conditions of fetal blood are such that CO_2 is set free more readily than in adult blood.

Arterial fetal blood reaches the tissues with a low oxygen content because it is mixed with venous blood, as it is distributed to the fetal portal system and through the ductus venosus and inferior vena cava to the heart (see "The fetal circulation," page 700). The normal condition of the fetus is therefore one of relative anoxia when compared with that of the child after birth.

After delivery, the placental circulation ceases suddenly and pulmonary respiration must be established immediately.

During fetal life there are a few rudimentary respiratory movements, which are inhibited during labor. After birth two factors initiate respiratory movements: (*a*) *asphyxia*, *i.e.*, a decrease in O_2 tension and an increase in CO_2 tension; (*b*) *reflexes* provoked by cold and by tactile or painful stimuli on the skin. The importance of asphyxia can be demonstrated by tying the uterine artery before birth; this procedure provokes respiratory movements in the fetus. Respiratory reflexes can be initiated by opening the uterus, but these do not take place if the fetus is submerged in saline solution at body temperature.

Prolonged and difficult labor increases fetal anoxia. Anesthetics, given to the mother to decrease pain, pass into the fetus and depress the excitability of the respiratory center. In these conditions the fetus frequently does not breathe after birth and enters into what is known as asphyxia neonatorum (fetal asphyxia). Classic remedies for fetal asphyxia are slapping the

baby, or submerging it alternately in warm and cold water to provoke respiratory reflexes by stimulation of the skin, or manual artificial respiration. In cases that are not serious, these methods are sufficient to bring about respiration.

A more efficacious method consists in rhythmic insufflation of the lungs with a mixture of 95 per cent O_2 and 5 per cent CO_2, by means of a rubber catheter introduced into the trachea. The pressure should not rise above 15 cm. of water; otherwise the delicate lung tissues may be damaged. Lobeline is sometimes injected into the umbilical vein in order to increase the excitability of the respiratory center.

Fetal atelectasia does not disappear completely unless the baby makes deep inspiratory movements, which are more efficient than insufflation for expanding the lungs. It is therefore advisable to make premature babies and those with severe asphyxia neonatorum breathe 95 per cent O_2 and 5 per cent CO_2 at intervals to stimulate the respiratory center and expand the lung by repeated deep inspiration, thus diminishing the risk of pulmonary infection.

PARTURITION

The expulsion of the fetus and its membranes is brought about by contractions of the muscle fibers of the uterus. The fetus is adapted to the genital canal through which it must pass by the adoption of adequate positions, and the canal is modified in the act of parturition in order to facilitate the passage of the fetus (Sellheim). Three stages can be distinguished in parturition: (*a*) dilatation of the cervix; (*b*) expulsion of the fetus; (*c*) expulsion of the placenta.[1] After the fetus and placenta have been evacuated the uterus enters into tonic contraction, the uterine cavity disappears, and the vascular sinuses are closed by compression, thus preventing further hemorrhage.

Records of uterine contractions can be obtained by external or internal hysterography. Tocodynamometers are used in external hysterography, placing them on the abdomen so as to record hardening on contraction of the upper, middle, and lower parts of the uterus (Reynolds). The technique of internal hysterography is shown in Fig. 286 (Alvarez and Caldeyro-Barcia).

[1] In rodents the fetuses have been removed leaving the placentas in the uterus. At term the placentas are expelled as in a normal delivery. In these animals, therefore, fetal factors are not essential for the onset of labor and parturition.

During the first two stages of labor (dilatation, and expulsion of the fetus) uterine contractions can be recorded by the pressure they exert on the amniotic fluid.[1] Records thus obtained (Fig. 286*A*) show the following facts: (*a*) the uterus contracts rhythmically; (*b*) the strength of contraction, measured by the increase in amniotic pressure, is 30 to 60 mm. Hg; (*c*) basal tonus, *i.e.*, amniotic pressure between contractions, is approximately 10 mm. Hg (intraperitoneal pressure is taken as the base line); (*d*) frequency of contraction varies between two and five every 10 min.; (*e*) each contraction lasts 60 to 120 sec. As labor advances, the strength, duration, and frequency of contraction increase. During the second stage (expulsion of the fetus) the abdominal muscles and the diaphragm contract and add their effect to the uterine pressure. These contractions are provoked by the entry of the fetus into the vagina, which evokes in the mother the desire to "push," as when evacuating the rectum. The duration of labor is 12 to 16 hr. in primiparas and diminishes to 6 to 10 hr. and even less in multiparas.

After the birth of the fetus, uterine contractions separate the placenta from the uterus and send it into the genital canal (lower segment, os, vagina); abdominal contractions are evoked, or the obstetrician exerts manual pressure on the lower abdomen, and the placenta is expelled. Uterine contractions during this stage can be registered by introducing a needle into the umbilical vein and connecting it to a mercury manometer. Changes in placental blood pressure are due to contraction and relaxation of the uterus. Uterine contractions during this stage follow without interruption, and with the same frequency and strength, the contractions of the previous stages (Fig. 286*B*). The first contractions after birth of the fetus are painless, and they were not known to exist before it was possible to register them. For this reason the 5 to 15 min. following delivery of the fetus was thought to be a period of uterine quiescence (physiologic rest period).

Optimum conditions in normal labor exist when (*a*) uterine contractions are strong (over 24 mm. Hg); (*b*) contraction of the fundus

[1] Alvarez, H., and R. Caldeyro-Barcia, *Surg., Gynec. & Obst.*, **91**, 1 and 641, 1950.

predominates over contractions of the middle and lower segments; (*c*) there is good synchronization between the different parts of the uterus; (*d*) rhythm and strength of contractions are regular; (*e*) the amniotic-fluid pressure falls between contractions to the normal tonus level (10 mm. Hg).

Registration of uterine contractions by means of four microballoons connected to electrical manometers has revealed the existence of two pacemakers, one on each side near the opening of the fallopian tubes. Contractions arise in these pacemakers and spread at a velocity of 1 to 2 cm./sec., the whole uterus being covered in 10 to 20 sec. One of the pacemakers may predominate or predominance may alternate between the two pacemakers. Contractions are stronger and more prolonged in the fundus and upper part of the uterus than in the lower segment and cervix; these latter parts are thus progressively dilated. Labor does not progress satisfactorily if the different parts contract asynchronously, or when contractions arise in the lower parts of the uterus.[1]

[1] Caldeyro-Barcia, R., and H. Alvarez, *J. Obst. Gynaec. Brit. Empire*, **49**, 646, 1952; First Congress on Sterility and Fertility, New York, 1953.

Uterine contractions are not painful; pain in labor is due to: (*a*) distention of the cervix (dilatation); (*b*) distention of the perineum and vulva (expulsion); (*c*) sustained abnormal hypertonic contraction causing uterine ischemia.[1]

The first arrow marks the passage of the placenta into the genital canal; the third arrow, manual compression and expulsion of the placenta. (*Alvarez and Caldeyro-Barcia.*)

The cause of the onset of labor after 40 weeks' gestation is still unknown. At term it is possible to initiate parturition by sensitizing the uterus with estrogens and then injecting oxytocic agents, or by dilating the cervix. The appearance of oxytocic substances in the blood at the end of gestation has been reported (Almagia, Fontes), but these substances have also been found in the blood of nonpregnant women (Figueroa-Casas).

The role of the neurohypophysis in parturition has been discussed in Chap. 52.

The uterus is innervated by sympathetic and parasympathetic fibers. Stimulation of these fibers causes the uterus to contract. Reflex contraction of the uterus is provoked by dilatation of the cervix and by stimulation of the nipples (sucking), bladder, or colon. The innervation of the uterus is not essential for parturition.

[1] Moir, J. C., *J. Obst. Gynaec. Brit. Empire*, **46**, 400, 1952; Alvarez, H., and R. Caldeyro-Barcia, *Surg. Gynaec. & Obst.*, **91**, 1, 1950.

Normal labor and delivery have been observed in bitches after denervation of the uterus (Rein, 1880) and after section of the spinal cord at the level of the thorax or destruction of the lumbar and sacral segments of the cord (Goltz, 1874). Parturition has been observed in women suffering from paraplegia (paralysis of the lower half of the body) and in a few women who had suffered transverse section of the spinal cord. Delivery has been observed after the death of the mother, and cases have been reported in which a full uterus contracted after having been surgically removed, the cervix dilated, and the contents were expelled. Destruction of the lumbar and sacral segments of the spinal cord, however, causes difficulties in labor, especially during the expulsive stage. The existence of a spinal center at the level of the tenth thoracic to second lumbar segments, which controls the movements of labor, has been postulated.

CHAPTER 62

Lactation

THE FUNCTION OF THE MAMMARY GLAND

The mammary gland is an essential constituent of the reproductive system in all mammals. It secretes milk, which is the natural food of the newborn and also an important foodstuff in adult human nutrition.

Four aspects can be considered when studying the function of the mammary gland: (*a*) the development of the gland; (*b*) galactogenesis, *i.e.*, the processes that originate the secretion of milk; (*c*) galactopoiesis, *i.e.*, the processes that maintain milk secretion; (*d*) the evacuation of milk from the gland.

The Formation and Development of the Mammary Gland

The mammary glands arise from the ectoderm. Lateral to the mid-line on the ventral aspect of the body are the so-called "mammary lines" on which there appear a series of growths that give rise to the mammae. Most mammals have several pairs of mammary glands, but in man only one pair develops, except in rare cases in which small accessory mammae are found.

There are two stages in the development of the mammary glands: at first the ducts grow and ramify; later, during pregnancy, alveoli are formed at the ends of the ducts, and the gland is fully developed.

Growth. The mammary gland develops and undergoes involution at certain ages and in certain physiologic conditions.

1. In the newborn of both sexes there is definite activity in the mammary gland, which is due to maternal hormones that have passed through the placenta into the fetus.
2. There is gradual, but not very considerable, mammary growth during childhood. The prepuberal gland consists of only a few rudimentary ducts.
3. At puberty the glands develop considerably in the female, but only slightly and transitorily in the male.
4. At each estrus there is some development, followed by retrogression during diestrus or anestrus. In women there is some retrogression during the first week of the cycle, and later proliferation up to the premenstrual stage. Some women experience tension and discomfort in the mammary glands just before the menses.
5. During pregnancy the mammary glands reach full development. In the course of the first half of pregnancy not only do the ducts grow, but also the alveoli and lobes are formed; during the second half the gland becomes engorged with the products of secretion.
6. In animals showing the phenomenon of pseudopregnancy at each unfertilized cycle, the mammae develop completely as in pregnancy (bitch, weasel), or incompletely, reaching only the degree of growth observed halfway through pregnancy (rabbit).
7. The mammary glands of women in lactation show still further growth.

Secretion. The newborn of both sexes frequently secrete a few drops of milk. During the last days of pregnancy and a day or two after delivery, small quantities of a fluid called colostrum are secreted. After this interval comes the ejection of milk (the "letdown"), and lactation, as it is usually understood, begins. The mammary glands secrete increasingly large quantities of milk during 6 to 9 months. Later the output diminishes gradually, and it ceases 12 to 18 months after delivery. If the child

continues to be nursed and sucks vigorously, lactation is kept up for a longer time; exceptional cases of lactation lasting 2 and 3 years have been reported.

Involution. If the offspring are not nursed, the mammary gland rapidly undergoes involution, and the same process takes place at whatever stage lactation is suspended. The gland retrogresses and in a few days returns to a condition similar to that which existed before pregnancy. Castration is quickly followed by marked involution. After the menopause the mammary glands retrogress gradually.

The male mammary gland. Slight transitory growth is observed in the male mammary glands at birth and at puberty. Deposition of fat in the mammary region may simulate glandular development, *e.g.*, in some cases of dystrophia adiposogenitalis. Growth of the mammary gland itself (gynecomastia) has been reported in males with certain testicular and corticoadrenal tumors, and in some chronic hepatic diseases, malnutrition, etc.

Hormonal Factors in the Development of the Mammary Gland

Growth and secretion of the mammary gland are stimulated and controlled by several endocrine factors, *i.e.*, internal secretions of the ovary, the corpus luteum, the placenta, and the pars distalis of the hypophysis. The ovary and the placenta secrete estrogens and progesterone, and the hypophysis secretes gonadotrophins, *i.e.*, FSH, LH, and luteotrophin (prolactin). Prolactin has a triple effect: it is luteotrophic, mammotrophic, and lactogenic. The mammae are influenced by adrenal and thyroid secretions and by nutritive conditions (Fig. 287). Neural factors also play a part but are not indispensable for normal development and function.
Fig. 287. Diagram of factors that control the secretion of milk.

Estrogens, secreted by the ovary or the placenta, initiate the development of the gland, and progesterone completes it. Hypophyseal function is a necessary factor in both stages.

The role of the ovary. Normal development of the mammary gland is due to the action of the ovary which (*a*) stimulates puberal growth of the gland, (*b*) maintains its development during adult life until the menopause; (*c*) provokes its growth during the first part of pregnancy (later the placenta also takes part in this process).

The importance of the ovary is demonstrated by the effects of castration and restitution of ovarian function. Prepuberal castration prevents the puberal growth of the mammae, and postpuberal castration causes rapid involution. Retrogression of the mammary gland after the menopause is also due to the decrease in ovarian function which occurs in old age. The effects of castration are prevented or controlled by ovarian grafts or the administration of natural

estrogens, such as estrone and estradiol, or of artificial estrogens, such as diethylstilbestrol.

The action of the ovary on the mammary glands is due to the secretion of estrogens which is afterward completed by the hormone of the corpus luteum (progesterone). Injections of these hormones in several species have shown that there are three types of response: (*a*) in many animals (*e.g.*, mice and dogs) estrogens provoke growth of the mammary ducts only, and progesterone also must be injected in order to obtain alveolar development; (*b*) in a few species (*e.g.*, guinea pigs[1] and monkeys) estrogen alone provokes growth of the ducts and alveoli; (*c*) in other species estrogens stimulate the development of the ducts and to a certain extent that of the alveoli; thus in cows and goats there is some alveolar growth and milk secretion, but full normal growth is obtained only if progesterone is also injected (Turner).

Estrogens have a direct effect on the mammary gland and a more important indirect effect which is exerted through the anterior hypophysis and which will be considered in a following paragraph. Direct stimulation of mammary growth by estrogens has been observed in castrated hypophysectomized animals, but it is less marked than in normal animals. Local application of estrogen on the breasts by means of ointments also causes mammary development not only in normal animals but also in hypophysectomized ones. If estrogen is applied to only one mammary gland, it develops and the others remain unchanged. If the dose of estrogen applied locally is high, some growth is also observed in the other glands. Local application of estrogen causes development of the nipple, areola, and mammary gland in women and to a certain extent in men.

Large doses of estrogen cause abnormal development of the ducts with formation of cysts (Gardner).

In certain strains of mice there is a high incidence of cancer of the mammary gland in the female; ovariectomy diminishes this incidence considerably (Loeb).

[1] In male castrated guinea pigs ovarian grafts cause full development of the mammae, similar to that which occurs in pregnancy, and the secretion of milk. In female castrates the effect is less marked. The difference has been attributed to the fact that the male hypophysis secretes continuously large quantities of gonadotrophin, which stimulate maximum follicular growth and estrogen secretion. The female hypophysis secretes more luteinizing hormone than the male; therefore corpora lutea are formed and the estrogenic effect is periodically inhibited.

Cancer of the mammae seldom occurs in the male; treatment with estrogen causes the glands to develop, however, and then many of them become cancerous.[1] Even in noncancerous strains of mice, early treatment with large doses of estrogens provokes the formation of adenocarcinomas of the mammae in almost half the individuals.[2] Moreover some of the cancerigenic substances provoke growth of the ducts and alveoli of the mammae.

Testosterone stimulates growth of the ducts, especially when given with an adequate dose of estrogen. In large doses it has an inhibitory effect and causes involution of the gland. Testosterone treatment is given in cases of cancer of the breast because often it reduces the size of the tumor, diminishes pain, and facilitates the surgical removal of the gland.

The hormone of the corpus luteum is needed for the full development of the mammae, except in the few cases just mentioned. This hormone given in very large doses can provoke alveolar growth, but its maximum effect is observed only after the glands have been sensitized by a previous treatment with estrogen. Associating both hormones in appropriate doses, each one potentiates the action of the other; if the relative doses are not adequate, they oppose each other's action.[3] The importance of the corpus luteum for mammary development can be easily demonstrated in species that show pseudopregnancy in the nonfertilized cycles. The growth of the mammae is parallel to that of the corpus luteum, and premature destruction of the latter causes retrogression in the former (Ancel and Bouin).

The role of the placenta. As pregnancy advances the placenta becomes the most important source of estrogens and gonadotrophin (chorionic), a less important source of progesterone, and a source of small amounts of prolactin and adrenocorticotrophin. Cases have been reported of women who have suffered ovariecto-

[1] Lacassagne, A., *Compt. rend. Acad. d. sc.*, **15**, 630, 1932; *Am. J. Cancer*, **37**, 414, 1939.

[2] Geschickter, C. F., and E. W. Byrnes, *Arch. Path.*, **33**, 334, 1942. Hypophysectomized animals did not respond to estrogens by the formation of tumors in the mammae. It has not been possible to provoke adenocarcinoma in the mammary glands of female monkeys and rabbits by estrogen treatment.

[3] Other substances have the same effect as the hormone of the corpus luteum; taking as 1 the activity of progesterone, that of methyltestosterone equals 1/6, desoxycorticosterone and dehydroandrosterone 1/8, and diethylstilbestrol 1/4 (Mixner and Turner, 1942).

my in the third or fourth month of pregnancy in whom the mammary glands continued to grow and secreted milk after the delivery. In mice the ovaries and fetuses can be removed without interfering with mammary growth if the placentas are left in the uterus, but the mammae undergo rapid involution if the placentas are also extirpated. The mammary development observed in the newborn is probably due to maternal ovarian, hypophyseal, and placental hormones which pass into the fetus during the last stages of pregnancy.

The role of the hypophysis. The pars distalis of the hypophysis plays an important and multiple role in the development of the mammary gland. Gonadotrophin secretion stimulates growth and secretion of the ovary and corpus luteum, *i.e.*, secretion of estrogens and progesterone. Hypophysectomy therefore causes ovarian hypoplasia (in young animals) or atrophy (in adults) and thus hypoplasia or atrophy of the mammary gland.

Three hormones are necessary for the complete development of the mammary gland: (*a*) estrogen; (*b*) progesterone; (*c*) prolactin. Estrogen and progesterone do not provoke mammary growth in hypophysectomized animals, but exert their full effects if a small amount of prolactin is also injected. No other hypophyseal hormone has this effect (Lyons, Nelson). Somatotrophin and adrenocorticotrophin cannot replace prolactin, but they increase the activity of the latter.

Estrogens have a direct effect on the mammary gland, but it is slight or nonexistent in hypophysectomized animals. This peripheral direct effect can be demonstrated by the application of salves or solutions of estrogens on one gland; the nipple, areola, and gland develop. The gland on the other side is not affected, unless large doses of estrogen have been absorbed, in which case it may develop, although in a lesser degree. A smaller effect can be produced in men by the local application of estrogen on the mammary area.

Prolactin has a local activity; if it is injected into a mammary gland, growth and milk secretion are provoked only in that gland, not in others.[1]

Turner and his associates demonstrated that injection of hypophyseal extracts provokes mammary development in hypophysectomized castrated animals. The active principles (two were postulated) were called mammogens. Later only one was considered as different from prolactin, but this mammogen has not been adequately separated from hypophyseal extracts, and its existence is still doubtful.

[1] Lyons, W. R., *Proc. Soc. Exper. Biol. & Med.*, **51**, 308, 1942.

The Secretion of Milk

Two aspects of milk secretion can be considered, *i.e.*, initiation (lactogenesis) and maintenance (galactopoiesis).

The fact that milk is not excreted until after delivery led to the belief that the "letdown" was due to the suppression of an inhibitory factor. Later positive hormonal and nervous factors that initiate and maintain the secretion of milk were demonstrated. The hormonal factors are hormones of (*a*) the pars distalis; (*b*) the sexual glands; (*c*) the adrenals; (*d*) the thyroid.

The action of the hypophysis. The part played by the pars distalis has been demonstrated by the effects of hypophysectomy and of injection of hypophyseal extracts or hormones.

Hypophysectomy in pregnant females provokes abortion in nearly all species,[1] but the secretion of milk that is usually seen after abortion does not occur in these animals. If the hypophysectomy is performed in a lactating female that is nursing her young, the secretion of milk ceases almost immediately; if it is performed shortly after delivery, a slight transitory secretion is sometimes observed.[2]

Daily injections of anterior hypophyseal lobe extract provoke copious milk secretion in a few days if the mammary glands are well developed.[3] In male dogs these extracts produce some secretion of milk if mammary development has first been obtained by estrogen treatment. In the bitch hypophyseal extracts stimulate the secretion of milk even after the ovaries, thyroid, and adrenal medulla have been extirpated.

Riddle obtained a lactogenic hormone from the hypophysis which he called "prolactin."[4] It is a protein with a molecular weight of 32,000 to 35,000, which has been purified and obtained in crystalline form.[5] This substance has the fol-

[1] In the rat hypophysectomy is followed not by abortion but by prolonged pregnancy.

[2] Allen and Wilkes, 1932; Collip, Selye, and Thomson, 1932; Houssay, 1935; Nelson, 1935.

[3] Stricker and Grüter, 1928; Corner, 1930; Houssay, 1935.

[4] It has also been called "galactin" (Turner), "mammotropin" (Lyons), "lactogen" (Turner), and "luteotrophin" (Hisaw and Astwood).

[5] White, A., *Ann. New York Acad. Sc.*, **43**, 341, 1943.

lowing specific effects: (*a*) it provokes milk secretion in fully developed mammary glands; (*b*) in pigeons, it stimulates hypertrophy of the crop glands and the milklike secretion of the crop; (*c*) it maintains the development of the corpus luteum; (*d*) injection of this hormone causes maternal behavior in virgin rats, and broodiness in hens; (*e*) metabolic effects are revealed by changes in the weight of several organs (Riddle *et al.*); (*f*) it provokes secretion of the oviduct in the toad (Allende, 1939).

The lactogenic hormone stimulates epithelial proliferation and desquamation in the crop of pigeons; this produces a caseous mass (the so-called "crop milk") which serves to nourish the young. This response is used for the biological standardization of prolactin. Two methods are used: (*a*) a micromethod, consisting in the injection of the substance to be assayed under the skin near the crop, by which very small amounts of prolactin can be detected such as those which have been found in the blood and urine of women in labor and in the hypophysis of small animals; (*b*) a macromethod, consisting in determining the increase in the weight of the crop after injecting the substance to be assayed into the pectoral muscles of the bird. The international unit of prolactin is the specific activity of 0.1 mg. of the international standard preparation.

Prolactin alone does not provoke milk secretion in hypophysectomized animals (*e.g.*, in guinea pigs). Milk secretion can be induced by the injection of total hypophyseal extract, or by injecting adrenocorticotrophin, or adrenocorticosteroids simultaneously with prolactin.[1] Milk secretion is due to the coordinated activity of a hormonal complex, in which prolactin is the main and indispensable lactogenic factor (Folley and Young).

Hypophyseal extracts increase the milk production of cows by 20 per cent when it begins to diminish, but not when it is at a maximum.[2] Somatotrophin has a similar effect. Total extract is more efficacious than prolactin, and its effect is apparently due to the combined activity of several hormones. The high cost of the treatment prevents its use to increase the commercial yield of dairy cows. In women no satisfactory results have so far been obtained.

[1] Nelson, W. O., R. Gaunt, and M. Schweizer, *Endocrinology*, 33, 325, 1943.

[2] Young, F. C., and S. J. Folley, *J. Endocrinol.*, 4, 194, 1944.

In human hypophyseal insufficiency there is sexual infantilism; therefore, owing to ovarian hypoplasia, the mammae do not grow. In acromegaly, on the other hand, lactation is prolonged, and in one reported case it lasted 5 years. Prolactin seems to be secreted by the acidophil cells of the anterohypophysis. The hypophyseal content of prolactin can be increased by injecting estrogens immediately after delivery, and by suckling (Turner).

Removal of the posterior lobe of the hypophysis in rats (Smith, 1932) and dogs (Houssay, 1935) does not cause any change in the secretion of milk.

The effect of estrogens. Natural and synthetic estrogens stimulate mammary growth and increase the lactogenic hormone content of the hypophysis, but they have inhibitory effects on milk secretion in large doses; their activity is increased by an adequate dose of progesterone.

In certain animals estrogens alone can develop the mammae and stimulate milk secretion if the hypophysis is intact. Thus diethylstilbestrol and hexestrol produce alveolar growth and copious milk secretion in virgin and adult goats, sheep, and cows.[1] Mammary development thus obtained differs cytologically from the normal development of pregnancy (Turner).

The main inhibitory effect of estrogens is apparently exerted by directly antagonizing the effect of prolactin (Nelson), but it may also diminish prolactin secretion by the hypophysis. Folley and Young point out that there are two thresholds: if estrogens increase up to a certain level, the secretory threshold is reached; a further increase of estrogens will reach the inhibitory threshold. Ovariectomy does not suppress milk secretion in lactating cows; frequently lactation is prolonged beyond the usual time for it to cease.

The action of the adrenals. Adrenalectomy diminishes but does not suppress the secretion of milk in most animals. The secretion is slightly improved by treating adrenalectomized animals with sodium chloride, and is restored to the normal level by corticoadrenal hormone. Corticoadrenal steroids with oxygen on C^{11}, *i.e.*, those which are active in protein and carbohydrate metabolism, are particularly efficacious. Desoxycorticosterone, which acts on salt and water metabolism, has little effect on the milk secretion of rats (Gaunt) and inhibits it in the guinea

[1] Folley, J. H., J. Hammond, and A. S. Parker, *J. Endocrinol.*, 4, 1, 1944.

pig. On the other hand, Verzár[1] has used it with success in the treatment of pregnant adrenalectomized cats, in which the fetuses were carried to term and, in some cases, nursed.

The lactogenic hormone does not produce milk secretion in hypophysectomized guinea pigs unless it is associated with corticoadrenotrophin or corticoadrenal hormones or extracts.[2] It is not yet possible to state whether disturbances in milk secretion following adrenalectomy are due to general metabolic disturbances or to the lack of a specific lactogenic hormone. There is no proof of the existence of a "corticolactin," which has been postulated by some workers.

The action of the thyroid. Thyroidectomy does not prevent the development of the mammae that occurs during pregnancy nor the secretion of milk following delivery, but the amount secreted is definitely subnormal. Thyroidectomy reduces the amount of milk secreted by lactating animals. The administration of thyroid preparations, thyroxine, or iodized proteins increases milk secretion. Diethylstilbestrol does not cause mammary growth in thyroidectomized cows unless thyroid insufficiency is improved by treatment with iodized proteins.[3]

The role of the nervous system. Stimulation of nerves going to the mammary gland produces only vasomotor effects and the expulsion of a little milk contained in the alveoli and ducts of the gland; it has no secretory effects. The dispensability of mammary innervation for the normal growth of the gland during pregnancy and milk secretion after delivery has been demonstrated in several ways:

1. Extirpation of the sympathetic chains or denervation of the mammary gland does not prevent milk secretion.
2. Milk secretion is not prevented by the destruction of the spinal cord from the third thoracic segment down (Goltz and Ewald, 1886). A case of a woman with section of the spinal cord at the level of the sixth thoracic segment, who delivered and nursed a child, has been reported.
3. A grafted mammary gland develops normally during pregnancy and secretes milk.
4. The pygopagus twins Theresa and Josepha Blazek had separate genital organs and nervous systems, but their circulations were anastomosed. One of them became pregnant and delivered a child, but the mammary glands of both of them developed and, after delivery, secreted milk.

On the other hand manipulation of the mammae, especially suction, can eventually provoke mammary development and milk secretion sufficient to nurse sucklings. This has been observed in nonpregnant and virgin females and exceptionally in males in many species (man, dog, goat, rats, mice, etc.). The following facts are evidence that suckling initiates a reflex which increases secretion of galactopoietic hormones by the hypophysis: (*a*) suckling does not maintain milk secretion of lactating animals after hypophysectomy or adrenalectomy; (*b*) suckling stimulates the secretion of prolactin; (*c*) it causes loss of granules in the acidophil cells, and it prevents the appearance of castration cells in the hypophysis after ovariectomy (Desclin).

Suckling plays an important part in other phenomena: (*a*) it provokes uterine contractions after parturition, and accelerates normal uterine involution during the puerperium; (*b*) it prolongs the life of the corpus luteum (corpus luteum of lactation), thus inhibiting ovulation and the menstrual cycle.

Suckling or milking is necessary for the maintenance of normal milk secretion. Soon after they are discontinued, the secretion ceases and involution of the mammary gland commences. Frequent suckling or milking, with complete evacuation of the gland, is the most powerful known factor for increasing milk secretion when it begins, or declines, or is scarce. Habitual incomplete evacuation causes a decrease in milk secretion and, eventually, involution of the gland.

Suction may act by initiating reflexes from the nipple, or simply by preventing dilatation of the gland due to the milk retained. According to Selye, suction provokes reflex discharges which act on the hypophysis. This is demonstrated by tying the ducts so as prevent the evacuation of the gland. As long as suction is maintained, secretion continues; but soon after suction is discontinued, or if the nipples are cut, the gland rapidly undergoes involution. Undoubtedly there is a local factor acting on the

[1] Verzár, F., *Helvet. Physiol. et Pharmacol. Acta*, **1**, 385, 1943.

[2] Nelson, W. O., R. Gaunt, and M. Schweizer, *Endocrinology*, **33**, 325, 1943.

[3] Petersen, W. E., *et al.*, *Proc. Soc. Exper. Biol. & Med.*, **57**, 332, 1944.

gland, because if one gland is not sucked it suffers involution to a certain extent, while the others which are sucked remain fully developed and continue to secrete. Involution of the unsucked gland is nevertheless more gradual than the involution that occurs when no gland is sucked. This is probably due to the secretion of prolactin stimulated by sucking, because injections of prolactin delay involution of unsucked glands.

The flow of milk that occurs after parturition has been attributed to (*a*) the delivery of the fetus; (*b*) expulsion of the placenta; (*c*) ceasing of distention of the uterus; (*d*) neurohypophyseal hormones. It does not occur if the hypophysis is extirpated. In rats, if the placentas remain in the uterus after the fetuses have been removed, milk flow does not begin until the placentas have been expelled. The mechanism of this phenomenon is not yet well understood. It has been suggested it is due to (*a*) ceasing of inhibition of prolactin by progesterone (Turner); (*b*) ceasing of the inhibitory effect of estrogens on the action of prolactin on the mammary gland (Nelson); (*c*) the decrease in estrogen from the inhibitory threshold level to the stimulatory threshold level (Folley).

Other factors. Nutritive conditions are important for the development of the mammary glands, which grow less in response to estrogens in undernourished or fasting animals. Progesterone has little effect on animals submitted to high temperatures. It is common knowledge that emotional shock causes a decrease in milk secretion. Acute and chronic infections have unfavorable effects on the secretion of milk.

The Emptying of the Mammary Gland

The evacuation of the mammary gland is of importance not only for the actual supply of milk to the offspring but also for the continuance of secretion and the prevention of involution. Complete evacuation increases the yield of milk and prolongs lactation; it has therefore been the subject of much study from the point of view of dairy farming.

The emptying of the mammae is not only the passive result of sucking or milking; it is accompanied by contraction of the glandular ducts and controlled by hormonal and nervous factors.

Psychic phenomena exert a definite influence on the evacuation of the mammae. A cow will "hide her milk" if she is disturbed by unfamiliar noises or is frightened, or if the milker is changed. The presence of the calf, on the contrary, produces a more copious flow, and suction by the calf at the end of milking will stimulate further secretion. Conditioned reflexes that facilitate milking can also be provoked by preliminary manipulation of the mammae such as is performed in washing the udder. In nursing women the presence of the child, or hearing it cry, may provoke the flow of milk. When the child sucks at one breast, frequently a little milk flows from the other.

The evacuation of milk is a reflex. The afferent paths are not yet known, but impulses reach hypothalamic centers and are relayed to the neurohypophysis, which secretes hormones provoking contraction of the alveoli and ducts of the mammary glands.

Injection of posterior hypophyseal lobe extract or oxytocin rapidly provokes an abundant flow of milk if the main duct is catheterized or the nipple has been cut off.

Moreover, if a cow or goat that has been milked dry is injected with posterior lobe extract or oxytocin, on further milking it will yield a new amount of milk rich in fat.[1] Oxytocin causes a rise in pressure in the milk ducts, and histological examination shows the almost complete evacuation of the gland. Oxytocin has about five times the activity of purified vasopressin.[2]

Suckling and milking provoke contraction of the smooth muscles of the ducts and the myoepithelial cells of the acini, and the intramammary pressure rises. Stimulation of the nerves to the mammary gland does not produce this effect, so a direct nervous action is still to be demonstrated. A humoral factor is released during milking, because blood collected from a gland which is being milked, if perfused through another gland, will cause this one to evacuate its milk.[3]

The hypothalamic-neurohypophyseal link in the mechanism of milk evacuation is demonstrated by the following facts: Electrical stimulation of the supraoptic nucleus (in ewes)[4] or of

[1] Ott and Scott, 1910–1921; Schüfer *et al.*, 1911–1913; Hammond, 1912; Houssay *et al.*, 1913–1914.

the supraopticohypophyseal tract (in rabbits)[1] provokes evacuation of milk, even after denervation of the mammary gland. Hypertonic salt solution injected into the carotid has the same effect. The antidiuretic hormone is released at the same time as the milk-evacuating factor, so that urinary secretion diminishes and an antidiuretic substance appears in the urine. Section of the pituitary stalk in nursing females is followed by the death of the offspring, probably owing to deficient evacuation of milk; if oxytocin is injected into the female, the offspring survive.

Table 79. The Chemical Composition of Mammary Secretion

Mammary secretion	*Constituent, gm. per 100 cc.*

Colostrum...........	....	2.06	...	...	4.6	2.6	0.35	50

MILK

Amount secreted. In women immediately after delivery a small amount of colostrum is secreted; the flow of milk does not begin till 2 or 3 days later. The amount of milk secreted increases gradually up to the sixth or ninth month, and then diminishes until it ceases 12 to 18 months after delivery, but it may last longer if vigorous suction is continued. The total daily amount reaches a maximum of 1,000 to 1,500 cc., but secretions of 2.5 and 3 liters daily, without any harmful consequences to the mother, have been reported. Women who nurse two babies secrete more milk than those nursing only one.

Composition and nutritive value. Milk is a dispersion of corpuscles, micellae, molecules, and ions. The color and opacity of milk are due to fine fat droplets which it holds in suspension.

The specific gravity of milk is seldom below 1.028 or above 1.034. The freezing point is usually between −0.5 and −0.6°C. The pH is 6.6 to 6.8 in human milk and 6.3 to 6.6 in cow's milk. After extraction, if the milk stands at room temperature, the pH is lowered owing to the development of microorganisms, mainly the lactic bacilli which split lactose into lactic acid and sour the milk. The addition of acids coagulates milk when the pH falls to 5.34 in raw milk and to 5.37 in boiled milk. If acid milk is warmed it clots.

The components of milk (Tables 79 and 80) are water, salts, and organic substances.

The principal proteins in milk are (*a*) *caseinogen*, a phosphoprotein which is converted into paracasein by the rennin in gastric juice (paracasein combines with calcium and forms solid casein); (*b*) *lactalbumin;* (*c*) *lactoglobulin*, identical to serum globulin, which includes maternal antibodies; (*d*) a small amount of alcohol-soluble protein. There is also some nonprotein nitrogen (35 mg. per cent).

Table 80. Salts in Milk

Milk	*Salt, mg. per 100 cc.*						
	K	*Ca*	*P*	*Na*	*Mg*	*Cl*	*Fe*
Human....	41	30	13	11	6	36	0.10
Cow's......	150	120	95	50	12	110	0.05

Lactose is the principal sugar in milk, but there are small quantities of other carbohydrates.

The fat in milk is made up mainly (90 per cent) by the glycerides of oleic, myristic, and palmitic acid, and smaller amounts of stearic acid and acids with carbon chains of 4 to 24 carbon atoms. Phosphatides, such as lecithin and kephalin, and sterols are also found.

The main cations in milk are potassium, calcium, and sodium, and the main anions are phosphate and chloride, with small quantities of citrate and lactate.

Vitamins A, C, and most of those in the B groups are found in sufficient quantities to satisfy the needs of the child, but there is not enough vitamin D (Tables 69 and 70, Chap. 49; Table 81).

[1] Cross, B. A., and G. W. Harris, *J. Endocrinol.*, **8**, 148, 1952.

Milk contains antibodies which circulate in the mother's blood and a certain number of enzymes (catalase, oxydase, reductase, etc.). These enzymes are destroyed by heat, and their absence serves as a test of whether the milk has been boiled.

Table 81. Vitamins in Milk

Vitamin	Amount per 100 cc.	
	Cow's	*Human*
Vitamin A, IU	180	290
Vitamin D, IU	2.5	5
Vitamin C, mg	2.0	6.4
Thiamine, mg	0.035	0.013
Riboflavin, mg	0.20	0.04
Niacin, mg	0.1	0.1
Pantothenic acid, mg	0.35	
Biotin, μg	3	
Pyridoxin, mg	0.04	
Choline, mg	15	
Inositol, mg	18	
Folic acid, mg	5	

The composition of milk differs from one species to another. The milk of the offspring's own species is the one best adapted to satisfy its needs. The nutritive value, especially the protein concentration, increases with the speed of growth of the offspring (Table 82). The fact that the composition of the ash of milk is similar to that of the newborn offspring, and not to that of the maternal plasma, is further evidence of the adjustment of the composition of milk to the needs of the offspring.

Milk is the indispensable food of the newborn and the principal foodstuff of the growing child. It is also an excellent food for adults. It is an almost complete food; the only deficiencies are the low iron and vitamin D content. A child that is fed exclusively on milk for too long a time becomes anemic when the iron stored in its body (mainly in the liver and spleen) is exhausted.[1] It is also advisable to add vitamin D to the diet of a milk-fed child, either in the form of cod-liver oil or other fish-liver oils, or by adding it to the milk (see "Vitamin D," Chap. 49).

A 70-kg. adult could obtain the total caloric requirement and an adequate amount of high-class protein from 5 to 6 liters of milk daily. The fat content of such a diet would be too high.

[1] Rats fed exclusively on milk cease to grow and eventually die. Iron and copper must be added to cure the symptoms of deficiency.

Milk not only is an excellent food from a biological point of view, but it has also many advantages from the economic standpoint. The cow puts out in milk 35 per cent of the energy of the food digested and is therefore the most efficient machine for converting energy into animal food of high quality, well adjusted to human needs.

Table 82. Composition of Milk in Relation to Growth of Offspring

Animal	Days taken for offspring to double birth weight	Constituent, gm. %			
		Protein	*Salts*	*Ca*	*Phosphoric acid*

Source: after Porcher, modified.

Colostrum. This is an opalescent, turbid fluid which has in suspension fatty droplets and multinucleated cells filled with fat. It has 2 to 8 per cent protein and coagulates when heated. It has less calories, fat, and carbohydrate than milk, and more protein; it is also more alkaline and has more vitamin A, thiamine, riboflavin, and ascorbic acid, and less niacin. It does not contain vitamin K.[1] It is popularly considered to have laxative properties (Table 79).

Comparison between human and cow's milk. Cow's milk is commonly used as a food for children and adults. Its composition differs from that of human milk (Tables 79 and 80), and it is not possible to make it identical with the latter simply by dilution and the addition of different substances. The main differences between human and cow's milk are the following: (*a*) human milk has much less casein than cow's milk (about one-eighth as much), but the total protein content has a higher nutritive value per gram because the ratio of casein to lactalbumin is between 1:1 and 2:1, while in cow's milk it is between 4:1 and 8:1 (there is

[1] Escudero, P., *Bol. Acad. nac. de med. de Buenos Aires*, p. 355, 1942.

more lactalbumin per gram of total protein in human than in cow's milk); (*b*) the concentration and physicochemical properties of casein in human milk are such that on coagulating it forms a finer, softer, and more uniform curd, which is more easily digested than the firmer curd formed by cow's milk; (*c*) human milk contains less salts, especially Ca and P, than cow's milk;[1] (*d*) the buffer effect is less in human than in cow's milk; (*e*) human milk contains more lactose than cow's milk; (*f*) human milk contains only one-tenth the amount of volatile fatty acids in cow's milk. The characteristic smell of babies is due to the action of saliva and gastric juice on milk (Arthus).

Origin of milk constituents. The use of isotopes, biochemical studies on mammary-tissue slices *in vitro*, and perfusion of the mammary gland have given valuable information on the processes of milk production.

There is no caseinogen in the blood; it is synthesized by the mammary gland from the amino acids that it takes up from the blood. Part of the milk fat probably comes from the blood; thus a certain amount of the fatty acids in food pass into the milk and may contribute to its taste. If the female is fasting, storage fat is mobilized for the formation of milk fat. The mammary gland, however, also synthesizes fat from acetate, a process which is increased by the action of insulin. Thus the composition of milk fat is, to a certain extent, maintained constant. Lactose is formed from glucose in the blood. A special enzyme and coenzyme convert glucose-1-phosphate into galactose-1-phosphate.[2] Lactose formed in the mammary gland of lactating women may pass into the blood and be excreted in the urine.

The influence of the diet on the composition of milk. An increase in the protein content of the diet increases the amount of milk secreted and its fat content up to a certain limit, but does not modify the protein content. An increase of fat in the diet above 1 gm. per kg. per day does not increase the fat content of milk, but if the diet does not contain enough fat, milk fat diminishes. The composition of the diet has little or no influence on the lactose content of milk.

If the diet is adequate in amount and composition, an increase in the ingestion of food does not increase the output of milk. If the diet is inadequate the female takes from the stores in her body those substances which are needed for the formation of milk, but the milk output diminishes. Thus, if there is deficiency of Ca and P in the diet, the female will remove these elements from her own bones and teeth and keep their concentration in the milk nearly normal for a fairly long time, but eventually they will diminish. Iodine and vitamins in milk are dependent on the maternal intake of these substances. In Chap. 50 the importance of supplementing the diet of pregnant and lactating women with iron, iodine, vitamins, etc., was emphasized.

Excretion of foreign substances in milk. Many substances ingested in the food are excreted in the milk and may give it a peculiar odor or taste. Certain drugs also pass into the milk, *e.g.*, alcohol, belladonna, opium, salicylates, iodides, bromides, saline purges, etc.

[1] There is more K, Na, and Cl per gram of Ca in human milk than in cow's milk.

SECTION EIGHT

The Formation and Excretion of Urine

CHAPTER 63

The Kidney

THE KIDNEY IS undoubtedly the most important of all the organs that take part in the maintenance of the constancy of the internal environment, because, as Smith has remarked, "in the last analysis the composition of the *milieu intérieur* is determined not by what the body takes in, but by what is retained and what is excreted." The lung excretes CO_2 and water, and the skin water and a few salts. Through the intestine some of the heavy metals, the residue of food ingested, and the digestive secretions are excreted. The paramount importance of the kidney is due not only to the quantity, but also to the variety, of the substances eliminated in the urine.

Apart from the elimination of waste products of metabolism (nitrogen, sulfur, hormonal substances, etc.) and of toxic substances, the kidney by means of its excretory activity performs several other functions:

1. The regulation of the plasma volume and water content of the organism. When large amounts of water are ingested, the kidney responds by eliminating great quantities of dilute urine. When there is an abundant loss of water, due to profuse sweating, vomiting, diarrhea, etc., the kidney responds by excreting a smaller volume of greatly concentrated urine.
2. The regulation of the osmotic equilibrium and the maintenance of an optimal ionic balance in the plasma. The kidney performs this function by increasing or diminishing the excretion of such ions as sodium, potassium, calcium, chloride, phosphate, etc.
3. The regulation of the acid-base equilibrium of the organism. The kidney plays a part in this by eliminating a more or less alkaline or acid urine, in relation to the pH of the blood. Moreover, when nonvolatile acids are formed in the organism, the kidney produces NH_3 and thus spares the inorganic base in the blood.

The kidney also produces renin, an internal secretion, which plays a part in renal hypertension and seems to act in the normal regulation of blood pressure.

ANATOMY

In order to understand the processes by means of which urine is formed, it is necessary to describe briefly the structure of the kidneys.

The structural unit or nephron. The kidneys are made up of a great number of primary structural and functional units called nephrons (Fig. 288). These units are surrounded by connective tissue and are provided with an abundant blood supply. It has been calculated that there are about a million nephrons in each human kidney. Each nephron is made up of a malpighian body and a renal tube.

The malpighian body is situated in the cortex of the kidney and is formed by the blind end of a renal tube invaginated so as to contain a bundle of sinuous capillaries, which wind around each other; this is the glomerulus. The glomerulus is a capillary area placed between two arterioles, the afferent arteriole and the efferent arteriole, the former being larger than the latter. Both these arterioles have a well-developed muscular layer made up of circular smooth-muscle fibers. The visceral or internal layer of epithelium that covers the glomerulus is closely attached to the capillaries; the external or parietal layer forms a spherical capsule (Bowman's capsule) which contains the glomerulus. Between the layers there is a cleftlike space continuous with the lumen of the renal tube.

The renal tube arises in the malpighian body, to which it is joined by a short communicating

tube or "neck." It has three segments: (*a*) the proximal tube; (*b*) the thin segment; (*c*) the distal tube.

The proximal tube contains a pars convoluta situated in the renal cortex, near the glomerulus, and a pars recta, which goes toward the medulla and forms the first part of the descending branch of Henle's loop. The cells in the epithelium of the proximal tube have the shape of truncated pyramids, with a "brush border" on the free or luminal surface.

The thin segment is placed between the pars recta of the proximal tube and the pars recta of the distal tube, forming part of Henle's loop. This loop is that part of the renal tube which first goes toward the medulla (the descending branch) and then back to the cortex (the ascending branch). The thin segment occupies a variable position in the loop; it can form part of the descending branch, the ascending branch, or both. The epithelium of the thin segment is made up of flat cells with a clear cytoplasm and a nucleus that bulges into the lumen of the tube.
FIG. 288. Diagram showing the essential features of a typical nephron of the human kidney. (*Smith, H. W., "The Physiology of the Kidney," Oxford, New York, 1937.*)

The distal tube has a pars recta which follows the thin segment in the ascending branch of Henle's loops, and a pars convoluta continuous with the former and placed in the renal cortex. According to some observers the distal tube always comes into contact with the afferent arteriole of the glomerulus in which it begins,

and at this point the cells of the epithelium take on a columnar shape and the nuclei appear to be close to each other (macula densa). The epithelium of the distal tube is lower than that of the proximal tube; its cells project irregularly into the lumen of the tube, and they do not have a brush border. The distal tube is joined to the collecting tube by a short connecting segment.

The collecting tubes, so called because several nephrons open into each of them, descend, together with other collecting tubes, into the medulla and end in the cribriform area on the papillae of these pyramids. The fluid from the tubes flows into the minor calyces of the renal pelvis and thence through the ureter into the bladder. The connecting and collecting tubes are lined by an epithelium of cuboidal cells with clear cytoplasm and a nucleus that stains intensely.

The proximal tubes with a typical brush-border epithelium and the distal tubes are found in all animals. The thin segment is found only in the higher vertebrates (mammals and some of the birds). In the lower vertebrates this segment does not exist or is replaced by a short narrow tube lined by a ciliated epithelium called the intermediate segment (Fig. 289). The fact that the thin segment is found only in those animals which excrete urine of a higher osmotic pressure than that of the blood plasma has suggested the idea that in this segment most of the reabsorption of water takes place.

The differences in structure of the three segments of the nephron indicate functional differences, which have been demonstrated by physiological experiments (to be described further on) and which are substantiated by the distribution of the blood vessels of the kidney.
Fig. 289. Diagram of nephrons in different vertebrates. (*Marshall, E. K., Physiol. Rev., vol. 14, p. 133, 1934.*)

Blood vessels. The renal artery divides on arriving at the hilum of the kidney into ventral and dorsal branches, which again divide and subdivide, giving origin to the lobular arteries. These go to the base of Malpighi's pyramids where the arcuate arteries arise and run between the cortex and the medulla in a direction almost parallel to the surface of the kidney (Fig. 290). Each arcuate artery can be considered as a terminal vessel, because it does not anastomose with other arteries. Peripherally it gives out numerous ascending interlobular arteries from which the afferent arterioles of the glomeruli arise. These afferent arterioles have a well-developed muscular coat. In the neighborhood of the glomerulus the number of cells in the media and adventitia increase, forming a kind of cap on one side of the glomerulus (*Polkissen*). The cells of the *Polkissen* are free from granules and fibrils, and in certain species they have an epithelioid aspect. The term "juxtaglomerular apparatus" has

been given by Goormaghtigh to the formation constituted by the thickened vascular wall and the neighboring extravascular cells; he attributed an endocrine function to this apparatus. Others maintain that it modifies the lumen of the arteriole, thus regulating the blood flow through the glomerulus.
FIG. 290. Diagram showing significant differences between a cortical nephron (right) and one located in the juxtamedullary region (left). (*Smith, H. W., "The Kidney," Oxford, New York, 1951.*)

Trueta and his associates[1] have demonstrated that the ulterior course of the blood coming from the *cortical glomeruli* (situated in the external two-thirds of the cortex) differs from that taken by the blood from the *juxtamedullary g lomeruli* (situated in the internal third of the cortex). The efferent vessel of the former has a small caliber and soon divides into a capillary network surrounding the cortical tubes. The efferent vessel of the juxtamedullary glomeruli is of greater, or at least the same, caliber as the afferent vessel, and goes toward the medulla, where it divides into the *vasa recta*, large straight vessels which run parallel to the collecting tubes (Fig. 290).

The work of Trueta and his associates shows that these vessels can act as a short circuit in renal circulation. In certain physiologic and pathologic conditions, by means of a nervous mechanism the circulation in the cortex is considerably diminished, without any significant decrease in the renal blood flow. In these cases the vasa recta and the juxtamedullary glomeruli are found to be full of blood, while there is marked ischemia of the cortex. The juxtamedullary glomeruli and the arteriae rectae would therefore serve to short-circuit the blood when nervous and humoral factors constrict the afferent arterioles of the cortical glomeruli.

From the tubular capillaries the blood passes into the interlobular veins, which are originated in star-shaped groups on the renal surface. The interlobular veins, together with the ascending veins from the medulla, form the arcuate veins, which join to form the renal vein.

Between the tubes there is a complicated network of lymphatic capillaries, which flow into the deep lymphatics running next to the blood vessels and into the superficial lymphatics flowing from the surface of the kidney toward the hilum.

Innervation of the kidney. The kidney has a rich sympathetic innervation. Sympathetic fibers emerge from the spinal cord in the anterior roots of the fourth dorsal through the fourth lumbar segments. After passing through the prevertebral ganglia these fibers form a plexus around the renal artery. Some of the fibers in this plexus are preganglionic and end on nerve cells in the kidney. Sensory endings have been demonstrated in the adventitia of the blood vessels, and motor endings in the muscular coat. Nerve endings around the renal tubes and between the cells of the convoluted tubes have also been described.

Structural features. The following structural features of the kidney should be particularly noted: (*a*) the renal artery is wide and short, and soon branches out so that a high blood pressure is assured in the afferent arteriole; (*b*) the efferent arteriole of the cortical glomeruli is of a smaller diameter than the afferent arteriole, so that a high blood pressure is maintained in these glomeruli; (*c*) the renal tubes are supplied by a capillary network with blood at low pressure (this blood has already passed through the glomerulus); (*d*) the structural differences in the renal tube indicate the existence of functional differences in its several parts.

URINE[1]

Physical properties. The volume of urine formed daily by an adult man is from 1,000 to

[1] TRUETA, J., A. E. BARCLAY, P. DANIEL, K. J. FRANKLIN, and M. M. L. PRICHARD, *Lancet*, 2, 237, 1946; "Studies of the Renal Circulation," Blackwell, Oxford, 1947.

[1] More details are given in textbooks of biochemistry.

1,500 cc.; two-thirds to three-fourths is excreted during the day and the rest during the night. Children excrete three to four times more urine per kilogram of body weight than adults.

The volume of urine varies with the amount of fluid ingested and according to the amount of fluid excreted by other paths (skin, lung, intestine). Several other conditions influence the urinary volume:

1. Diet. A protein diet increases the amount of urea excreted and therefore the total volume of urine. In fasting less urine is excreted.
2. The temperature of the environment. A high temperature that provokes sweating diminishes the amount of urine formed.
3. Body posture. The urinary volume increases in the horizontal position.
4. Exercise (see Chap. 47, Changes in Renal Function).

The color of urine is golden yellow, the intensity of which increases with the concentration. It has an aromatic odor, which varies with the nature of food taken. The specific gravity at 15°C. is usually between 1.015 and 1.020, but can be 1.002 when large quantities of urine are excreted and 1.040 when the volume is small. The osmotic pressure is usually far above that of blood plasma. The freezing point of urine varies from −0.9 to −2.7°C., while that of plasma is −0.56°C.

The urine of man on a mixed diet is slightly acid; the pH is about 6. This is due to the end products of protein metabolism, which give several acids on oxidation (see page 459). The food of herbivora, on the contrary, gives many basic end products. The salts of tartaric, malic, and citric acids when oxidized set free fixed base; because of this the urine of herbivorous animals is alkaline. The urine of man on a vegetarian diet also becomes alkaline. The extreme values of urinary pH are 4.8 and 8.2.

Chemical composition. The chemical composition of urine is extremely variable. Its constituent substances can be classified as (*a*) inorganic; (*b*) organic.

Inorganic constituents. The inorganic constituents of urine are the acid ions (chloride, sulfate, and phosphate) and the basic ions (sodium, potassium, calcium, magnesium, and ammonia).

Urinary *chloride* has its source in the chloride of the food. The normal daily excretion of Cl is 6 to 10 gm. A diet rich in chloride increases this excretion, which diminishes or even ceases on a chloride-free diet.

Urinary *sulfates* (of Na, K, Ca, Mg) are produced almost exclusively by the oxidation of sulfur-containing amino acids, cystine, and methionine. A high-protein diet will provoke an increase in urinary sulfate, which is normally about 2 gm. daily (expressed as SO_3).

Urinary *phosphates* (of Na and K, and smaller amounts of Ca and Mg) originate partly in the inorganic phosphate of the food, but mostly in the metabolism of phosphorus-containing substances such as phosphoproteins, phospholipids, nucleoproteins, etc. The total phosphate (as P_2O_5) excreted daily in the urine varies from 1 to 5 gm.; this amount is dependent on the phosphorus-containing substances ingested and on the elimination of Ca and Mg phosphates in the feces. Within the pH range found in urine only monobasic and dibasic phosphates can be found. The relative amount of each is conditioned by the pH; as the pH rises so does the B_2HPO_4, and on the contrary, as acidity increases the BH_2PO_4 also increases. When the urine is alkaline, Ca and Mg phosphates are precipitated.

The amount of *sodium* and *potassium* excreted is dependent on the diet. Normally 2 gm. of K and 4 gm. of Na are eliminated daily. There are only small quantities of *calcium* (0.2 gm. per day) and *magnesium* (0.15 gm. per day).

Ammonia is a normal constituent of urine; the daily excretion is about 0.7 gm. The amount of NH_3 in the urine is conditioned by the excess of acid over base excreted. An increase in acid formation (high-protein diet, diabetic acidosis, etc.) results in an increase in urinary ammonia.

Organic constituents. The principal organic constituents of urine are urea, uric acid, creatinine, hippuric acid, urinary indican, urinary pigments, and lactic acid.

Urea, the principal nitrogenous substance in the urine, is an end product of protein metabolism. The greater part of the urea excreted in the urine is the result of the metabolism of ingested protein. The total daily excretion of urea is normally 25 to 35 gm. daily, but it varies with the protein intake.

Uric acid is a product of nucleoprotein metabolism. The exogenous uric acid varies with the diet, the endogenous uric acid comes from tissue destruction. In mammals (excepting man, the anthropoids, and the Dalmatian coach hound)

the end product of nucleoprotein metabolism is *allantoin*, resulting from the oxidation of uric acid. The daily excretion is 0.6 to 0.9 gm. In acid urine, uric acid has a tendency to precipitate.

Creatinine (1 to 2 gm. daily) is a normal urinary constituent (see Chap. 43, Protein Metabolism).

Hippuric acid is formed in the body by the combination of benzoic acid ingested with the food and glycine, which is split off from the proteins in the food or synthesized in the body. In the dog the kidney synthesizes hippuric acid, but in man and most other animals this operation is principally carried out by the liver. The daily excretion is 0.1 to 1 gm.; it increases when the diet contains much fruit and vegetables.

Urinary indican (potassium indoxylsulfate) comes from the indole produced from tryptophane in the course of intestinal putrefaction. The indole is absorbed, and in the liver it is oxidized to indoxyl, which combined with sulfuric acid gives urinary indican.

The principal *urinary pigment* is *urochrome*, the nature and significance of which are not well known. There is also *urobilinogen* derived from bilirubin by reduction in the intestine; it is oxidized into urobilin. The total amount of both these pigments is not more than 0.5 mg. daily; larger quantities are abnormal. In certain diseases bilirubin, hemoglobin, etc., can be found in the urine. Dyes such as methylene blue, prontosil, etc., injected or taken by mouth can be excreted in the urine, giving it their peculiar color.

THEORIES OF RENAL FUNCTION

Apart from a few simple experiments performed by Galen, no significant work on the mechanism of the formation of urine was done before the second half of the nineteenth century. Up to that time there were only surmises based on anatomical data. Galen, who was convinced of the truth of Aristotle's dictum that "nature does nothing in vain," when writing on the renal arteries stated, "If it is not to purify the blood they carry, tell me why nature has made them so large and why do they penetrate and ramify, the same as the veins, right into the depth of the renal cavities." Malpighi,[1] who discovered in the renal cortex small globular capsules containing a capillary knot which hung from the small arterioles "like apples on the branches of a tree," deduced that in these capsules (Malpighi's bodies) the urine was formed and then carried to the renal pelvis by the renal tubes. Malpighi's conclusions were not accepted by some of the writers at the beginning of the nineteenth century, but in 1842 Bowman[1] demonstrated the continuity of the capsule, which is now known by his name, with the renal tubes; he studied the epithelium of these tubes and remarked on its similarity to that of other glands. Based on these observations he formulated the hypothesis that the cells of the renal tubes eliminate from the blood the specific urinary constituents (urea, uric acid, etc.), while water (and salts) are filtered through the walls of the glomerular capillaries. This filtrate furnishes the water needed for the separation of urinous products from the epithelium of the tube.

Two years later Ludwig,[2] the famous German physiologist, in opposition to this vitalistic or physiological theory proposed one that was purely mechanical. He considered the glomerulus as a filtration apparatus. His theory of renal function is essentially the following: The difference between the pressure in the capillary and that in the cavity of Bowman's capsule causes an ultrafiltrate of plasma to pass through the capillary wall, *i.e.*, water and all the crystalloids, not only water and salts as Bowman believed. On passing through the renal tubes this ultrafiltrate is concentrated by reabsorption of water and certain salts into the blood of the peritubular capillaries. The low hydrostatic pressure within the capillaries, and the high oncotic pressure due to the loss of water as the blood passes through the glomerulus, assure the reabsorption of water by a process of "endosmosis."

In 1874 Heidenhain[3] modified Bowman's theory. He stated that the glomerulus secreted water and salts and that the tubular cells also secreted additional salts, metabolic waste products, and foreign substances. He and his pupils performed a great number of experiments to prove that the rate of urine formation depended on the rate of blood flow and not on the blood pressure in the glomerular capillaries; they also

[3] HEIDENHAIN, R., *Arch. f. mikr. Anat.*, **10**, 1, 1874; in Hermann's "Handbuch der Physiologie," **5**, 318, F. C. W. Vogel, Leipzig, 1883.

demonstrated that dyes injected into the blood stream were excreted into the lumen of the tubes by the cells of the tubular epithelium. For many years the philosophical bias of the investigators with regard to vitalism or mechanism had as much weight as the experimental evidence to incline them in favor of one or other of these theories.

Cushny[1] proposed, in 1917, what he then called the "modern view." He admitted that the first step in the formation of urine is a process of filtration through the glomerulus of a fluid, similar to blood plasma by its content of crystalloids and water, but free from proteins. This ultrafiltrate is concentrated as it passes down the renal tube, because a fluid of constant composition is reabsorbed. This fluid, a perfected Locke's solution, is returned to the blood, while in the tube remain and are concentrated the waste products to be eliminated in the urine. The reabsorption of this optimal fluid, according to Cushny, was due to the "vital activity of the tubular epithelium." He denied the capacity of the cells to excrete into the lumen of the tubes.

THE MECHANISM OF RENAL FUNCTION

Thanks to the important work of Richards, Rehberg, Marshall, Smith, Winton, Shannon, and others[2] the following facts have been demonstrated:

1. There is a process of filtration through the walls of the glomerulus, by which a fluid is formed similar in composition to the blood plasma, but without proteins and other large molecules; in other words, the fluid is an ultrafiltrate of plasma (glomerular filtration).
2. Along the renal tube, water and several substances (glucose, chloride, phosphate, urea, etc.) are reabsorbed, each one by a more or less independent process (tubular reabsorption).
3. The cells of the renal tubes can excrete certain substances from the blood into the tubular fluid (tubular excretion).
4. The cells of the renal tubes can produce certain substances and secrete them into the blood stream (renin) or into the tubular fluid (ammonia, hippuric acid).

[1] CUSHNY, A. R., "The Secretion of Urine," Longmans, New York, 1917.

[2] See the bibliography at the end of the chapter.

Each one of these functions of the kidney will now be considered in detail.

Glomerular Filtration

In the glomeruli, water and the crystalloids in the plasma are filtered through the glomerular
FIG. 291. Diagram of Richards' method for obtaining samples of glomerular filtrate.

membrane. Blood pressure is the only force acting in this process of simple ultrafiltration; the cells of Bowman's capsule and the capillary epithelium do not take an active part.

There is ample evidence of the truth of this statement. Ludwig and his pupils had demonstrated the relation between blood pressure and the amount of urine excreted. Heidenhain, who defended the secretory theory, maintained that variations in blood pressure were paralleled by variations in the rate of blood flow and that this was the important factor in determining the amount of urine secreted by the cells of the malpighian body. Later experiments by Richards and Plant[1] and others have shown that when a constant blood flow is maintained, the volume of urine diminishes when the blood pressure is lowered and vice versa.

Filtration takes place when the blood pressure in the glomerular capillaries is greater than the sum ot the osmotic pressure of the plasma proteins plus the pressure in Bowman's capsule:

$$Pb - (Po + Pc) = Pf$$

where Pb is the blood pressure, Po is the osmotic pressure of the plasma proteins, Pc is the hydrostatic pressure in Bowman's capsule, and Pf is the effective filtration pressure (Fig. 292).

[1] RICHARDS, A. N., and O. H. PLANT, *Am. J. Physiol.*, **59**, 144, 1922.

Many experiments have demonstrated the existence of this effective filtration pressure; *i.e.*, that the blood pressure exceeds the pressure opposed to the process of filtration and that the amount of filtrate is conditioned by the value of this effective pressure.

AFFERENT EFFERENT
BP 75 - OP 30
CAPS P 5
EFP 40
FIG 292. Diagram of factors in glomerular filtration.

Hayman[1] made direct measurements of the glomerular capillary pressure in the frog's kidney and found that it was 54 per cent of the mean aortic pressure. Winton[2] arrived at a similar figure (65 per cent) in the dog, using an indirect method. The osmotic pressure of the plasma proteins was first determined by Starling and others, who found values between 20 and 30 mm. Hg. The pressure in Bowman's capsule has been calculated to be from 5 to 10 mm. Hg. If the mean aortic pressure is 125 mm. Hg and the glomerular capillary pressure is 60 per cent of the aortic pressure, the effective filtration pressure is 40 mm. Hg.

$$Pb - (Po + Pc) = Pf$$
$$75 - (30 + 5) = 40$$

When the aortic pressure falls to 40–50 mm. Hg, and therefore *Pb* is only 24–30 mm. Hg, urine is not produced. The same result is obtained by artificially increasing the pressure in the ureter. On the other hand if the osmotic pressure of the plasma proteins is lowered by intravenous injection of saline solution, the urinary volume increases, and urine formation continues even when the blood pressure falls to 20 mm. Hg.

The pressure in the glomerular capillaries can change independently of the aortic pressure. This can occur when there is relaxation of the afferent arteriole; the resistance to the passage of blood into the glomerular capillaries is diminished, and thus the pressure in these capillaries rises. This takes place when the renal nerves are cut or when a drug that dilates the afferent arterioles is injected. Constriction of the efferent arteriole also increases the glomerular capillary pressure (adrenaline, splanchnic stimulation). Constriction of the afferent arteriole and dilatation of the efferent arteriole decrease the glomerular capillary pressure. Intravenous injection of Ringer's solution in the cat or the dog increases considerably the urinary flow without changing the oxygen consumption of the kidney. If the urine were formed by a process of secretion, there should be parallel changes in the urinary flow and the oxygen consumption, as the latter is conditioned by the activity of the cells.

The injection of proteins of different molecular weight has shown that the glomerular membranes are permeable to the smaller molecules. Thus, for example, hemoglobin (molecular weight, 68,000), egg albumen (35,000), Bence Jones protein (35,000), and gelatine (35,000) pass through the glomerular membranes, while serum albumin (70,000), serum globulin (170,000), casein (200,000), etc., do not. These data have served to indicate the size of the pores of the glomerular membrane, which is approximately 50A. When there is a pathologic disturbance that increases the permeability, serum albumin can be passed into the urine, but the larger serum globulins or fibrinogen very rarely filter through.

All these experiments are evidence in favor of the theory that in the glomerulus a process of simple filtration takes place. Richards and his collaborators have given a direct demonstration of this process of filtration. They used Chambers' technique of microdissection to obtain fluid from Bowman's capsule in the frog and necturus (Fig. 291). They then developed special methods to analyze the minute amounts of fluid collected

and compared their composition with that of the blood plasma. They found that the fluid in Bowman's capsule in the frog and necturus is slightly alkaline, is free from protein, and contains glucose, chloride, and potassium, while the urine in these animals is acid and has neither glucose nor chloride. The capsular fluid has the same osmotic pressure, the same electrical conductivity, the same pH, and the same concentration of urea, glucose, inorganic phosphate, creatinine, and uric acid as the blood plasma. The concentration of chloride is somewhat higher, a fact that can be due to the Donnan equilibrium.

Until recently these experiments, which give a brilliant demonstration of glomerular filtration, could be held valid only for amphibians, and it was not legitimate to deduce from them that in mammals there is a similar process. Now, experiments in rats and guinea pigs have confirmed the fundamental facts found in amphibians. There is therefore sufficient evidence to maintain that through the glomerular capillaries a fluid free from proteins, containing the same crystalloids in the same concentration as in the blood plasma, is passed. This is exactly what occurs in the process of ultrafiltration of plasma through a semipermeable membrane.

Tubular Reabsorption

A comparison between the composition of the blood plasma, which is almost the same as that of the glomerular ultrafiltrate, and that of urine obtained from the bladder (Table 83) shows that some of the components of the plasma (or the glomerular ultrafiltrate) are not found in the urine (*e.g.*, glucose), others have been considerably concentrated, and others are in almost the same concentration in plasma and urine.

Table 83. Chemical Composition of Blood Plasma and of Urine

Constituent	*Blood plasma, mg. per 100 cc.*	*Urine, mg. per 100 cc.*	*Change in concentration in kidney*
Glucose	100		
Urea	30	2,000	60
Uric acid	2	50	25
Na	320	350	1
K	20	150	7
Ca	8	15	2
Mg	2.5	6	2
Cl	370	600	2

Fig. 293. *a*, collection of fluid from the upper (*A*), middle (*B*), and lower (*C*) portions of the renal tubes of necturus; *b*, perfusion of a single proximal tube of necturus. The shaded parts represent droplets of mercury placed to seal the tubes.

To explain the disappearance of glucose from the ultrafiltrate, it is necessary to admit that it has been reabsorbed as it passes down the renal tube. Changes observed in other components can be explained in either of two ways: (*a*) the tubes excrete concentrated solutions of some substances which are added to the glomerular ultrafiltrate; (*b*) the tubes, besides water, reabsorb selectively some of the substances in the glomerular filtrate, and the urine is the resulting residue of this filtrate.

Richards and his collaborators have given conclusive proof of reabsorption in the renal tubes of amphibians and mammals. Most of their experiments were made by collecting the fluid at different and well-located levels of the renal tube of the necturus, which has larger and less sinuous tubes than the frog (Fig. 293). To avoid contamination of the fluid in one part of the tube by that of other parts, the segment was blocked with a droplet of mercury placed in the lumen.

This method showed in the first place that the renal tubes of the necturus do not excrete water, as no fluid was collected from a segment separated from the glomerulus. The urine of this amphibian is extremely hypotonic; the fluid collected from the proximal tube and the intermediate segment had the same total concentration and chloride concentration as the blood plasma; on the other hand the fluid in the distal tube became more and more hypotonic, a fact that can be explained only by the reabsorption of osmotically active substances, especially of sodium chloride (Fig. 294). The urine becomes acid in the middle third of the distal tube. Glucose is reabsorbed almost exclusively in the proximal tube, and phlorhizin inhibits this process (Fig. 295). These experiments show that at least glucose and sodium chloride are reabsorbed in the tubes.

Walker and his collaborators[1] have obtained glomerular and tubular fluid from the kidneys of mammals (rat, guinea pig, and opossum) and have analyzed them by the microchemical methods employed by Richards, comparing the results with those obtained by the chemical analysis of blood plasma. The exact localization of the place punctured to collect the fluid is determined by subsequent dissection and isolation of the nephron. The fluid obtained from the glomerulus is usually free from protein; but even slight injuries can modify the permeability of the glomerular membrane and thus protein passes into the fluid. The concentration of glucose in the glomerular fluid is similar to that in the plasma (Fig. 296). It diminishes rapidly in the fluid obtained from successively lower levels of the proximal tube and disappears completely in the middle part of this segment. The reabsorption of glucose takes place in mammals, as in amphibians, in the first half of the proximal tube. Experiments in mammals injected with phlorhizin showed that this drug suppressed the reabsorption of glucose, as it did in amphibians; but in this case the concentration of glucose not only did not diminish, but increased progressively down the tube (Fig. 296). As there is no secretion of glucose, this increase can only be due to reabsorption of water. In experiments in rats and guinea pigs injected with 300 to 500 mg. per kg. of creatinine, an increasing concentration of this substance was found as the fluid progressed down the proximal tube. It has been calculated that, of 100 cc. filtered by the glomerulus, 80 cc. is reabsorbed in the proximal tube.

Two important facts have been observed by making a comparative study of the osmotic pressure and the chloride concentration in the tubular fluid with that of plasma:

1. The osmotic pressure of the tubular fluid does not change in the proximal tube, nor even in the first part of the distal tube. As a great amount of fluid is reabsorbed in the proximal tube, the reabsorbed fluid must have the same osmotic pressure as the plasma. The few results so far obtained by puncture of the distal tube seem to show that the reabsorption of water that results in the concentration of the urine takes place in the last part of the distal tube and not in Henle's loop as it was supposed up to now (Fig. 297).
2. Although an isosmotic fluid is reabsorbed in the proximal tube, chloride concentration increases progressively down this tube, but in the bladder the chloride concentration of the urine is lower than that of blood plasma. To explain these facts, it must be admitted (*a*) that there is an active and selective reabsorption in the proximal tube (the osmotic pressure does not change, although there is an increase in chloride concentration; therefore some other electrolyte, perhaps bicarbonate, is preferentially reabsorbed); (*b*) that there is reabsorption in the distal tube of a fluid that contains 1.4 the chloride concentration of the plasma (Fig. 297). Recent work[1] by Wesson, Anslow, and Smith has brought forward evidence in support of the hypothesis that a fluid isosmotic to blood plasma is reabsorbed in the proximal tube. Reabsorption of sodium in the proximal tube, however, does not depend on the reabsorption of water; therefore a fluid, the composition of which is constant, is not reabsorbed by this part of the renal tube, as was supposed by Cushny, and suggested by Pitts and Lotspeich[2] in the case of bicarbonate and chloride.

[2] Pitts, R. F., and W. D. Lotspeich, *Am. J. Physiol.*, **138**, 147, 1946; Lotspeich, W. D., R. C. Swan, and R. F. Pitts, *Am. J. Physiol.*, **148**, 445, 1947.
Fig. 294. Chloride and molecular concentrations in the glomerular filtrate are identical to those in plasma. In the proximal tube this identity is preserved; in the distal tube, chloride and necessarily sodium are reabsorbed. (*Adapted from Walker, A. M., C. L. Hudson, T. Findley, and A. N. Richards, Am. J. Physiol., vol. 118, p. 121, 1937.*)
Fig. 295. The glucose in the glomerular filtrate is normally reabsorbed in the proximal tube of the necturus and frog. Adequate doses of phlorhizin block the tubular reabsorption of glucose, and as water is reabsorbed, glucose is concentrated in the proximal tube. (*Walker, A. M., and C. L. Hudson, Am. J. Physiol., vol. 118, p. 130, 1937.*)
FIG. 296. Ratio of glucose (with and without previous phlorhizin injection) and creatinine concentration in plasma, in glomerular filtrate, and in the proximal tube. (*Walker, Bott, Oliver, and MacDowell, Am. J. Physiol., vol. 134, p. 562, 1941.*)
FIG. 297. Ratios of Cl and Na concentrations and osmotic pressure in blood plasma, glomerular filtrate, proximal and distal tubes, and in the bladder. On the left the figures correspond to glomerular filtrate and on the right to the bladder urine. (*From Walker, Bott, Oliver, and MacDowell, Am. J. Physiol., vol. 134, p. 562, 1941.*)

According to Wesson and his associates (Fig. 298), sodium, chloride, and bicarbonate are reabsorbed from the proximal tube by an active process which leaves a hypotonic fluid in the tube; water from this fluid is then reabsorbed passively. The functional significance of the thin segment would consist in the establishment of conditions favorable for the reabsorption of water, so that a fluid isosmotic to blood plasma would enter the distal tube. Approximately seven-eighths of the glomerular filtrate is reabsorbed in the proximal tube and the thin segment. Water and sodium are reabsorbed actively in the distal tube by processes which are independent of each other and which have a maximum that is not surpassed. The antidiuretic hormone promotes reabsorption of water in the distal tube.

FIG. 298. Passive and active reabsorption in the renal tubes.

TUBULAR EXCRETION

The expression "tubular excretion" will be used to signify the process by means of which the tubular cells take substances from the blood and discharge them into the lumen of the tubes. The word "secretion" would be equally appropriate, because the renal cells must perform work to transport substances from the blood to the urine. The word "excretion" is preferred because the process consists in the elimination of substances that have no longer any function in the organism.

Since the time of Heidenhain, many experiments have been made to prove the excretion of substances by the renal tube, which would in this way contribute to the formation of urine. Heidenhain injected indigo carmine intravenously under certain experimental conditions; the animals were killed and the kidneys examined microscopically; the pigment was found in the lumen of the tubes and in the cells of the proximal tube. This result would be obtained whether the dye were secreted by the cells, or filtered by the glomerulus and reabsorbed in the tubes.

The first conclusive demonstration that the tubes can excrete certain substances was given by Marshall and Grafflin[1] and by Edwards and Condorelli;[2] later Homer Smith and his collaborators gave further evidence of this property of the tubes. They studied the formation of urine in teleostean fishes, the kidneys of which have no glomeruli (aglomerular fishes) but consist essentially of tubes lined by an epithelium similar to that which lines the proximal tubes in amphibians and mammals. Water, creatine, creatinine, urea, uric acid, magnesium, potassium, sulfate, chloride, and several foreign substances are excreted. In these animals tubular excretion is the only mechanism for the formation of urine. On the other hand, they cannot excrete glucose and other carbohydrates, even after phlorhizin has been injected. The work in comparative anatomy and physiology of these investigators seems to prove that in the course of phylogenetic development the capacity

[1] MARSHALL, E. K., and A. L. GRAFFLIN, *Bull. Johns Hopkins Hosp.*, **43**, 205, 1928.

[2] EDWARDS, J. G., and L. CONDORELLI, *Am. J. Physiol.*, **86**, 383, 1928.

to excrete carbohydrate has never appeared in the renal tubes.

Chambers and Kempton[1] have also given a demonstration of tubular excretion. They cultivated *in vitro* the renal tubes of chick embryos. The extremities of the tubes are soon closed and the lumen is filled with fluid. Small quantities of phenol red (phenolsulfonphthalein) added to the culture medium are taken up by the tubular cells and excreted into the lumen of the tube, where the dye becomes considerably concentrated. On the other hand, phenol red injected into the tubes does not pass out into the culture medium.

To know if a substance in the urine is concentrated exclusively by the reabsorption of water or also by its excretion into the tubes, it is necessary to compare its concentration with that of a substance that is neither reabsorbed, nor excreted, nor synthesized by the tubes. Such a substance is glucose in animals intoxicated with phlorhizin. Let it be supposed that in an animal injected with phlorhizin the glucose concentration in blood is 100 mg. per cent and in urine 300 mg. per cent; glucose is therefore three times more concentrated in the urine than in the blood. If in the same experiment urea concentration in blood were 50 mg. per cent and in urine 400 mg. per cent, therefore eight times more concentrated, part of it must have been excreted by the tubes. If another substance (*e.g.*, inulin, creatinine) were concentrated three times, it would neither be reabsorbed nor excreted by the tubes; if yet another substance (*e.g.*, chloride) were found in the urine in the same concentration as in the blood it must have been reabsorbed in the tubes. There is satisfactory evidence that in the phlorhizinized animal glucose is neither reabsorbed nor excreted by the tubes; nevertheless these experiments are open to the objection that phlorhizin may disturb other functions of the tubes beside the reabsorption of glucose, and theretore in normal conditions the tubes perhaps behave in a different way. Further on it will be seen that there are other substances, among which is inulin, that are filtered through the glomerulus and are neither reabsorbed, nor excreted, nor synthesized by the tubes, nor do they disturb tubular functions.

In the phlorhizinized frog the ratio of the concentrations of glucose in urine and plasma (U/P) is 2.7:1; the concentration of urea in the urine is seven to eight times that of the plasma. This proves that in this amphibian urea is, at least in part, excreted by the tubes.

[1] Chambers, R., and R. T. Kempton, *J. Cell. & Comp. Physiol.*, **3**, 131, 1933.

The evidence for tubular excretion is therefore sufficient to admit that it exists, but the conclusions so far accepted cannot be applied to man in their entirety without further examination. Undoubtedly in mammals and in man the tubes can excrete certain substances, but "in respect to the relative importance of glomerular filtration, tubular reabsorption and tubular excretion, the human kidney must be examined on its own rights—and, in fact, the normal human kidney may be expected to differ considerably from the kidney that is altered by disease" (Homer Smith).

Active renal tubular transport. For a substance in solution to pass through an epithelium against the concentration gradient, the cells must perform work, the energy for which is obtained from intracellular metabolic processes. This type of secretion or absorption has been called "active transport."

The enzyme systems which take part in renal tubular active transport (secretion or absorption) are not yet well known. There is indirect evidence that glucose is reabsorbed in the proximal tube by successive processes of phosphorylation and dephosphorylation, activated by phosphorylase. Aerobic phosphorylation, according to Taggart,[1] Mudge, and others, plays a part in the excretion of para-aminohippurate, diodrast, and phenol red. Excretion of these substances is inhibited in the dog by 2,4-dinitrophenol, an inhibitor of aerobic oxidation and phosphorylation coupling in certain enzyme systems. Acetate and, to a lesser degree, pyruvate and lactate, which stimulate respiratory metabolism in slices of kidney, increase the rate of accumulation of para-aminohippurate in kidney slices; they also increase the maximum tubular excretion capacity for this substance.

Acetate seems to be an essential component of the enzyme system of tubular excretion. As it is found in very low concentrations in the cells and organic fluids, it is perhaps the limiting factor in tubular transport of the substances mentioned above.

Renal Clearance Tests

A method that has given important results in the study of renal function in man and other mammals is the determination of the renal clearance tests.

Ambard[1] made an experimental study of the relations between the supply and output of urea, and formulated his third law: "If the concentrations of urea in the blood and in the urine are both variable, the output of urea $(U \times V)$, in grams per 24 hr. is directly proportional to the square of the concentration of urea in the blood (P) in grams per liter, and inversely proportional to the square root of the concentration of urea in the urine (U) in grams per liter." This law can be expressed as follows:

$$(U \times V) = K \frac{P^2}{\sqrt{U}}$$

$$K = \frac{P}{\sqrt{(U \times V)\sqrt{U}}}$$

The constant K, called by Ambard the "ureosecretory constant," commonly known as "Ambard's constant," was used for many years to measure the functional capacity of the kidney. The value of K is 0.07 in a normal man of 70 kg. weight; in cases of renal insufficiency, K increases.

Later work showed that Ambard's laws were not strictly accurate. Austin, Stillman, and van

Fig. 299. "Standard" and "maximal" urea clearance and their relation to the filtration rate (*Smith, H. W., "The Physiology of the Kidney," Oxford University Press, New York, 1937.*)

The excretory activity of the kidney can be determined by measuring the total amount of a given substance eliminated in standard time. This is the renal output, easily calculated by multiplying the amount of urine secreted in 1 min. by the concentration of the substance in the urine. For example, if the rate of urinary secretion is 2.2 cc. of urine per minute (V), and if it contains 10 mg. of urea per cc. (U), the output of urea will be $2.2 \times 10 = 22$ mg./min.

The output is conditioned by the functional capacity of the kidney, but the most important factor is the concentration of the substance in the plasma (P), *i.e.*, the supply. This is easily understood if a substance that filters through the glomerulus is considered, and only its concentration in the glomerular filtrate is taken into account; thus if the ultrafiltrate is produced at a constant rate of 100 cc. per min. and the concentration of the substance in the plasma is 5 mg. per cent, the glomerular output will be 5 mg. per min.; if the concentration in the plasma is 10 mg. per cent, the output will be 10 mg. per min.

[1] Ambard, D., and A. Weill, *J. de physiol. et de path. gén.*, **14**, 753, 1912.

Slyke[1] observed that when the flow of urine was below 2 cc. per min. (the augmentation limit) the output of urea was proportional to the square root of the urine flow and not to the square root of the concentration of urea in urine, as Ambard had stated. When the urine flow was more than 2 cc. per min. (Fig. 299), the output of urea was directly proportional to the concentration of urea in the plasma (*i.e.*, to the supply), $U \times V = KP$, and the ratio of output to supply is constant $UV/P = K$. For example, if for a concentration of urea in plasma of 0.03 gm. per cent the output is 0.022 gm. per min., for a concentration of 0.06 gm. per cent, the output will be 0.044 gm. per min., etc.

What does this constant signify? Still using the figures in the example given, with an output of 0.022 gm. per min., urea concentration in urine 1 gm. per cent (U), urine flow 2.2 cc. per min. (V), and urea concentration in plasma 0.03 gm. per cent (P), the following result is obtained:

$$\frac{UV}{P} = K$$

$$\frac{1 \times 2.2}{0.03} = 73$$

where U is the concentration of urea in urine in grams per cent, P is the concentration of urea in plasma in grams per cent, and V is the urine flow in cubic centimeters per minute.

[1] AUSTIN, J. H., E. STILLMAN, and D. D. VAN SLYKE, *J. Biol. Chem.*, **46**, 91, 1921.

K is therefore the virtual quantity of plasma, in cubic centimeters, that would be completely deprived or cleared of urea by the activity of the kidney during 1 min.; in other words, the volume of plasma, in cubic centimeters, which contained the urea (or any other substance) excreted by the kidney during 1 min. The term "clearance" was first used in this sense by van Slyke and his collaborators[1] as an expression of renal function.
FIG. 300. Diagram illustrating the physiological concept of renal clearance. (*Smith, H. W., "The Physiology of the Kidney," Oxford University Press, New York, 1937.*)

The renal clearance of a substance is determined in the following way: The bladder is washed and completely evacuated, preferably by catheter. The urine excreted during a given time is collected and measured, and the concentration of the substance in the urine is determined. Several samples of blood are drawn at frequent intervals during the course of the experiment, and the concentration of the substance is determined. These values are plotted against time, and the concentration in blood at the middle of the period during which the urine is collected is accurately established. When the substance in question is not normally found in the blood, or exists in very small amounts, a certain quantity is injected or given

[1] MÖLLER, E., J. F. MCINTOSH, and D. D. VAN SLYKE, *J. Clin. Investigation*, **6**, 427, 1928.

by mouth. A constant plasma concentration can be kept up by continuous intravenous infusion of the substance.

The renal clearance of any substance can be determined. Experiments in man and in animals have demonstrated that this is an accurate and sensitive method of determining the conditions of renal function. Moreover by comparing the clearance of different substances several facts have been discovered, which are of importance in the understanding of renal function.

Not all substances have equal clearances. For example, urea clearance is 75 (*i.e.*, 75 cc. of plasma contain the urea eliminated in 1 min. of renal activity); inulin clearance is from 120 to 130; diodrast[1] clearance is 500 to 600. As will be shown later, the differences in clearance are due to the different ways in which the kidneys eliminate these substances. There are three possible ways in which this elimination can be performed: (*a*) glomerular ultrafiltration; (*b*) glomerular ultrafiltration and tubular excretion; (*c*) glomerular ultrafiltration and tubular reabsorption.

A substance in the plasma that filters through the glomerulus but is completely reabsorbed in the tubes is not found in the urine, *e.g.*, glucose in normal conditions. In this case the clearance will be zero (Fig. 300*A*). If tubular reabsorption is incomplete (urea), the substance will appear in the urine and its clearance will increase as reabsorption diminishes (Fig. 300*B* and *C*). If there is no reabsorption (inulin) the clearance will be equal to the volume of the glomerular filtrate in 1 min., *i.e.*, the rate of glomerular filtration (Fig. 300*D*).

This last case can be better understood by taking an example. Suppose the glomeruli filter at the rate of 125 cc. per min., and a substance that passes through the glomerulus and is not reabsorbed by the tubes is found in the plasma in a concentration of 100 mg. per cent. In 1 min., 125 mg. of the substance will pass into the tubes, where water will be reabsorbed. The volume of urine excreted per minute will be much smaller than that of the glomerular filtrate, but the substance will be eliminated in the urine at the rate of 125 mg. per min. If the rate of excretion of urine is 10 cc. per min., the concentration of the substance will be 1,250 mg. per cent; if it is 2 cc. per min., it will be 6,250 mg. per cent; but in any case $UV = 12{,}500$, and as $P = 100$, $UV/P = 12{,}500/100 = 125$ cc. In this case the plasma volume that contained the amount of substance eliminated, *i.e.*, the clearance, *equals the volume of glomerular filtrate* (Fig. 301).

In the case of a substance that not only filters through the glomerulus but also is excreted by the tubes, the clearance will increase with the tubular excretion. Maximum or complete clearance is reached when all the blood that passes through the kidney has been cleared of the substance (Fig. 300*X*), thus no longer containing any when it leaves the kidney by the renal vein. In this case the *clearance equals the volume of plasma that flows through the kidney in 1 min.* (renal plasma flow). Actually the clearance for most substances is well below the plasma flow.

The clearance of any substance considered by itself would therefore have little value, as different excretory operations take part in the elimination of the substance. On the other hand if a substance has a clearance equivalent to the glomerular filtration rate, it can serve by comparison with the clearances of other substances to determine what factors play a part in the elimination of these. Glucose clearance in the phlorhizinized animal is equivalent to the glomerular filtration volume, but this method has drawbacks that have already been discussed.

Glomerular Filtration Rate

According to Smith,[1] a substance suitable for measuring the glomerular filtration rate must fulfill certain specifications:

1. It must be completely filterable at the glomerulus; *i.e.*, its molecular size must be such that it can pass through the glomerular membranes, and it must not combine with the unfilterable plasma proteins.
2. It must not be reabsorbed, excreted, or synthesized by the tubes.
3. It must be physiologically inert, so as not to produce any damage to the organism in general and to the kidney in particular.
4. It must be of a chemical nature such that its concentration in plasma and urine can be easily and accurately determined.

[1] 3:5 diiodo-4-pyridon-N-acetic diethanolamine.

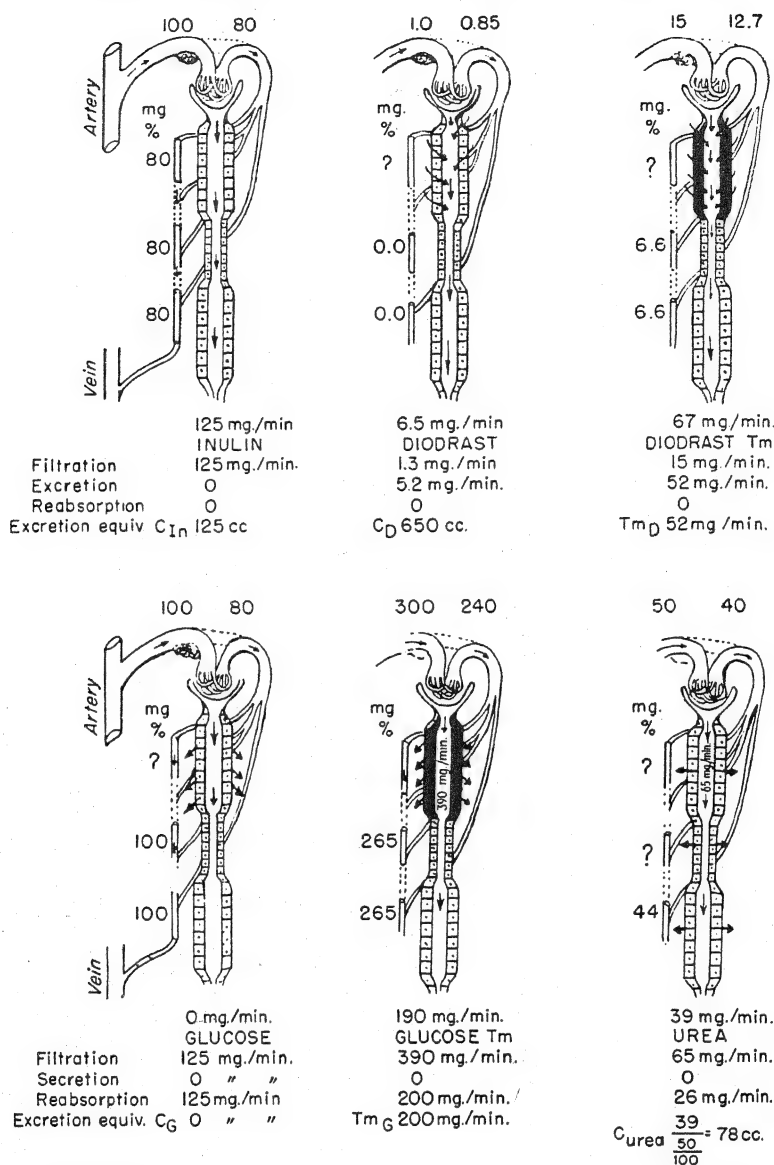
[1] Smith, H. W., "The Physiology of the Kidney," Oxford, New York, 1937.


FIG. 301. Diagrams illustrating mechanisms of inulin, diodrast, glucose, and urea excretion. One nephron is diagrammatically represented, and the concentration, in milligrams per cent, of the different substances in plasma, the afferent and efferent arterioles, and the renal vein. The arrows indicate the direction in which the substance goes. The blackened parts represent cells functioning at a maximum. The figures given are only approximately those observed. C_{In}, C_D, and C_G represent inulin, diodrast, and glucose clearances, respectively; Tm_D and Tm_G, diodrast and glucose tubular mass. (*Adapted from Corcoran, A. C., West. J. Surg., vol. 51, p. 622, 1942.*)

Rehberg,[1] who was the first to measure the glomerular filtration rate using such a substance, believed that creatinine fulfilled the requisite conditions. Later work showed that in man creatinine is in part excreted by the tubes; therefore its clearance is greater than the glomerular filtrate. In the dog, rabbit, rat, sheep, and seal it is eliminated exclusively through the glomerulus and is not reabsorbed by the tubes.

Smith and his collaborators[1] and Richards

[1] REHBERG, P. B., *Biochem. J.*, **20**, 447, 1926.

[1] JOLIFFE, N., J. A. SHANNON, and H. W. SMITH, *Am. J. Physiol.*, **100**, 301, 1932; SMITH, H. W., The Excretion of

and his collaborators,[1] independently of each other, found that inulin is one of the substances that most satisfactorily corresponds to the specifications required for measuring the glomerular filtration rate.

FIG. 302. Diagrams illustrating clearance of several substances.

Inulin is a polysaccharide similar to starch, which on hydrolysis gives fructose. It is almost insoluble in cold water but is dissolved by hot water, which on cooling gives a supersaturated solution. It cannot be given by mouth, as creatinine can, but must be injected, because the digestive enzymes destroy it. The molecular weight of inulin is 5,000, the equivalent of 32 molecules of hexose. It is inert, and the blood has no enzymes that destroy it. The glomerular membranes do not retain inulin, but because of the size and elongated shape of its molecules it does not diffuse through the tubular walls. Besides creatinine and inulin, manitol, sodium thiosulfate, and several other substances have been used to measure the glomerular filtration rate.

Inulin clearance in a man of 1.73 sq. m. body surface is around 120. This means that the glomerular filtration rate is 120 cc. per min.; therefore 170 liters per day. The volume of urine excreted per day is 1.5 liters. Therefore 168.5 liters, 99 per cent of the glomerular filtrate, is reabsorbed by the renal tubes.

In basal conditions the glomerular filtration rate is fairly constant. The variations in the volume of urine excreted are therefore due to variations in water tubular reabsorption, which, as shown later, is regulated by the hypophysis.

By comparing the clearance of a substance x with that of inulin, many useful facts on the mechanism of excretion of the substance in question can be obtained. Thus if the ratio of x clearance to inulin clearance is less than 1:1, x is reabsorbed by the tubes. If this ratio equals 1:1, x is simply filtered at the glomerulus. If the ratio is greater than 1:1, x is not only filtered through the glomerulus but also excreted by the tubes.

Urea clearance, when the rate of urine excretion is above 2 cc. per min. (maximum urea clearance), is 75 cc. The ratio of urea clearance to inulin clearance is $75/120 = 0.6$, showing that urea is filtered through the glomerulus and then reabsorbed in part in the tubes, apparently by simple diffusion (Figs. 301, 302, and 303).

Renal Plasma Flow

Diodrast is an organic iodine compound used for x-ray visualization of the urinary tract. Its clearance is considerably greater than that of inulin; therefore besides filtering through the glomerulus it is excreted by the tubes. When the plasma concentration of diodrast (calculated from the plasma concentration of iodine) is high, its clearance equals UV/P. When its concentration in plasma decreases (*i.e.*, when the value of P decreases), the clearance increases up to a maximum reached when the plasma iodine is about 0.8 to 2 mg. per cent. When the plasma

Non-metabolized Sugars in the Dogfish, the Dog and Man, in Berglund and Medes, "The Kidney in Health and Disease," Lea & Febiger, Philadelphia, 1935.

[1] RICHARDS, A. N., P. B. WESTFALL, and P. A. BOTT, *Proc. Soc. Exper. Biol. & Med.*, **32**, 73, 1934.

concentration is below 2 mg. per cent there is complete plasma clearance of diodrast, *i.e.*, there is none in the blood of the renal vein (Fig. 301). The diodrast clearance (C_D) in this case equals the total plasma flow through the active renal tissue. The average flow in man is 669 cc. per min.[1] The blood flow through the kidney can be calculated by determining the plasma-cell ratio in the hematocrit. On an average, the blood flow is 1,115 cc. per min. If these determinations are accurate, approximately 25 per cent of the cardiac output (±5 liters per min.) goes to the kidneys, although these organs make up only 0.42 per cent of the body weight.

The renal circulation has a considerable degree of autonomy. The blood flow through the kidney is not greatly influenced by changes in blood pressure, even after the renal nerves have been cut. There are only three known ways of increasing the renal blood flow: (*a*) unilateral nephrectomy in the dog and in man causes an increase of 50 to 70 per cent in the renal blood flow of the remaining kidney; (*b*) in the unilaterally nephrectomized dog a meat diet increases the renal blood flow (*c*) certain pyretic agents (antityphoid vaccine, pyrogenic inulin) increase the renal blood flow in man.[2]

THE TUBULAR EXCRETORY MASS

When the diodrast concentration in plasma increases, its clearance diminishes (Figs. 302 and 303). At a plasma-iodine concentration of 30 mg. per cent or more, the tubes are excreting at full rate, and tubular excretion of diodrast reaches a maximum that cannot be surpassed. The amount of diodrast excreted ($U \times V$) in milligrams of iodine per minute, minus the amount eliminated by glomerular filtration (which can be calculated from the inulin clearance, the concentration of diodrast in blood, and a factor dependent on the concentration of albumin in plasma, which is 0.72 ± 0.025), gives the maximum amount excreted by the renal tubes. This amount is expressed in milligrams of iodine excreted per minute (on an average, 51.6 mg.) and is called the tubular excretory mass (T_m) (Fig. 301).

Smith and his collaborators[1] have found other substances that behave like diodrast and can therefore be used to measure the renal plasma flow and the tubular excretory mass. The one most frequently used is the sodium salt of para-aminohippuric acid.

Not only can the tubular excretory mass be measured, the maximal rate of reabsorption can also be determined. For example, there is satis-

[1] SMITH, H. W., N. FINKELSTEIN, L. ALIMINOSA, B. CRAWFORD, and M. GRABER, *J. Clin. Investigation,* **24**, 388, 1945.

FIG. 303. Variations in diodrast and glucose clearances when the plasma concentration of these substances increases.

factory proof that when the concentration of glucose in blood is sufficiently high, the rate of reabsorption of glucose by the tubes reaches a maximum that cannot be surpassed[1] (Figs. 302 and 303). The maximal reabsorption rate of glucose by the proximal tubes can thus be measured (Fig. 301). This constant maximal reabsorption rate of glucose is determined by the clearance methods and is known as the glucose Tm. It is interesting to note that the simultaneous determination of the Tm of glucose and that of para-aminohippuric acid shows a reciprocal depression of both functions. This seems to occur with many other substances, and the fact has been used to retard the excretion of certain drugs by the renal tubes (*e.g.*, penicillin). The depression is attributed to competition for the available cellular energy, more than to competition for a substance in the cell which takes part in both the process of tubular reabsorption and that of excretion.

Table 84. Mean Values of Renal Functional Measurements in Normal Subjects, by Sex

Measurement	*Males*		*Females*	
	Number of subjects	*Mean value*	*Number of subjects*	*Mean value*
Rate of glomerular filtration (inulin clearance, C_{In}), cc. per min	67	131 ± 21.5	21	117 ± 15.6
Effective renal plasma flow (diodrast clearance, C_D), cc. per min	61	697 ± 135.9	17	594 ± 102.4
Maximal tubular excretory capacity (diodrast Tm, Tm_D), mg. iodine per min	40	51.8 ± 8.73	14	42.6 ± 9.46
Maximal tubular reabsorptive capacity (glucose Tm, Tm_G), mg. glucose per min	24	375 ± 79.7	11	303 ± 55.3
Filtration fraction, C_{In}/C_D	61	0.19 ± 0.02	17	0.20 ± 0.03
$\frac{\text{Effective renal plasma flow}}{\text{Maximal tubular excretory capacity}} \left(\frac{C_D}{Tm_D}\right)$	34	14.0 ± 2.16	14	14.2 ± 2.36

Renal indexes. The ratio of diodrast clearance to diodrast tubular mass, C_D/Tm_D, expresses the virtual quantity of plasma completely cleared of diodrast by each unit of excretory tissue taking part in the operation. This ratio is fairly constant in normal subjects, and it gives a more accurate picture than the ratio of C_D to the body surface, as there is no constant ratio of kidney weight to body surface, and the amount of active tissue varies. When C_D/Tm_D is below normal there is renal ischemia.

The ratio of inulin clearance to diodrast clearance, C_{In}/C_D, known as the "filtration fraction," indicates the relative amount of plasma filtered through the glomerulus and gives information on the tone of the glomerular efferent arterioles. When the glomerular capillary pressure increases because of constriction of the efferent arterioles, C_{In}/C_D increases, and vice versa.

An increase in renal blood flow caused by a pyretic substance is accompanied by a decrease in the filtration fraction; it is therefore due in great part to dilatation of the efferent arterioles. On the contrary, orthostatic vasoconstriction and that produced by adrenaline injection or of psychic origin are accompanied by an increase in the tone of the efferent arteriole and therefore an increase in the filtration fraction.

The normal values corresponding to these different ratios are given in Table 84.[1]

CLINICAL TESTS OF RENAL FUNCTION

Several clinical tests, based on renal physiology, are used to obtain information as to the normal or abnormal condition of renal function. The more commonly used tests measure the capacity of the kidney to concentrate the urine.

Concentration and dilution. Volhard first proposed this simple and informative test. The

[1] SHANNON, J. A., and S. FISCHER, *Am. J. Physiol.*, **112**, 765, 1938.

[1] GOLDRING, CHASIS, RANGES, and SMITH, *loc. cit.*

original procedure has been modified by several observers, and it is now as follows: After emptying his bladder, the patient drinks 1,500 cc. of water or weak tea in the course of 30 to 45 min. He is kept in bed and is made to empty his bladder every ½ hr. The volume and specific gravity of each fraction of urine are measured. A normal subject eliminates the 1,500 cc. of water in 2 to 3 hr., or 4 hr. at the latest. The specific gravity can drop to 1.002. After 4 hr. the patient is fed on a dry diet. The specific gravity of the urine increases rapidly and reaches 1.030 in the course of the same day or night. One of the first signs of renal insufficiency is the loss of power to concentrate the urine, a function of the renal tubes. In cases of glomerular lesions the kidney cannot secrete large quantities of dilute urine.

Forced tubular reabsorption.[1] This test is performed as follows: The patient drinks 1 liter of water in the course of 10 min., and the volume of urine passed in the second and third half hours following the ingestion is measured. On the next day the same amount of water is taken after an intramuscular injection of 5 vasopressor units of pitressin (0.5 cc.). A normal subject eliminates about 200 cc. of urine in each half-hour period of the first day (without pitressin) and about 20 cc. on the second day (with pitressin). The reabsorption coefficient $\left(\frac{\text{diuresis without pitressin}}{\text{diuresis with pitressin}}\right)$ is greater than 5 and usually 10 to 12 in normal subjects. Low values are observed in cases where a certain number of renal tubes are damaged or are functionally incompetent.

Urea clearance.[2] Urea clearance is frequently used as a clinical test of renal function. It must be kept in mind that the normal figure varies with the quantity of urine excreted. When diuresis exceeds 2 cc. per min. (augmentation limit) the clearance does not increase with the rate of urine formation but remains fairly constant. This maximal urea clearance is determined by the formula $(U \times V)/P$, and is 75 cc. per min. in normal subjects. When diuresis is below 2 cc. per min., urea clearance is less and is dependent on the rate of urine formation. This standard urea clearance responds to the formula $(U \times \sqrt{V})/P$ and is 54 cc. in normal subjects. Urea clearance is measured, as was explained above, applying one or other formula according to whether the rate of urine excretion is above or below 2 cc. per minute. Usually the results are given as a percentage of the normal figure; the value found is multiplied by $100/75$ or 1.33 for maximal urea clearance, and by $100/54$ or 1.85 for standard urea clearance. The determination of urea clearance is the most valuable of all the clinical tests so far in use for the early diagnosis of renal insufficiency.

FUNCTIONS OF THE KIDNEY

The Excretion of Water

The rate of urine excretion depends on the one hand on the rate of glomerular filtration and on the other on the rate of tubular reabsorption. The rate of glomerular filtration is conditioned by several factors. The most important are the following: (*a*) the permeability and filtration area of the glomerular membranes; (*b*) glomerular capillary pressure, dependent on arterial blood pressure and the tone of the afferent and efferent glomerular arterioles; (*c*) osmotic pressure of plasma proteins; (*d*) the number of active glomeruli. Recent work has shown that in man and other mammals all the nephrons seem to be permanently active; they do not function alternately as in the amphibian kidney.

The existence of these factors that can influence glomerular filtration rate (measured by inulin clearance) does not prevent it from remaining relatively constant in the dog and in man, even in conditions that cause widely diverging urinary excretion rates. On the other hand the glomerular filtration rate varies as the diuresis—in other words, with the degree of hydration—in the newborn child,[1] the rat,[2] and the rabbit.[3]

The renal tubes reabsorb always at least 100 cc. of the 120 cc. passing through the glomeruli in 1 min., as even in the most severe cases of diabetes insipidus the urine excreted does not exceed 20 cc. per min. This "obligatory" reabsorption of 80 to 87 per cent of the total glomerular filtrate takes place mostly in the proximal tube, along which the urine remains

[1] McCance, R. A., and W. F. Young, *J. Physiol.*, **99**, 265, 1941.

isosmotic with the blood plasma. At this level reabsorption of water is *passive;* it diffuses through the epithelium together with sodium, chloride, bicarbonate, glucose, etc., and the urine is not concentrated. The partial reabsorption of the remaining 13 to 20 per cent is "facultative," and takes place principally in the distal tube, although the collecting tubes may play a part in this process. This second fraction of water is reabsorbed against the osmotic pressure of the urine (active reabsorption), which is thus concentrated. The energy necessary to produce a hypertonic fluid is probably provided by metabolic operations in the cells of the renal tubes.

Facultative reabsorption of water (as distinct from the obligatory reabsorption of five-sixths of the glomerular filtrate) is regulated by the antidiuretic hormone of the posterior lobe of the hypophysis. This hormone acts on the cells of the distal tubes, increasing the rate of water reabsorption, and is thus responsible for the urine having a higher osmotic pressure than plasma. The term "antidiuretic hormone" is an appropriate one, as the diuretic response normally following the ingestion of water is suppressed by this hormone. On the other hand it does not diminish diuresis provoked by the ingestion of salt or urea; therefore its effect is to promote the reabsorption of water not needed to excrete dissolved substances. Marshall maintains that the antidiuretic hormone has no effect in those animals which have no thin segment.[1] The antidiuretic hormone acts directly on the kidney, without the mediation of the nervous system; its effect is not altered by cutting the renal nerves, and it is observed in transplanted kidneys. When the hormone is no longer secreted, as occurs after cutting the hypophyseal stalk or removing the neurohypophysis and in diabetes insipidus, there is polyuria and hypotonic urine is excreted; five-sixths of the glomerular filtrate is still reabsorbed, but facultative reabsorption of water ceases. There seems to be a continuous secretion of this hormone (1 to 5 milliunits per hour in the dog) in normal conditions. The secretion is dependent on the integrity of the central nervous system[2] (see "Functions of the neurohypophysis," Chap. 52).

Functions of the Renal Nerves

The wealth of the innervation of the kidney suggests that it must play some part, perhaps an important one, in the functions of the renal tubes and in glomerular filtration. Nevertheless it has been repeatedly demonstrated that a single completely denervated kidney or a transplanted kidney can keep an animal alive and without any sign of renal insufficiency. This single denervated kidney responds normally to all internal and external factors that modify renal function.

Claude Bernard observed that denervation of the kidney provokes polyuria, a fact that has been repeatedly confirmed. More recent well-controlled experiments by Verney and his collaborators[1] in unanesthetized normal animals have shown that denervation polyuria is a transitory artefact, induced by unfavorable experimental conditions (anesthesia, etc.).

So far there is no proof that the renal nerves play any part in tubular reabsorption or excretion. On the other hand, the renal nerves can undoubtedly modify the tone of the afferent and efferent glomerular arterioles and thus act on glomerular filtration and renal blood flow.

The work of Trueta and his associates suggests that the innervation of the kidney may have great importance in certain normal and pathologic states, because when the renal nerves are stimulated a fundamental change in the distribution of renal blood occurs and cortical ischemia is produced. O'Connor and Verney[2] have shown that water diuresis is inhibited in the dog in certain emotional states and by electrical stimulation of the skin. Inhibition that takes place rapidly is mediated by the sympathetic; that which takes place more slowly is due to the release of antidiuretic hormone.

Diuresis

"Diuresis" means the excretion of urine, but it is generally used to signify an increase in the formation and excretion of urine. Diuresis, in the latter meaning of the term, can be provoked

[1] KLISIECKI, A., M. PICKFORD, P. ROTSCHILD, and E. B. VERNEY, *Proc. Roy. Soc., London, s.B.*, **112**, 521, 1933; THEOBALD, G. W., and E. B. VERNEY, *J. Physiol.*, **83**, 341, 1935.

[2] O'CONNOR, W. J., and E. B. VERNEY, *loc. cit.; ibid.*, **33**, 70, 1945.

in many ways, by administering water, saline solutions, and certain diuretic drugs.

Water diuresis. Ingestion of a more or less large amount of water (1 to 2 liters) provokes diuresis in man, beginning in less than ½ hr., reaching its peak in 1 or 2 hr., and returning to the initial rate in 3 to 5 hr. Usually more water is excreted than the amount taken in, and pale urine of low specific gravity is passed.

The cause of this diuresis is the sudden dilution of the blood, which is nevertheless not very marked and lasts only a short time, as the water rapidly passes into the interstitial fluid. The change that takes place, whatever it may be (decrease in the osmotic pressure, or in the total base, or in the concentration of certain ions, etc.), does not act directly on the kidneys, but through the hypophysis. Verney and his collaborators[1] have shown that the secretion of the antidiuretic hormone of the hypophysis is controlled by the osmotic pressure of the plasma and extracellular fluids. Changes in osmotic pressure stimulate osmoreceptors situated in the territory of the internal carotid artery, probably in the central nervous system (supraoptic nuclei, etc.). During water diuresis the antidiuretic hormone circulating in the blood diminishes, and the time necessary for this decrease explains the delay between maximal diuresis and maximal hydration of the blood. Intravenous injection of hypotonic salt solution also provokes diuresis. As in the case of diuresis following ingestion of water, the maximal rate of urine excretion is delayed with respect to the maximal dilution of the plasma. Verney refers to water diuresis as a "physiological diabetes insipidus."

Water diuresis can be inhibited in several circumstances which provoke the secretion of the antidiuretic hormone. Thus exercise and certain conditioned reflexes, when they occur in the course of water diuresis, diminish the excretion of urine within a few minutes, even in denervated kidneys. In both these cases the posterior lobe of the hypophysis is stimulated through the central nervous system and secretes a larger amount of antidiuretic hormone.

On the other hand, morphine and other nonvolatile anesthetics provoke oliguria and prevent water diuresis. Possibly this type of anesthesia suppresses a normal inhibitory mechanism that acts on the hypophysis and there is an excess secretion of the antidiuretic hormone.

[1] VERNEY, E. B., *Lancet*, **2,** 739 and 781, 1946.

Saline diuresis. Intravenous injection, or ingestion of concentrated saline solution, produces transitory and more or less marked diuresis. Two mechanisms are active in this type of diuresis, according to whether the substance is readily reabsorbed by the tubes (chloride, glucose) or is either not reabsorbed or reabsorbed only in a slight degree (urea, sulfate, nitrate, phosphate, mannitol). In the first case, *e.g.*, with a concentrated NaCl solution, there is hydremia due to the passage of fluid from the tissues into the blood. This plethora increases the blood pressure and renal blood flow, with a consequent increase in glomerular filtration; this alone can increase diuresis even if no change in tubular reabsorption takes place. In the second case (urea, sodium sulfate, sucrose, mannitol, etc.) the substances, on not being reabsorbed by the tubes, increase the osmotic pressure and retain water in the lumen, thus acting as diuretics. Acidotic salts (NH_4Cl, $CaCl_2$) perhaps act in the same way, but it is impossible to deny that their diuretic activity may be due to changes in the blood plasma. Polyuria in pancreatic diabetes and in phlorhizin diabetes is due, at least in part, to the high concentration of glucose in the tubes, which on not being totally reabsorbed acts by osmosis and prevents the reabsorption of water.

Diuretic drugs. Certain xanthine compounds (caffeine, theobromine, theophylline) have a moderate diuretic effect in man. The mechanism by which they act is not well known. They increase the circulating blood volume and also have a direct effect on the kidney (increased glomerular filtration, and perhaps diminished tubular reabsorption).

Mercurial diuretics (salyrgan, novasurol)[1] act directly on the kidney. Their main effect consists in diminishing tubular reabsorption of sodium and chloride, and the urinary excretion of these substances increases considerably. The excretion of water also increases, but not necessarily because of a direct effect of the diuretic on the mechanism of water reabsorption. Probably the increase in water excretion is due to the loss of sodium from the plasma, or to the osmotic effect of the electrolytes which are not reabsorbed in the proximal tube. Simultaneous administration of NH_4Cl reinforces the effect of mercurial diuretics.

[1] GOVAERTS, P., *Arch. internat. de pharmacodyn. et de thérap.*, **36,** 99, 1929.

Excretion of Electrolytes

The clearances of many substances have been measured. Some of these occur normally in the organism (creatinine, urea, phosphate, sulfate, uric acid, amino acids, chloride, sodium, etc.); others are foreign substances (inulin, diodrast, phenolsulfonphthalein, xylose, saccharose, sulfonamides, etc.). It would not be profitable to examine here all the results obtained. Nevertheless it is interesting to note that there is a maximum reabsorption rate of phosphate, amino acids, creatinine, and ascorbic acid, just as in the case of glucose. This maximum is not constant but changes from time to time, perhaps in response to hormonal influences. In normal conditions the kidney discriminates between Na^+ and K^+, between Cl^- and HCO_3^-, and between other anions and cations. Thus a constant ionic equilibrium is maintained in the plasma. Within certain limits one special ion can be retained if it is scarce, or can be excreted if its concentration in the plasma is excessive. However, the amount of water and the total electrolyte concentration in plasma have a greater influence on renal function than the relative amounts of the different ions and the hydrogen ion concentration.

The effect of the corticoadrenal hormones on renal excretion of electrolytes is well known. Tubular reabsorption of Na is in great part dependent on the effect of these hormones, which cause it to be reabsorbed. The effect of parathyroid hormone on the renal excretion of calcium and phosphate has been explained in the chapter on mineral metabolism.

In dogs submitted to certain experimental conditions (excess K, urea diuresis), the ratio between potassium and creatinine clearances is more than 1; therefore, the distal tubes can excrete potassium.[1] Barclay, Cooke, and Kenney[2] believe that urea, phosphate, potassium, and other substances are eliminated by a triple process of glomerular filtration, tubular reabsorption, and tubular secretion. Tubular secretion would then occur only when the concentration in plasma of these substances was exceedingly high.

Functions of the Kidney in Acid-Base Equilibrium

A constant hydrogen ion concentration is an outstanding feature of blood plasma. The pH is kept around 7.4 by the buffer action of the salts of weak acids (H_2CO_3, HPr, H_3PO_4, etc.). Carbonic acid is the principal acid produced in the process of oxidation of foodstuffs. A normal subject has an output of over 20 gram molecules in 24 hr., the equivalent of 2 liters of concentrated HCl, and about twenty times the total available base in the body. The anhydride of this acid (CO_2) is volatile and is therefore excreted almost exclusively by the lung, but the concentration of $BHCO_3$ in the plasma—quite as important as H_2CO_3 in determining the pH of the plasma—is regulated not by the lung but by the kidney (see page 287).

Other acids besides H_2CO_3 are formed in both the normal and the diseased organism. These acids are not volatile, and therefore cannot be excreted by the lungs. The metabolism of 100 gm. of protein ingested daily produces 60 mEq. of sulfate by oxidation of the protein S, and about 50 mEq. of phosphate by oxidation of the protein P; the metabolism of 100 gm. of fat, with 10 per cent lecithin, produces another 50 mEq. of phosphate. In cases of severe ketosis, up to 500 mEq. of β-hydroxybutyric acid can be added. The production of acid exceeds that of base by 30 to 80 mEq. daily.

This excess acid is neutralized by the base in the body fluids, but if the acid were excreted combined with this base, the alkaline reserve would be rapidly exhausted. The kidney has two different mechanisms by which it can excrete acid and retain the base, especially plasma bicarbonate. One of these mechanisms consists in the excretion of free acid; the other in the substitution of the fixed base by NH_3, which is synthesized in the kidney from the N of amino acids (page 742). By means of the first mechanism 10 to 30 mEq. of acid is eliminated daily, and 20 to 50 mEq. by means of the second.

The kidney contributes to the regulation of the hydrogen ion concentration in the first place by excreting an acid or an alkaline urine. Usually the pH of human urine is around 6, but it can fall to 4.8 in cases of acidosis and rise to 8.2 in cases of alkalosis. The power to excrete acid urine (retaining fixed base) is dependent

on the available buffer. Normally this buffer consists mostly of phosphate. At pH 7.4 in blood plasma there is Na_2HPO_4 and NaH_2PO_4 in a ratio of 4:1. In urine at pH 4.8, 99 per cent of the phosphate is found as NaH_2PO_4; therefore there is some sparing of base. At this same pH all the sulfate is in the form of B_2SO_4 and 90 per cent of the lactate as B-lactate. The excretion of free acid therefore has little physiologic significance, but when β-hydroxybutyric acid is excreted in urine at pH 4.8, 55 per cent is free; in this case there is an effective economy of fixed base.

Three explanations have been proposed to account for the acidification of urine in the renal tubes: (*a*) reabsorption of dibasic phosphate by the tubes; (*b*) glomerular filtration of H_2CO_3 and subsequent reabsorption of $NaHCO_3$; (*c*) the exchange of H^+ for Na^+ as the glomerular filtrate passes down the tube, so that Na_2HPO_4 is converted into NaH_2PO_4. The source of H^+ would be the H_2CO_3 produced by the tubular cells from the CO_2 in the blood or in the course of cellular oxidation.[1]

The administration of the ammonium salts of mineral acids (*e.g.*, NH_4Cl) is used to provoke experimental or therapeutic acidosis. The ammonia is almost completely converted into urea, and the free Cl combines with base displaced from HCO_3, the resulting CO_2 being excreted by the lung. Mineral salts of Ca, Mg, and Sr also provoke acidosis because the basic ion is excreted in the feces as phosphate or carbonate or as soaps formed with fatty acids, and the acid ion (Cl^-, $SO_4^{=}$) is set free, so it displaces base from HCO_3^-. In both cases there is a shift toward the acid in the urinary pH. This same process occurs when there is a high-protein diet, which produces a large quantity of acid.

When the plasma contains an excess of fixed base, either because of ingestion of alkaline salts or because of a vegetarian diet, the kidney contributes to the regulation of the acid-base equilibrium of the *milieu intérieur* by forming an alkaline urine; bicarbonate replaces Cl^-, and the dibasic phosphate increases. In both ways Cl^- is retained and its excretion combined with the excess base is prevented.

The "alkaline tide." Leathes observed that urinary acidity diminishes during the hours following awakening and after a meal. The morning "alkaline tide" seems to be related to changes in respiratory rhythm caused by the waking state. Hyperpnea increases urinary alkalinity because of the excess elimination of CO_2 by the lung and the subsequent excretion of $BHCO_3$ by the kidney. The postprandial alkaline tide is attributed to the accumulation in the blood of base set free by the secretion of HCl in the gastric juice. The increase in base in the blood, counteracted in part by the excretion of the alkaline pancreatic and intestinal juices, causes a reduction in the excretion of acid and NH_3 by the kidney. When HCl is reabsorbed the urine again becomes acid. In cases of achlorhydria the postprandial alkaline tide cannot be demonstrated.

[1] PITTS, R. F., and R. S. ALEXANDER, *Am. J. Physiol.*, **144**, 239, 1945.

FORMATION OF NEW SUBSTANCES BY THE KIDNEY

Bunge and Schmiedeberg[1] discovered that the injection of benzoic acid (sodium benzoate) and glycine is followed by the accumulation of hippuric acid in the blood, but no hippuric acid is formed if the renal blood vessels are first tied off. The perfusion of a kidney with blood containing benzoate and glycine showed that this organ synthesizes hippuric acid. This observation, which has been repeatedly confirmed, proves that the kidney has a power of synthesis of metabolic importance. In this particular case it forms part of an antitoxic defensive mechanism. In carnivora, especially in the dog, the kidney alone performs this operation, but in herbivora and in omnivora, including man, the liver plays a more important part than the kidney, to such an extent that the rate of excretion of hippuric acid after the administration of benzoic acid has been used as a test of hepatic function.

The kidney can also synthesize ammonia, which is excreted as ammonium salts and plays an important part in the maintenance of the acid-base equilibrium. By combining with acid ions, NH_3 spares fixed bases (Na, K). When the ingestion of acids, or of foodstuffs that give acids as end products, increases, the urinary excretion of ammonia also increases. On the contrary, when base or base-forming foodstuffs are ingested, the production of ammonia diminishes. Ammonia is produced and excreted by the distal tube. Ammonia is excreted by sim-

[1] BUNGE, G., and O. SCHMIEDEBERG, *Arch. f. exper. Path. u. Pharmakol.*, **6**, 233, 1876.

ple diffusion, according to some workers; others maintain that there is active secretion of ammonia.

Urea is not the source of urinary ammonia, as was at one time believed. The renal cortex has a very strong deaminating activity. The principal precursors of urinary NH_3 seem to be glutamic acid and its amide, glutamine. The conversion of glutamine into NH_3 increases with the degree of acidosis. Glycerine, D-L-alanine, L-leucine, and D-L-aspartic acid can also increase renal production of ammonia. The capacity of an amino acid to increase the formation of ammonia by the kidney is related to the facility with which it is deaminated by renal enzymes *in vitro* and to the readiness with which it is reabsorbed by the renal tubes.[1]

Synthesis of hippuric acid and the formation of ammonia from amino acids are not the only processes of this type carried out by the kidneys. Recent work has shown that other substances are also produced. The secretion of renin will be discussed below.

The Work of the Kidney

In order to concentrate the urine and to excrete substances, the renal tubes perform work and consume energy. Renal work in man when excreting highly concentrated urine is equivalent to 0.6 cal./min. The oxygen consumption of the human kidneys is about 10 cc./min. (equivalent to 50 cal./min.) and is subject to only small variations in spite of considerable changes in the osmotic work of the kidney. The efficiency of the kidney even in extreme conditions, compared with that of other organs, is very low; it is not much more than 1 per cent.

The kidney not only excretes urine but has other important functions. Probably the greater part of the energy consumed is employed in cell processes not directly concerned with external osmotic work.

ARTERIAL HYPERTENSION OF RENAL ORIGIN

Renin has been mentioned as a substance formed by the kidney and secreted into the blood. Renin is a protein found in renal extracts,[2] which produces an increase in blood pressure when it is injected into the blood stream. The increase in pressure is not due to the direct action of renin on the diameter of the blood vessels. Renin is not per se a vasoconstrictor, it is a proteolytic enzyme which acts on a serum globulin (hypertensinogen) and splits off a simpler substance, possibly a polypeptide, hypertensin, which constricts the blood vessels and stimulates the heart. Hypertensin is destroyed in the body by another enzyme or group of enzymes, called hypertensinase.

Hypertensinogen

Renin → | Hypertensinase

↓ ↓

Hypertensin ——→ Inactive substance
Renin in certain experimental conditions is secreted into the blood; therefore it can be considered as an internal secretion. The kidney secretes renin in two different conditions:

1. In arterial hypotension provoked by (*a*) the injection of substances that lower the blood pressure; (*b*) hemorrhage; (*c*) shock;[1] etc.
2. When the renal blood flow decreases (partial occlusion of the renal artery, perinephritis, ureteral occlusion, etc.) or there is total suppression of the renal circulation (temporary occlusion of the renal artery).

In the first case, when the general blood pressure falls, renin secretion is one of the mechanisms of homeostasis. In the same way as arterial hypotension provokes reflex vasoconstriction and adrenaline secretion, which help to restore the normal blood pressure level, so it also provokes renin secretion, which by the formation of hypertensin contributes to raise the lowered blood pressure. The mechanism by which it provokes the secretion, however, is unknown.

In the second case, *i.e.*, when the renal circulation is diminished, the renin secreted causes a pathologic syndrome: arterial hypertension. The hemodynamic conditions of the kidney are probably the same in both cases; the renal blood flow diminishes, the pressure in the renal arteries falls, and the pulse pressure is less. In the first case, however, renin secretion has a physiologic function to perform; it helps to restore the normal blood pressure level. In the second case the general blood pressure is not below normal;

therefore the secreted renin causes the abnormal syndrome of arterial hypertension. Probably in arterial hypertension of renal origin there are other factors beside those mentioned here, but undoubtedly in the first stages of experimental hypertension of renal origin,[1] in acute experimental hypertension, and in certain cases of hypertension in man (acute nephritis, eclampsia, etc.)[2] renin plays an important part.

Since Bright's classic observations, clinicians had associated arterial hypertension with renal damage, and many efforts were made to reproduce the disease in laboratory animals. Many unsuccessful attempts were made (surgical reduction of the renal mass; incomplete ligature of the renal vein; parenchymatous lesions of the kidney by x-rays, toxic substances, etc.) before Goldblatt and his collaborators[3] discovered that an incomplete obstruction of the renal artery provoked permanent hypertension in the dog.

Hypertension of renal origin, produced by these and similar methods, has many points of resemblance to human "essential hypertension." This simple method of obtaining experimental hypertension encouraged several groups of workers to search for the mechanism of the disturbance. It was soon demonstrated that this type of hypertension was not due to a nervous mechanism, as it was not prevented by renal denervation. The different endocrine glands were also eliminated as causes of the condition. A humoral mechanism therefore seemed to be its probable cause.

Houssay and Fasciolo[4] proved that a humoral mechanism existed. They transplanted the ischemic kidneys (with partially occluded renal arteries) of dogs with experimental hypertension into the neck of nephrectomized dogs, which thereupon showed an increase in blood pressure (Figs. 304 and 305). It is now known that this rise in blood pressure is due to the renin secreted by the ischemic kidney.

Houssay and Taquini[5] observed that the citrated plasma obtained from the venous blood of the ischemic kidney has a vasoconstrictor effect on the blood vessels of the toad (Läwen-Trendelenburg method).[1] This effect is now known to be produced by hypertensin formed in the blood by the action of renin on the hypertensinogen of blood plasma. Later it was seen that acute partial ischemia has an effect similar to that of chronic ischemia; it increases the blood pressure, and the renal venous blood plasma acquires a vasoconstrictor action. Moreover intravenous injection of the venous blood of kidneys in acute partial ischemia into normal dogs causes in the latter a rise in blood pressure.[2] Shortly afterward extracts of this blood were prepared and a pressor substance, which was called "hypertensin," was discovered[3] (Fig. 306). This substance could be formed *in vitro* by incubating blood plasma or serum with renin at 37°C. (Fig. 307). Hypertensin is formed in the blood by the action of renin, secreted by the kidney, on the hypertensinogen of plasma.

Page and his collaborators, following another path, arrived almost simultaneously at the same conclusions. In 1938[4] they observed that purified renin did not produce peripheral vasoconstriction (in the rabbit's ear or the dog's tail); the vasoconstrictor effect was reestablished by adding a plasma protein which they called "renin activator." It was then discovered that the interaction of renin and renin activator gave rise to a pressor and vasoconstrictor substance which was called "angiotonin."[5] There is therefore only a difference in the names given to the same principles by the two groups of workers.

Renin. This substance is a protein found in renal extracts, which acts on hypertensinogen and forms hypertensin. This is an enzymatic process, with an optimum pH of 7.5 to 8.5 and an optimum temperature of 37 to 39°C. The velocity of the reaction is dependent on the renin concentration, a fact that has been used for the

quantitative estimation of renin.[1] Renin can be considered as a proteolytic enzyme,[2] but it is difficult to identify it as one of the known cellular proteases.[3]

The renins obtained from different species behave differently. The renins of man, monkey, and baboon are active on the hypertensinogens of all mammals and give rise to hypertensin, but the renins of the latter do not act on the hypertensinogen of the former.[1] The renin of birds is active only on the hypertensinogen of birds. No renin has been found in amphibians, reptiles, and fishes.[2]

Intravenous injection of renin provokes an increase in blood pressure which lasts 30 to 40 min. This increase is due to the hypertensin formed by the action of renin on the hypertensinogen in the blood. Repeated injections of renin produce a progressively smaller response (tachyphylaxis), in great part because of the exhaustion of the hypertensinogen (Fig. 308).

Pepsin acting on hypertensinogen produces a substance called "pepsitensin,"[1] which has pharmacologic and chemical properties similar to those of hypertensin.[2] Nevertheless it is possible to differentiate these substances by means of the enzymes that destroy them.[3]

Interval between (1) and (2) was 13 min.; at (3) the record was interrupted for 15 min. Note the decrease in the effect of the second and third injections. (*Braun-Menéndez, E., J. C. Fasciolo, L. F. Leloir, J. M. Muñoz, and A. C. Taquini, "Renal Hypertension," translated by Lewis Dexter, Charles C. Thomas, Springfield, Ill., 1946.*)

Hypertensinogen. This substance is one of the plasma proteins, and it forms part of the α globulins.[1] It is formed in the liver,[2] and the adrenal cortex seems to condition the velocity of its formation. In some cases of hypertension with renal insufficiency in man, the concentration of hypertensinogen in the blood has been found to be increased, and it has been found below normal in cases of hepatic insufficiency.[3] Page and his collaborators have proposed the name of "renin substrate α-2-globulin" for this substance.

Hypertensin (angiotonin). This substance is probably a polypeptide of relatively low molecular weight (approximately 2,700), which is produced by the action of renin on hypertensinogen. It is dialyzable, thermostable, and acid-resistant, and it is destroyed by alkalies and proteolytic enzymes (pepsin, trypsin, papain). It is soluble in water but is insoluble in the organic solvents.[4]

Hypertensin has a strong vasoconstrictor action. In intravenous injection it produces a brief increase in blood pressure in amphibians, reptiles, birds, and mammals (Figs. 306 and 307). Intravenous infusion produces a rise in blood pressure which lasts as long as the infusion is continued (Fig. 309). The pressor effect of hypertensin is not inverted by sympatholytic drugs, nor is it reinforced by cocaine. It is potentiated by veritol, tyramine, and ephetonine. It has a stimulating effect on the heart and produces contraction in most plain muscles. It has been classified among the musculotropic drugs, as it seems to act directly on the muscle fiber.[4]

Hypertensinase. Hypertensin is destroyed by serum, plasma, red blood cells, and tissue extracts (kidney, liver, spleen, intestinal mucosa, etc.). This effect is due to a thermolabile nondialyzable substance which has the properties of an enzyme and which has been called hypertensinase.[5] Several of the known enzymes destroy hypertensin.[6] The activity of tissue extracts is

probably due to proteolytic enzymes that destroy hypertensin by hydrolysis.

The experimental study of hypertension of renal origin has influenced our ideas on the pathogenesis of human arterial hypertension, a disease that because of its frequency and severity is one of the major problems of medicine. These experimental studies have contributed directly and indirectly to a better understanding of this disease; nevertheless there remain many obscure points which require further research. The renal origin of those cases of hypertension which are cured by extirpation of the diseased kidney cannot be denied. In cases of acute hypertension with renal lesions (acute glomerulonephritis and toxemia of pregnancy) the presence of renin in the blood has been demonstrated. In cases of chronic hypertension there are also renal lesions, but it has not been possible to demonstrate an increase in the renin concentration in blood, either in experimental animals or in man. This is a weak point in the hypothesis that considers the renin-hypertensin mechanism as the cause of hypertension. Several explanations of this fact can be suggested: (*a*) once the hypertension is established, the amount of renin needed to maintain the high blood pressure may be so small that it cannot be detected by the methods so far available; (*b*) once hypertension is established, central, peripheral, and reflex nervous mechanisms may contribute to maintain the high blood pressure level.

Very small amounts of renin can be detected in the blood by means of highly sensitive methods recently developed.[1] Small amounts of renin have thus been detected in the circulating blood of normal and hypertensive dogs and rats; also in the blood of normal human subjects and of patients suffering from chronic hypertension. The same renin concentration has been found, however, in the blood of normal and hypertensive animals and men.[1] These facts show that vasoconstriction in human or experimental hypertension is not due to an increase in blood-renin concentration, but they do not completely discard renin as a factor in the pathogenesis of hypertension, and other experimental evidence shows that it can play a part in this process. Prolonged hypertension can be produced in rabbits by continuous injection of very small amounts of renin.[2] Repeated injections of heterologous renin into dogs have provoked the appearance of antirenin with a high titer in the blood plasma;[3] in hypertensive dogs the blood pressure falls when antirenin appears. In dogs with antirenin in their blood, occlusion of the renal arteries has not been followed by hypertension. Renin also has a diuretic effect[4] and causes proteinuria and loss of sodium in the urine. It also provokes hypertrophy of the glomerular zone of the adrenals.

The second hypothesis referred to above is supported by certain experimental evidence, which shows that a high blood pressure may be maintained by nervous and humoral mechanisms

FIG. 309. Continuous intravenous injection of hypertensin at the rate of 1 unit per minute. 1, injection started; 2, injection ended. Chloralosed, vagotomized dog with artificial respiration. not dependent on the action of renin. Thus a substance called vasoexcitor material (VEM) arising in the kidney has recently been studied, but it is not yet possible to say what part it plays in the pathogenesis of arterial hypertension. Chambers, Zweifach, and their associates[1] have followed the reactions of the blood vessels in the exteriorized mesoappendix of rats submitted to shock. They were able to distinguish two phases: (*a*) a first period during which there is compensation, the meta-arterioles and the precapillary sphincters are hyperactive, and there is an increase in the response to adrenaline; (*b*) a final phase of progressive decompensation in which the activity of the terminal arterioles and precapillaries is depressed, and their response to adrenaline is decreased. Blood taken from animals in these conditions was injected into normal rats with the mesoappendix exposed, and the same vascular responses were provoked as were observed in the donor. They conclude that there are two substances in the blood of animals in shock: (*a*) vasoexcitor material (VEM), which appears during the first stages of shock; (*b*) vasodepressor material (VDM), which appears after prolonged tissue anoxia and rises to a high concentration at the beginning of the irreversible phase of shock. VEM is produced in the kidney and VDM in the liver and muscles submitted to severe anoxia.[2] These substances are apparently part of a homeostatic mechanism that contributes to the regulation of blood pressure and peripheral blood flow. VEM has certain similarities with hypertensin, although some of its vascular effects differ from those of the latter. It is destroyed by kidney tissue *in vitro* in aerobic conditions, and it appears in the blood of the renal vein after a few minutes of acute partial ischemia. The blood of dogs with constriction of the renal artery has a strong vasoexcitatory effect, but when the blood pressure is stabilized at a high level the blood has little or no excitatory effect.[3] This "neutral effect" of the blood may be due not to a fall in VEM but to a rise in VDM, which has been

identified with ferritin.[1] Blood from hypertensive dogs or patients with chronic hypertension incubated with slices of kidney in aerobic conditions, so as to destroy VEM, shows VDM activity. On the other hand, antibodies for VDM have been prepared which counteract its effects and reveal the activity of VEM when added to blood from hypertensive animals or patients. Blood taken from animals with experimental hypertension and patients with chronic hypertension treated in this way consistently revealed appreciable amounts of VEM and VDM. Blood of normal animals and men was found to be inactive before and after incubation with kidney tissue. In chronic arterial hypertension in man and dogs, therefore, there is an increase in VEM masked by an equivalent increase in VDM.[2]

These observations confirm and extend the role of the kidney as an organ secreting substances with vascular activity and increase its importance in the pathogenesis of hypertension.

CHAPTER 64

The Physiology of Micturition

URINE FORMED IN the kidney passes out of the orifices of the cribriform area into the renal calyces and pelvis. It then descends along the ureter to the bladder, where it accumulates. Periodically the bladder is emptied by the act of micturition.

The renal pelvis and the ureter are made up of three layers: an external connective adventitia, a middle muscular coat, and an internal mucous membrane. The muscular coat consists of two layers of plain muscle—a deep one of longitudinal fibers, surrounded by another of circular fibers; in the lower part of the ureter there is an outside layer of longitudinal fibers. The ureter penetrates obliquely into the bladder wall, opening into its cavity (ureteral meatus) in such a way that a fold is formed which acts as a valve and prevents the reflux of urine from the bladder to the ureter. Rhythmic contractions of the pelvic and ureteral muscle are observed. They are propagated from the pelvis down the ureter in the form of a peristaltic wave at the rate of 2 to 3 cm. per sec.

These peristaltic waves are responsible for moving the urine along the ureter; the rhythmic ejaculation of a few drops of urine from the ureteral meatus can be directly observed by cystoscopy. These waves recur with a frequency of one to five per minute in man. Their amplitude and frequency increase when the ureter is distended by a greater volume of urine, by resistance to flow caused by a mechanical obstacle, or by a rise in temperature.

The ureter is innervated by sympathetic fibers from the renal, hypogastric, and spermatic plexuses. The lower third of the ureter also receives fibers from the pelvic parasympathetic. In the lower part of the ureter ganglionic neurons are found, but not in the upper part. The peristaltic waves of the ureter are not dependent on the integrity of its innervation; the ureter, like the heart, has an automatic rhythm. The ureter contracts rhythmically when isolated in the same way as it does *in situ*.

The bladder and the prostatic and membranous segments of the urethra are one functional unit, the object of which is (*a*) the accumulation in the bladder of urine coming from the kidneys; (*b*) its periodic evacuation.

The bladder has a coat of plain-muscle fibers, disposed in three layers. The contraction of these fibers (detrusor urinae) reduces the capacity of the bladder. The outside layer is made up of longitudinal fibers going from the fundus to the base of the bladder; the anterior fibers end by insertion on the pubis, and the posterior fibers on the prostate in the male and on the connective tissue of the urethrovaginal cleft in the female. The internal or plexiform layer is formed by longitudinal fibers, which anastomose with each other. The middle layer consists of circular fibers, forming an annular muscle around the opening of the urethra which extends into the depth of the prostate in man; this is the vesical or internal sphincter of the urethra. Urine is retained in the bladder by the involuntary tonic contraction of the smooth fibers of this sphincter. A coat of striated muscular fibers surrounds the prostatic and membranous segments of the urethra, forming the external sphincter. Voluntary contraction of this sphincter constricts the urethra and reinforces the retaining effect of the internal sphincter. By its contraction this muscle also empties the upper segment of the urethra at the end of micturition. The same effect is produced by the contraction of the urethral portion of the bulbocavernous muscle, an effect that has given it the name "accelerator urinae."

Innervation of the bladder. (Fig. 310.) The muscles of the bladder wall and the internal sphincter (plain muscle) have a double innervation: they receive sympathetic fibers from the hypogastric nerves (hypogastric plexus in man) and parasympathetic fibers from the pelvic nerves (nervi erigentes). The striated external sphincter is innervated by a perineal branch of the internal pudic nerve. The sympathetic fibers come from neurons in the lateral gray column of the upper lumbar segments of the spinal cord; their axons pass into the lumbar sympathetic chain and the mesenteric plexus. The majority of the fibers join the presacral nerve (upper hypogastric plexus), from which the hypogastric nerves branch off to end in the hypogastric ganglion situated on each side of the rectum. The neurons that give off the postganglionic fibers for the bladder are in these ganglia. Stimulation of the sympathetic provokes vasoconstriction, but there is no evidence that it has any other action on the bladder.

FIG. 310. Innervation of the bladder by the inferior mesenteric and hypogastric plexuses. (*White, J. C., and R. H. Smithwick, "The Autonomic Nervous System,"* 2d *ed., Macmillan, New York, 1945.*)

The parasympathetic fibers arise in the second to fourth sacral segments of the spinal cord; they join the pelvic nerves and end on neurons situated in the hypogastric ganglia or in the bladder wall. The axons of these neurons are the postganglionic fibers that end in the muscle fibers of the bladder. Stimulation of the parasympathetic contracts the bladder muscle (detrusor urinae) and relaxes the internal sphincter. Both these actions serve to empty the bladder. Acetylcholine has the same effect.

Afferent impulses from the bladder are conducted almost exclusively by fibers in the pelvic nerve. These fibers enter the spinal cord by the dorsal roots of the second and third sacral segments. The fibers that conduct painful impulses enter the spinal cord in the dorsal roots of the upper two or three lumbar nerves.

The pudic nerves innervate the external sphincter. They come from the three upper sacral nerves. They also carry the afferent fibers from the urethra.

The filling of the bladder. Urine is propelled into the bladder by the rhythmic peristaltic contractions of the ureters, gradually filling it. The bladder muscle, in the same way as the muscular coat of other hollow viscera, can adapt its capacity to the contents without any considerable change in the intravesical pressure. This postural adaptation reflex can be demonstrated by catheterizing the bladder and connecting the catheter to a manometer. If fluid is then injected into the bladder, 50 cc. at a time, the injection of the first 400 cc. produces only slight and transitory changes in pressure. This fact proves that the detrusor presents only a momentary tonic resistance to distention and then adapts its tonus to the content. The pressure nevertheless rises gradually as fluid is injected into the bladder (Fig. 311). When the contents of the bladder are more than 400 cc., the pressure curve rises more steeply, especially when the contents reach 600 to 800 cc. Rhythmic, painful contractions commence at this level. Micturition can be prevented by a voluntary effort, but when the pressure is above 100 cm. H_2O the bladder is evacuated however strong the will to retain the urine.

Retention of urine in the bladder. Urine is retained in the bladder by the closure of the ureteral meatuses, which prevents its returning to the kidney, and by the tonic contraction of the sphincters, which prevents its flowing into the urethra. The oblique opening of the ureter, the fold formed by the upper lip of the meatus, and the contraction of the bladder wall ensure the closure of the ureteral meatus. The sphinc-

ters resist a pressure of 70 to 100 cm. H_2O. This resistance is due to a reflex contraction of the internal (plain-muscle) sphincter, adapted to the volume of urine in the bladder (postural reflex) and to automatic or voluntary contraction of the external (striated-muscle) sphincter. When the pressure rises to 15 or 18 cm. H_2O, as normally happens when the contents are about 400 cc., afferent impulses are sent to the nerve centers and a desire to micturate is felt.

Micturition. Micturition is a reflex act, but normally it is commenced voluntarily. A purely involuntary micturition takes place only in children and in cases where the bladder has been deprived of its connections with the higher nerve centers. When the desire to micturate is felt, evacuation is prevented or performed voluntarily. In the first case voluntary contraction of the external sphincter reinforces the effect of the internal sphincter and there is reciprocal relaxation of the detrusor; the intravesical pressure diminishes and the desire to micturate ceases for a time. The desire to evacuate the bladder can be voluntarily overcome as long as the bladder contents are less than 700 cc.; there is then a painful sensation in the hypogastrium and urgent need to evacuate. When the desire to micturate is complied with, the voluntary contraction of the external sphincter is inhibited and a chain of reflexes commences, which results in the emptying of the bladder. Nevertheless micturition can be interrupted voluntarily by contraction of the external sphincter.

During micturition the detrusor contracts, the internal sphincter is relaxed, and urine is evacuated with considerable force; the pressure within the bladder can rise up to 130 cm. H_2O. Micturition is usually preceded by contraction of the abdominal muscles and a slight expiratory effort with the glottis closed. This effort assists micturition but is not indispensable to it. Abdominal contraction can be sustained throughout the act to accelerate evacuation. In the male the bulbocavernous muscle contracts rhythmically at the end of micturition, and thus the last drops of urine in the urethra are expelled (Janet's "piston stroke"). In the female micturition ends more abruptly.

Reflex mechanism of micturition. Barrington's[1] work in the cat has demonstrated the existence of a series of coordinated reflexes in the act of micturition:

1. Contraction of the bladder wall (detrusor) when the internal pressure reaches 10 cm. H_2O. The afferent and efferent paths of this reflex are in the pelvic nerve; the reflex center is situated in the pons and the medulla.
FIG. 311. Intravesical pressure: *a*, solid line, record of pressure following repeated injections of 50 cc. at short intervals; the vertical drop indicates postural adaptation of the bladder during these intervals; *b*, dotted line, record of pressure variations in a similar experiment made after the bladder was submitted to prolonged distention. (*Denny-Brown, D., and E. G. Robertson, Brain, vol. 56, pp. 149 and 397, 1933.*)

2. Contraction of the bladder wall, provoked by the flow of urine into the urethra. This reflex ensures the complete evacuation of the bladder once it has commenced. Its afferent fibers form part of the pudic nerve, the efferent path is in the pelvic nerve, and the center is situated in the pons and the medulla.
3. Weak, transitory contraction of the bladder caused by distention of the first part of the urethra. The afferent and efferent paths of this reflex are in the hypogastric nerve.
4. Relaxation of the external sphincter when urine flows through the urethra. The pudic nerve carries the afferent and efferent paths of this reflex.
5. Relaxation of the sphincter provoked by the contraction of the bladder wall. The afferent

[1] BARRINGTON, F. J. F., *Quart. J. Exper. Physiol.*, **8**, 33, 1914; **9**, 261, 1915; **15**, 81, 1925; *Brain*, **44**, 23, 1921; **45**, 126, 1922; **51**, 209, 1928; **54**, 177, 1931.

path is in the pelvic nerve and the efferent path in the pudic nerve.

6. Relaxation of the plain muscle of the upper third of the urethra when the bladder is distended. The afferent and efferent paths of this reflex are in the pelvic nerve.

The centers of the last four reflexes are situated in the sacral segments of the spinal cord.

In the course of micturition each one of these reflexes, with the exception of the third, provokes the following one, and thus the bladder is completely evacuated.

The nervous system and the functions of the bladder. A bladder that has been separated from the organism, or completely denervated, has its sphincter tonically contracted. This contraction is also observed in cases of severe injury to the spinal cord. As the bladder is filled, the internal pressure rises much more rapidly than when its innervation is intact. At first the detrusor loses its tonus, but after a time, when the intravesical pressure increases, tonic or rhythmic contractions are stimulated by filling the bladder. These contractions increase as the bladder is filled until they overcome the resistance of the sphincter and the urine is expelled. There is only an incomplete evacuation of the bladder, as the pressure soon falls below the level needed to overcome the tonically contracted sphincter. These incomplete automatic and involuntary micturitions are frequently repeated (incontinence due to overflow).

Barrington has demonstrated the existence of a center, extending from the middle of the motor nucleus of the fifth nerve to the rostral end of the hind brain. Bilateral destruction of this center permanently suppresses normal evacuation of the bladder.

There are also centers for micturition in the hypothalamus and in the cerebral cortex. The latter are responsible for the voluntary control of the bladder and urethra, the voluntary commencement and interruption of micturition, and the contraction of the external sphincter. The spinal centers are situated in the second to the fourth sacral segments; another spinal center has been located in the fourth to the sixth lumbar segments.

SECTION NINE

The Nervous System

CHAPTER 65

The Organization of the Nervous System

ADAPTATION TO THE environment and its variations is essential for the survival of living organisms and for the maintenance of their normal state. *Excitability* is the capacity of an organism to respond with an internal variation to changes in the environment. A *stimulus* is a modification in energy which takes place in the environment and which can evoke a response from an organism. Complex animals have specialized structures, sensitive to different kinds of stimuli, which are known as *receptors*. The excitatory state produced by a stimulus in the receptor is transmitted by *conductors* (nerves) to *centers*, where it is controlled and may be distributed by means of other conductors to the *effectors*, *i.e.*, structures that react to perform the necessary adaptation. Simpler organisms have no centers; the excitatory state is transmitted directly by conductors from the receptors to the effectors. In unicellular organisms reception, transmission, and response take place in the same cell. When a paramecium, for example, swimming in its environment by means of the regular movements of its cilia, comes up against an obstacle, the impact acts as a stimulus. An excitatory state is produced at the site of stimulation and is transmitted through the protoplasm to the cilia (the effectors) which reverse their movements. The whole organism now displaces itself in another direction owing to the adequate response that has followed the stimulus. Leukocytes and other migratory cells of vertebrates behave as isolated cells.

Multicellular organisms constitute an integrated unit. The different parts are kept together by intercellular substances in an orderly arrangement, according to laws regulating the development of form in the particular species. This static correlation makes the organism a unit in space; there are other mechanisms that assure its dynamic unity. Thus, changes in one part of the body can influence the activity of other and distant parts, provoking adaptation responses that serve to maintain the vital equilibrium of the whole animal. There are two mechanisms of dynamic correlation, the humoral and the nervous.

Cells pour the products of their activity into the circulating fluids of the body and in this way can act on other distant cells. Complex animals have an important differentiated mechanism of humoral correlation, the endocrine glands. These glands produce specific substances, known as hormones, which are secreted into the body fluids and serve to regulate the activity of certain tissues or organs. Humoral correlation is relatively slow and diffuse. The "chemical messengers" are transported at the speed of the circulating fluids, which is measured in minutes and seconds, and they act on all the cells that can respond to them.

Celenterates and animals of greater complexity have also a more rapid and precise mechanism of correlation, the nervous system, made up of cells in which excitability and the capacity to transmit the excitatory state are highly developed. The time of reaction in this system is measured in seconds and thousandths of a second. According to the circumstances the effects produced can be localized (with great precision in vertebrates) or transmitted to the whole organism. The nervous system, in those species in which it is well developed, is the principal mechanism of internal correlation and

of communication with the environment. It is the main agency by means of which the organism is able to react as a unit. This is *the integrative action of the nervous system.*

The importance of the nervous system in the maintenance of the activity of the whole organism is demonstrated by the results of its suppression. Celenterates have only a rudimentary nervous system; nevertheless anesthesia, which eliminates nervous activity, produces in them a condition of immobility and lack of activity. The nervous system is highly developed in vertebrates; therefore considerably greater effects are produced by its annulment. A decapitated frog, in which the higher coordinating nerve centers have been eliminated, remains passive in any position in which it is placed, but its muscles still have tonus and it responds to stimuli with reflex movements. If now the dorsal spinal roots are cut, no impulses coming from the periphery can reach the centers. The muscles are flaccid, because tonus depends on afferent impulses coming from the muscles and other peripheral structures, and even the strongest stimuli provoke no response. Occasionally, apparently spontaneous movements may be observed. When all the nerve centers have been destroyed the animal remains flaccid and still. Its tissues are alive, the heart beats and the blood circulates, but the animal is no longer an integrated unit, which can search for and obtain food and which can defend itself or flee from danger. The different organs continue to function with no other correlation than that of the body fluids, and soon the final disintegration of death takes place.

Disturbances in nervous functions may cause a decrease in the capacity to receive stimuli (sensory disorders) or in the coordination and execution of movement (motor disorders). Suppression of the activity of the higher coordinating centers causes loss of consciousness in those animals in which conscious phenomena can be recognized. The nervous system is the necessary instrument of intelligence and is essential for the acquisition of knowledge. The external universe (the cosmos) and the internal universe (the organism) are known through the sensorium. The normal functioning of the complex nervous mechanisms of association is indispensable for correct thinking; if these functions are perturbed, the mental faculties, *i.e.*, memory, the formation of ideas, reasoning, etc., are deranged, and an independent, free life is no lo ge r possible. There is no possibility of wisdom for man if the higher functions of his nervous system are not normally performed; knowledge cannot be acquired or integrated with activity so as to do good. Gaskell expressed its importance in a famous epigram, "*The race is not to the swift, nor to the strong, but to the wise.*" The greater the development of the nervous system, the greater is the capacity of adaptation and the surer the control of the environment. In this respect man has an eminent position among all living organisms.

Plants do not respond by rapid adaptation to changes in their environment; their conditions of life do not require it. They have no nervous system comparable to that of animals, but the excitatory state can be transmitted to organs distant from the site of stimulation and thus provoke an adequate response. Notable examples are to be found in the folding of the leaves of sensitive and carnivorous plants.

THE ELEMENTARY NERVOUS SYSTEM

The study of the general features of the nervous system of simpler animals makes it easier to understand the complicated nervous system of vertebrates.

Independent effectors. Sponges have differentiated effectors but no nervous system to initiate and coordinate their activity. On the outer surface there are many pores, covered by a membrane, which open into the subdermal spaces, from which canals lead to chambers lined by an epithelium of flagellated cells. These chambers all communicate with the central cavity. The opening of this cavity, called the osculum, and the pore canals are surrounded by elongated cells arranged to form sphincters. Currents in the water in which the sponge is submerged, several chemical compounds, and other stimuli, produce retraction or expansion of the membranes covering the dermal pores, and contraction or relaxation of the sphincters. The continuous movements of the flagella in the internal chambers keep the water circulating through the animal, from the dermal pores to the central cavity and out by the osculum. A considerable amount of water can pass through; its volume is regulated by the opening and closing of the ingoing and outgoing channels. Each one of the effectors (dermal membrane or

sphincter) acts on its own in response to stimuli that activate it. The excitatory state can be slowly transmitted for a short distance (neuroid transmission), but there is no mechanism for the simultaneous and coordinated action of several effectors. The regulation of the movements of the entrance and exit orifices results from the simultaneous response to stimuli acting on them at the same time. This simple mechanism is sufficient for the achievement of functional unity in the relatively limited and stable conditions in which these animals live.

Nearly all the effectors in vertebrates are under the influence of the nervous system, but a few respond to stimuli directly applied to them, *i.e.*, they behave as independent effectors. The muscle in the amniotic membrane has no nerves, yet it contracts and relaxes, and the heart starts beating in the embryo before it is innervated. The capacity to respond to direct stimuli remains latent in those effectors which are normally activated by the nervous system, as can be demonstrated by severing their nerves. Striated muscles are paralyzed by denervation, but even after the cut nerves have degenerated completely, they contract on application of an electric stimulus. Isolated strips of intestinal muscle, in which there are no nerve cells or fibers, contract rhythmically and show variations in tone. Fragments of heart muscle, free of nerves, continue to beat in tissue cultures long after they have been separated from the organism of which they originally formed part.

Neuroid transmission is also found in vertebrates. The movements of cilia can be modified by stimuli applied at a distance, the excitatory state being conveyed by the epithelial cells.

Systems with Receptors, Effectors, and a Nerve Net

The nervous system of celenterates (hydroids, actiniae, and medusae) consists of differentiated receptors connected by a nerve net to the effectors.

Receptors. Certain epithelial cells in the outer layers of the ectoderm and endoderm are differentiated sensory cells. Superficially they have bristlelike endings. At the internal end they emit a delicate process, which penetrates into the deeper layers and branches out, coming in contact with the processes of the nerve cells. In certain parts, the majority of the fibers follow a preferred direction, *e.g.*, in the tentacle of the sea anemone they go toward the root of the tentacle. In certain cases these receptor cells are grouped in a rudimentary sense organ, *e.g.*, the marginal bodies of the jellyfish *Aurelia*. They have an elementary specific irritability, being more sensitive to certain stimuli than to others.
Fig. 312. Diagram of the nervous system of celenterates. Sensory or receptor cell, motor cell, and muscle or effector cell. (*Parker, G. H., "The Elementary Nervous System," J. B. Lippincott Company, Philadelphia, 1919.*)

Effectors. The ciliated cells, mucous glands, sting cells, and muscle sheets are the effectors. Some of them behave as independent effectors; thus the sting cells respond to direct stimulation, and there is no evidence that nervous excitation can cause them to discharge. Certain muscles, even though they may be stimulated through the nervous system, also respond to direct stimulation, *e.g.*, a beam of light falling on the column of an actinian will provoke localized contraction of the longitudinal parietal muscle so that the animal bends to the light. Muscles can contract to 20 per cent, or even 5 per cent, of their extended length, and they may be anywhere between full extension and maximal contraction. In some cases contraction is very slow, and the "muscle twitch" may last 5 min.; in others it is relatively rapid.

Nerve net. Lying above the muscle layer there is a plexus made up mainly of relatively large bipolar nerve cells, with two long processes or axons, which may reach 7 or 8 mm. in length. These axons have a fibrillar structure and maintain their individuality; when one axon comes

into contact with another, they do not fuse and form a syncytium. At the place where they touch there is a "synapse" (Fig. 313).[1] The axons of the nerve cells in some cases run in a preferential direction, *e.g.*, in the mesenteries of actiniae they run parallel to the muscle fibers or obliquely

FIG. 313. Parallel axon in mesentery of *Metridium* with four synaptic contacts. (*Pantin, C. F. A., Proc. Roy. Soc., London, s.B., vol. 140, p. 147, 1952.*)

from the body wall toward the retractor muscle, where they end in small expansions (end-plates, Fig. 314).

Nervous activity of celenterates. There are several types of nervous activity besides the direct response of independent effectors.

Reflex responses. Adequate stimulation will cause certain fairly rapid responses, such as contraction of the marginal sphincter or retraction of the oral disk by contraction of the mesenteric retractors. If the stimulus attains a certain threshold, a wave of excitation spreads at a definite velocity in all directions along the nerve net, followed by an absolute and relative refractory period. The response is of the "all-or-nothing" type as in vertebrates (see Chap. 66). These features are demonstrated by the following experiment: all except one of the marginal bodies are removed from a medusa; the remaining one, whichever it may be, sends out impulses which spread through the nerve net in all directions, producing waves of contraction throughout the muscle of the bell (Fig. 315). There is no polarized conduction in a definite direction, no irreciprocal spread of excitation at the points of contacts of the axon, as occurs in the synapses of vertebrates. Polarization of conduction is, however, achieved to a certain extent by the anatomical distribution of the fibers, *e.g.*, in the tentacles of actiniae the majority of sensory processes go toward the root and few toward the tip.

FIG. 314. End-plate of axon on retractor muscle of the oral disk of *Metridium*. (*Pantin, C. F. A., Proc. Roy. Soc., London, s.B., vol. 140, p. 147, 1952.*)

[1] According to Leghissa (*Pubbl. d. stazione zool. di Napoli*, **21**, 272, 1949), there is synaptic contact between the sensory and nerve cells, and between the nerve cells and muscle fibers, but the nerve net itself is syncytial. The weight of evidence is in favor of synaptic contact in the nerve net of medusae and actiniae, but the nature of the nerve net in *Hydra* is not yet definitely known. The giant-fiber system of certain worms, however, is syncytial (NICOL, J. A. C., *Quart. J. Biol.*, **23**, 291, 1948).

A single impulse usually does not provoke contraction, but it leaves a facilitating effect so that a second impulse initiates contraction. This process apparently takes place at the junction of the axon with the muscle (Pantin's neuromuscular facilitation).

Rapid reflex responses are mediated by nerve nets which conduct at relatively high speed; *e.g.*, in a metridium 10 cm. high an impulse spreads up the mesenteries in about 50 msec. This system has been called by Pantin the "through-conduction system."

Local responses. Stimulation of a tentacle or the oral disk of an actinian will awake only a local response in the neighborhood of the stimulus. Repeated application of strong stimuli (mechanical, chemical, or electrical), such as occurs in the feeding reaction, is followed first by a local response which later spreads to neighboring tentacles and may involve the whole disk. All-or-nothing impulses are generated which enable their successors to spread over wider areas activating neighboring units. The nerve net mediating these local responses seems to be distributed in units connected with each other (interneural system) so that facilitation (interneural facilitation) may take place between them and excitation spread to several units. There is evidence that the interneural and the through-conduction systems are connected, and that stimulation of one may facilitate conduction in the other.

Spontaneous activity. In widespread and local responses so far described, activity is awakened by an external agent. Celenterates also have spontaneous activity, in the sense that it has its origin within the animal. It is difficult to appreciate because of its extreme slowness; but it has been recorded by kymographic registration and by lapse-rate cinematography. This activity is periodic, the cycles lasting from several minutes to several hours. Thus actiniae expand and retract in 10 to 20-hr. cycles even when kept in complete darkness and in a stable environment. This type of activity is especially developed in certain parts of the animal, *e.g.*, the "column action system" (Jennings). Outside stimuli modify its activity usually by changing the pattern of behavior, not by provoking a definite localized or widespread response. Contraction and expansion of the different muscles are well coordinated; thus, lengthening of the column is brought about by relaxation of the longitudinal parietal muscle and waves of peristaltic contractions of the circular muscle. This sometimes involves reciprocal inhibition (see Chap. 69), *e.g.*, a local contraction of the circular muscle may temporarily inhibit the response of the parietal muscle to excitation.

R
Fig. 315. Diagram of the medusa *Aurelia.* The body has been cut in several parts and all the receptor organs extirpated, except one, *R.* Stimulation of this organ provokes a wave of contraction in the muscle of the bell in the direction of the arrows. When two waves meet they annul each other. (*Parker, G. H., "The Elementary Nervous System," J. B. Lippincott Company, Philadelphia, 1919.*)

Locomotion in actiniae is carried out by this same type of slow semi-independent activity of the pedal disk and column of the animal.

The condition of the animal may modify its capacity to respond. For example, feeding or the introduction of meat juice into the esophagus results in a diminished activity of the tentacles, as if the threshold had been raised. On the contrary a starved animal may go through the whole series of feeding reactions, without any obvious outside stimulation, as if the threshold has been lowered by starvation.

Signs of fatigue may be observed when a stimulus is repeatedly applied, so that it loses its efficiency and fails to evoke a response. This is most evident in widespread and local reflex responses.

Spontaneous activity continues for a time in animals anesthetized with magnesium, in which the through-conduction system no longer responds.

The different parts have considerable autonomy; thus a tentacle which has been cut off continues to react to stimulation, and the pedal half of an actinian amputated from the rest of the animal has movements of locomotion (Parker). These observations led to the belief that celenterates should be considered as a sum of autonomous parts rather than as integrated units (Uexkull). The intact animal, however, shows coordinated activity, and "wherever autonomy is most evident it is invariably associated with the local development of specialized action systems" (Pantin).

Systems with Receptors, Effectors, and Nerve Centers

The formation of nerve centers is an outstanding feature in the nervous system of worms, arthropods, and vertebrates. Nervous structures migrate below the surface in the course of embryonic development, and consequently the nervous paths are lengthened. Afferent fibers from the receptors converge toward centers, from which final motor paths, common to many sensory areas, pass out to the effectors.

Receptors. The sensory nerve cells are not found on the surface but are deeply placed, *e.g.*, the dorsal root ganglia of the vertebrates; they come into contact with the surface only through their fibers. These peripheral fibers branch freely in the outer layer, *e.g.*, the pain fibers of the human skin (Fig. 316). More frequently the peripheral fibers of the receptor cells are surrounded by specialized epithelial cells, sometimes forming complicated structures called the sense organs. The specialized cells respond easily to one kind of stimulus; other stimuli do not provoke a response unless they are of considerable strength (specific irritability of the receptors). The afferent neurons are not stimulated directly; the stimulus acts on the specialized epithelial cells, which transmit the excitatory state to the afferent nerve fibers.

Effectors. Nearly all the effectors are controlled by the nervous system, and even though they retain a latent capacity to respond to direct stimulation, in normal circumstances their activity is regulated by nerve impulses; thus striated muscle loses all movement once it is denervated. The influence of the nervous system is not so predominant in other effectors, *e.g.*, in most of the glands and the visceral muscles, which function almost as well after complete denervation as before. There are also a few independent effectors.
FIG. 316. Diagram of sensory cells. *a*, in celenterates; *b*, in worms; *c*, in vertebrates. (*Parker, G. H., "The Elementary Nervous System," J. B. Lippincott Company, Philadelphia, 1919.*)

The motor nerve cells also migrate into the deeper layers. Their polarization is complete; they are stimulated either directly on the cell body or by one of the fibers (dendrites), and they transmit the excitatory state exclusively by one special fiber, the axon (Fig. 317). This contrasts with what occurs in celenterates, where the excitatory state can spread in all directions.
FIG. 317. Diagram of the evolution of motor cells. *a*, in celenterates; *b*, in worms; *c*, in vertebrates. (*Parker, G. H., "The Elementary Nervous System," J. B. Lippincott Company, Philadelphia, 1919.*)

Nerve centers. The bodies of the cells are grouped together in deeply placed structures such as the dorsal root ganglia and the motor nuclei of the ventral horns of the spinal cord. Exceptionally they can be found in the receptor (retina) or the effector (intestines). The connec-

tion between neurons is established by contact, without continuity between the cells. This connection is called the *synapse*[1] (Greek συναπσις, clasping). The shortest paths are made up of only two nerve cells or neurons; one is connected with the receptor (afferent neuron) and the other with the effector (efferent neuron), and they are united by a synapse (Fig. 318*a*). The majority of paths are made up of many neurons; several connector or internuncial neurons are placed between the afferent and efferent neurons (Fig. 318*b*). The number of connector neurons increases with the complexity of the nervous system. The cell bodies of the connector neurons are also grouped in centers which regulate the activity of the lower motor centers. The paths connected with the cephalic receptors acquire great importance in vertebrates; the internuncial neurons of these paths form highly developed centers which are connected with many other centers. This process, known as "encephalization," progresses as the nervous system becomes more complicated. These centers control all the others in the integration of complicated reactions, while the lower centers coordinate only rudimentary sensibility and simple movements. The receptive capacity of the sensory organs and the variety and precision of movement increase with the development of these higher centers.

FIG. 318. Reflex arcs. *a*, bineuronal reflex arc; *R*, receptor; *SN*, sensory neuron; *MN*, motor neuron; *Sy*, synapse; *E*, effector. *b*, multineuron arc; one or more internuncial (*IN*) or connector neurons are interposed between the sensory and motor neurons.

In this type of nervous system the impulse is transmitted in a determined direction (Sherrington's law of forward direction of conduction); there is no diffuse radiation of the excitatory state, such as is seen in the nerve net of celenterates. This outstanding feature is not due to any specific property of neurons in these species, but to the manner in which they are connected with each other. The excitatory state diffuses through the whole neuron, cell body and fibers, but it is not transmitted to all the cells connected with the excited neuron—only to those with which the axon makes a synapse. In celenterates there is either protoplasmic continuity between all nerve cells, or else the membranes that separate them can transmit the excitatory state with equal ease from one cell to another, whatever the direction from which it arrives at the connecting surface. Vertebrate neurons, on the other hand, are anatomic units, surrounded by a membrane which conditions the irreciprocal conduction of the excitatory state and thus causes complete polarization of the neuron in the intact, normal nervous system.

Two different processes can take place: the *central excitatory state*, which transmits excitation from one neuron to the other, and the *central inhibitory state*, which annuls the former and puts a limit to its diffusion (see Chap. 69).

[1] Sherrington introduced this term. For further details see FULTON, J. F., "Physiology of the Nervous System," 3d ed., Oxford, New York, 1949.

THE NEURON

The nerve cell, or neuron, is the morphologic unit of the nervous system. It consists of a nucleus, surrounded by a protoplasmic mass, the *perikaryon*, and protoplasmic processes. The nucleus is usually large, spherical, and poor in chromatin, and it has a nucleolus. The protoplasm contains mitochondria, a Golgi apparatus, and two kinds of pigment. One of these, melanin, is found in great quantities in the cells of the locus coeruleus and the substantia nigra; the other is a yellow pigment, which increases in old age. There is also a substance which cannot be seen in live cells but which in fixed cells precipitates into granules, known as the Nissl bodies. These bodies are colored darkly by basic stains, such as methylene blue; they are found in the perikaryon and the roots of the dendrites. This substance probably plays a part in the metabolism of the cell, as it tends to disappear when the cell is injured or fatigued, a process called chromatolysis. There are numerous anastomosing fibrils in the protoplasm which pass into the dendrites and axons, running parallel to the main axis of the fiber.

Neuron processes are of two kinds: (*a*) the *dendrites;* (*b*) the *axons.*

The dendrites branch out in the proximity of the cell to which they belong. Most neurons have several dendrites, but some, among which are the sensory cells in the spinal root ganglia, apparently have none. In the course of embryonic development the dendrites of these cells take on the appearance of axons, although genetically and functionally they are dendrites, conducting impulses toward the cell body.

There is only one axon or axis cylinder in each neuron, although a few have two. These processes arise from a small eminence in the cell body, usually free from Nissl bodies, known as the "axon hillock," and they send off branches at right angles to the principal fiber. Some neurons have very long axons, which can be over 1 m. in length; they are called Golgi's type I neurons. Others have short axons, which send off branches near the cell body; they are Golgi's type II neurons. Axons branch off into numerous very thin fibers, which end in a swelling, known as the terminal bulb, *bouton*, end-knob, synaptic knob, or end-foot. The synaptic knobs come into contact with the dendrites or the perikaryon of another neuron. The site of contact is the synapse. Each neuron receives many of these knobs. On the large pyramid cells of the frontal cortex there are several thousand of them, and about one million on the Purkinje cells of the cerebellar cortex; the motor neurons of the human spinal cord have up to 23 per 100 sq. μ of cell surface (Fig. 319), and the sensory neurons up to 14 per 100 sq. μ. Approximately 38 per cent of the cell surface of the spinal motor neurons of the cat is covered by terminal bulbs. Large club-shaped endings have been described in certain small cells of the tegmentum; the area of contact is approximately 50 sq. μ instead of the 1 to 2 sq. μ of the ordinary synapse. This club ending covers about 10 per cent of the surface of the cell with which it comes into contact.[1] These facts are of importance in the interpretation of synaptic transmission (see Chap. 69). The dendrites and axon endings sometimes form a thick network around the neuron, which is called the neuropile.

The perikaryon and the dendrites are the receiving part of the neuron. This part has been called the *soma*[2] to differentiate it from the axon, which transmits the excitatory state or nerve impulse to other cells.

Nerves. These structures are the peripheral projection of the neuron processes. They are made up of fibers, *i.e.*, axons and their sheaths.[3] The diameter of the axons varies from 1 and 2 μ in the finer ones to 18 and 20 μ in the larger fibers. Many functional properties of axons, such as their excitability, refractory state, and speed of conduction, are related to the diameter.

Under the phase contrast microscope, axons appear to be made up of a homogeneous, doubly refracting substance, within which there are numerous dark bodies similar to mitochondrias. There are no signs of fibrillar structure.

The ultrastructure of the axon has been studied by means of the electron microscope in isolated giant axons of invertebrates; in vertebrate nerves after dissociating their fibers by the action of ultrasonic waves; in very thin sections; in tissue cultures and in axons extruded from their sheaths. The axon appears to be a

[3] Some of these are axons in the strict sense of the term, *i.e.*, they conduct impulses away from the perikaryon. Others are genetically and functionally dendrites, which in the course of development have acquired the aspect of axons; they conduct impulses toward the perikaryon.

large bundle of tightly packed fibrils placed in the longitudinal axis. The diameter of each fibril is 100 to 400 A (1 A = 0.1 mμ). Frequently the fibrils show a higher optical density along the edges, taking on the aspect of tubes (neurotubules). After the axon has been cut off from the perikaryon, the fibrils disintegrate very quickly, simultaneously with the fall in action potential. Between the fibrils there are many bodies of high optical density. The largest of these are rod-shaped, measuring 250 to 900 mμ; they have the appearance of mitochondria.[1]

The outer layer of the axon, the axilemma, acts as a membrane; inductance, resistance, capacity, and other electrical properties of this membrane have been measured in various physiologic conditions, in several species. It has a selective permeability; therefore the axoplasm differs from the surrounding media, *e.g.*, the concentration of K^+ is higher and that of Na^+ and Cl^- lower than in extracellular fluid.

In the course of development, when the diameter of the axon is between 1 and 2 μ, it is surrounded by a sheath of concentric layers of protids and lipids. This is the myelin sheath, which is interrupted at regular intervals by constrictions called the nodes of Ranvier. Studies with the electron microscope[2] have shown that the myelin sheath is made up of concentric lamellae 80 A thick; there are about 250 of these in a 2-μ sheath, separated by layers of water and protein. X-ray diffraction studies indicate that unimolecular layers of protein alternate with bimolecular layers of lipid. The thicker fibers have a relatively thinner myelin sheath than finer fibers. Myelin has a high electric specific resistance, about ten million times that of Ringer's fluid, and it acts as an insulator.

A thin protoplasmic layer in which there are nuclei surrounds the myelin sheath; it is clearly visible only around the nuclei and at the nodes

of Ranvier. This layer is formed by the Schwann cells. A thin membrane, the neurilemma, covers the whole fiber; it comes into contact with the axon at the nodes of Ranvier, and it is only at these nodes that the axon sends off branches. The neurilemma is surrounded by another sheath made up of reticular fibers with a few collagenous fibers (Fig. 320*a*). The fibers of a nerve are kept together by a nucleated fine connective-tissue structure, the endoneurium, and the whole nerve is surrounded by a connective-tissue sheath, the epineurium.

Some nerve fibers do not have a myelin sheath; they are called Remak's fibers. The axon is of small diameter and is surrounded by a thin layer of lipids under the Schwann cells and the neurilemma (Fig. 320*b*). Most of the postganglionic fibers of the sympathetic are unmyelinated. This type of fiber is also found in sensory nerves in a proportion varying from 1:1 to 1:4 with respect to myelinated fibers. Section of the dorsal spinal roots, distal to the ganglia, causes degeneration of all the myelinated fibers and 80 to 90 per cent of unmyelinated fibers in peripheral nerves. The latter conduct impulses originated by painful stimuli.

There are four types of nerve fibers: (*a*) naked axons, found in the gray matter of the nerve centers and the peripheral endings of axons; (*b*) axons surrounded by a myelin sheath, but without the neurilemma, found in the white matter of nerve centers; (*c*) axons with myelin and neurilemma sheaths, which are the principal constituents of most peripheral nerves; (*d*) axons with no myelin, but only the Schwann cells and neurilemma (Remak's fibers), which are the postganglionic fibers of most visceral nerves and an important part of the sensory fibers of peripheral nerves.

Neuroglia. There is no connective tissue in the nerve centers, except around the blood vessels; neuroglia is the supporting tissue. Neuroglia proper includes several types of cell: (*a*) *protoplasmic astrocytes*, with multiple branching processes, which are the mossy cells in the gray matter of the spinal cord and brain; (*b*) *fibrous astrocytes*, with long unbranched fibers, which are the spider cells of the white matter; (*c*) *oligodendroglia*, small cells with very thin processes, few in number and rarely branching, which are found in close proximity to neurons and nerve fibers and to which metabolic functions have been attributed. In types (*a*) and (*b*) some of the processes are attached by "end-knobs" to the blood vessels. The surface of the brain and spinal cord is covered by the piaglial membrane, on the inner aspect of which there are numerous astrocytes. This membrane sends sheaths around the blood vessels that penetrate into the nerve centers

The ependymal cells are also supporting cells; they line the ventricles of the brain and the central canal of the spinal cord. These cells have a long, slender process, which goes into the

nerve tissue. In the embryo they also have numerous cilia on the free surface of the cell, but most of these are lost in the adult.

The white and gray matter of the brain and cord have small cells of mesodermal origin, which constitute the *microglia.* They have little protoplasm, two or three thorny, branching processes, and a small nucleus. They are phagocytic cells and play an important part in the removal of dead tissue.

The Trophic Function of the Neuron

The neuron is a trophic unit; the nucleus and the perikaryon play an indispensable part in the maintenance of the anatomic and functional integrity of the whole cell. When a process is cut, the part separated from the perikaryon disintegrates while the cell reacts and repairs the damage, provided the injury is not such that it kills the whole cell.

Degeneration of nerve fibers. After a nerve is cut or crushed, the part of the fiber separated from the perikaryon suffers profound changes in the axon and sheaths, which are known as "wallerian degeneration," after Waller, who was the first to describe them. The axon shortens and folds, and later is split into fragments. The fine submicroscopic tubes visible under the electronic microscope rapidly disintegrate, and the orderly distribution of molecules and micellae is lost.[1] Myelin also is split up into fragments. Phagocytic mesenchymatic cells invade the neural tube a few hours after the nerve has been cut and have been found up to 80 days after nerve section. The neurilemma sheath and endoneurium thicken and coalesce, the Schwann-cell nuclei multiply, the protoplasm increases, and the whole cell lengthens, taking on a fibrous aspect. Gradually the Schwann cells fill all the neural tube. This tube narrows down so that around the fiftieth day it is reduced to about half the original diameter.

Chemical changes occur in the course of degeneration and regeneration of nerve. The cut nerve swells and its wet weight increases. Neutral tat, found mainly in the connective-tissue sheath, decreases rapidly. Chemical disintegration of the myelin sheath does not begin until about 8 days arter the nerve has been cut. The myelin lipids (free cholesterol, cerebroside, and sphyngomyelin) diminish;[2] cholesterol is in part bound to the fatty acids set free by hydrolysis, and cholesterol esters appear; kephalin and lecithin, which are axon constituents, also decrease, the former more rapidly and the latter more slowly than the myelin lipids. Phosphoprotein and a lipoprotein complex which forms part of "neurokeratin" also diminish.

Nucleic acids increase coincidently with cell proliferation (Schwann cells, fibrocytes, macrophages). The curve representing changes of desoxypentosenucleic acid (DNA) is similar to the curve representing changes in the total number of cell nuclei. Pentosenucleic acid (PNA), an index of total mass of cytoplasm, increases more than DNA. The PNA:DNA ratio increases at the same time that an increase in Schwann-cell cytoplasm can be demonstrated.[1]

Acetylcholine and the enzyme system for its hydrolysis and synthesis (cholinesterase, cholinacetylase) diminish.[2] Other enzyme systems also undergo marked changes.[3] Acid phosphomonoesterase increases at the same time as DNA. Alkaline phosphomonoesterase diminishes. 5-Nucleotidase, active on substrates such as adenosine-5-phosphate and inosine-5-phosphate, increases.

During regeneration myelin lipids increase, spreading toward the periphery as myelin is built up, but they remain below normal concentration for a long time, perhaps permanently. Kephalin and lecithin also increase, but the latter does not return to the normal level; neither does neurokeratin. The concentration of nucleic acids remains high. The regenerated nerve differs chemically from normal nerve, as it differs by some of its physiologic properties (see "Regeneration of nerve fibers").

Degeneration of mammalian nerves is complete in about four days, but the different types of fibers do not degenerate at the same rate. Many years ago histological observation showed that certain sensory nerves degenerated more rapidly than motor nerves,[4] and recently[5]

registration of action potentials (see Chap. 66) has confirmed the fact that sensory fibers from the skin degenerate earlier than afferent and efferent fibers in motor nerves. Rosenblueth and Dempsey[1] have seen that thick fibers with a rapid conduction velocity cease to conduct nerve impulses before thin, slow-conducting fibers. There is some discussion as to whether degeneration progresses centrifugally (Parker, Rosenblueth, *et al.*) or centripetally, *i.e.*, whether the fibers cease to conduct earlier in the proximal or the distal end. Erlanger and Schoepfle[2] maintain that the evidence is consistent with abrupt failure of conduction at random loci increasing in frequency toward the periphery. They suggest that differences in the blood supply of the degenerating fibers may account for the differences observed.

The proximal end also shows alterations. The axon swells, and for a few millimeters of its length above the cut it is destroyed. Myelin is broken up and ingested by phagocytes, and the Schwann cells multiply. Sometimes the axon degenerates in its whole length up to the perikaryon. The cell body swells. The nucleus is displaced to an eccentric position. The Nissl bodies disappear from the base of the dendrites on the first day, and later from the rest of the perikaryon. This phenomenon is known as chromatolysis. It is more marked when the fiber is cut near the cell body and may be almost imperceptible when only the end of the fiber is injured. With time, the Nissl bodies reappear.

Gudden's atrophy. Retrograde cell degeneration is more severe in certain cases. Gudden saw that a destructive injury of the cerebral cortex made at birth was followed by degeneration of those nuclei in the thalamus which gave rise to the fibers destroyed in the cortex.
Fig. 321. Transverse section of the peripheral stump of rabbit's nerve, cut 150 days previously and left unsutured. The Schwann tubes contain one or more fibers, surrounded by a myelin sheath *MY*, and Schwann cells, with protoplasm *P* and nuclei *S*. *ET*, Schwann tube into which no fiber has penetrated; *M*, macrophage in a tube that contains several fibers in the process of regeneration; *F*, fibroblast. (*Young, J. Z., Physiol. Rev., vol. 22, p. 318, 1942.*)

Transneuronal degeneration. Destruction of neurons can provoke degeneration of the neurons that are usually stimulated by the destroyed nerve cells. A restricted lesion in the retina causes atrophy in the neurons of the geniculate body on which the axons of the destroyed retinal neurons end. This phenomenon occurs when injury has damaged the neurons that send the greater part of the impulses received by a nucleus; it can be considered as a case of "isolation atrophy."

Regeneration of nerve fibers. (Fig. 321.) The process of regeneration of an injured nerve fiber is accomplished by the joint activity of the perikaryon, the axon, and its sheaths. The Schwann cells play a very important part; they multiply and migrate from both ends, and can form a bridge up to 3 mm. in length. They are accompanied by the fibroblasts of the endoneurium, and the fibers formed by these cells give a certain solidity to the bridge. As soon as retrograde degeneration has ceased in the proximal end of the axon, a great number of

slender processes, sometimes as many as 100, are put out from the axon and grow in all directions. Their ends take on a bulbous aspect wherever they come up against an obstacle, such as a fibrous plane, that hinders their growth. These fibers form a thick network and give rise to nerve tumors (neuromas), which can be very painful.

When an axonic process comes into contact with a Schwann cell, this cell acts as a support along which the axon grows until it reaches the distal end of the cut nerve, eventually penetrating into the neural tube. The axon grows very slowly in the midst of scar tissue, only 0.25 mm. per day, but once it has entered a neural tube it grows at a greater speed, as much as 3 to 4 mm. daily.

Axons not only grow in length but also increase in diameter from the perikaryon down. Recovery of the physiologic properties progresses in linear relation to this increase in diameter. A small action potential (see Chap. 66), conducted at a speed of less than 1 m. per sec., can be registered in the distal end of a cut and sutured nerve of a cat 17 days after operation. With time the size, velocity, and complexity of the action potential increases, but even a year after, recovery of axon size is only 80 per cent of the normal.[1] Connection with an end organ is of great importance for the increase in diameter; when a fiber connects with an end organ it develops much faster than others in the same nerve.[2]

The importance of peripheral connections is well illustrated by the following experiment: The nerve to the middle head of the gastrocnemius of the rabbit, which has about 350 fibers, was crushed on both sides. On one side it was also cut lower down so that the regenerated fibers were unable to reach the periphery. Fiber size above and below the crushed points was measured 100 days after operation. Below the crushed point on the disconnected side there were 2,000 fibers; the largest were 14 μ (in normal nerve the largest fibers were 20 μ), and the majority were much smaller. On the side where peripheral connections had been established there were nearly 600 fibers, the largest being of nearly normal size (18 μ), and size distribution was similar to that in the normal nerve. Moreover, fibers above the crushed point on the disconnected side had shrunk considerably in diameter.[1] Fibers are, therefore, influenced not only by their central connections but also by their peripheral ones—a condition that has been called by Young one of "double dependence."

The myelin sheath is also regenerated when the axon belongs to a myelinated fiber. The nature of the neural tube does not condition the formation of a myelin sheath. Thus the axon of a somatic neuron that penetrates a neural tube of a degenerated sympathetic fiber is eventually surrounded by a myelin sheath, but on the other hand if the axon of a sympathetic neuron enters a tube that has belonged to a somatic fiber, a myelin sheath is not regenerated. Nevertheless the size of the neural tube limits the growth in diameter of the axon; therefore the recovery of its physiologic properties.[2]

The anatomic and functional restoration of a nerve depends on the penetration of its axons into the distal neural tubes. Therefore, to obtain good results rapidly, this penetration should be helped. When a nerve is severed by compression, the axons are destroyed without interrupting the continuity of the nerve; regeneration then takes place at a speedier rate, and the functional deficit is finally less marked than if the nerve had been cut and its ends separated. The suture of a cut nerve with approximation of the ends is of great value; it should be done with material that does not provoke an inflammatory reaction. Stretches of nerve kept frozen and dried, and hydrated at the time of use, have been employed to fill wide gaps due to extensive destruction of a nerve.[3] The importance of the fiber pattern of the funiculi used in grafting has been pointed out.[4] The graft should possess mainly large myelinated fibers, with as little branching and plexus formation as possible. Segments of cutaneous nerves such as the superficial radial and sural nerves are very suitable for this purpose. A serious obstacle encountered in nerve regeneration is the tendency of the free axon

tips to branch out and form neuromas. This can be prevented by encasing and joining the cut ends in a cuff, made by a fresh or adequately preserved artery or by tantalum foil. The nerve should fit snugly into the guiding tube, but it should not be tightly packed; otherwise the development in diameter of the axons will be limited, with unfavorable results in the recovery of physiologic properties. The suture of a cut nerve is successful even when made 1 month after the injury. It should not be delayed too long, however, because as time passes, the reproductive activity of the Schwann cells diminishes, the neural tubes become narrower, and the terminal organs, such as the end-plates, are atrophied.

Functional restoration of the cut nerve depends on (*a*) the entrance of a sufficient number of axons into neural tubes of appropriate diameter; (*b*) the establishment of adequate connections between fibers and end-organs, *e.g.*, between motor fibers and muscle end-plates; (*c*) the condition of the effector, which may have suffered irreversible atrophy if it has remained without functioning for too long a period.

The neurons in the nerve centers have lost all reproductive power; if they are destroyed they cannot be replaced. Spinal-cord transection in man is not followed by regeneration of the spinal tracts, even when done with surgical care and asepsis, as in operations performed to relieve pain. The absence of Schwann cells, which play so important a part in peripheral nerve fiber regeneration, and the complexity of central connections may account for some of the difficulty in the regeneration of severed or injured tracts in the nerve centers.

Excitability.

Electrical Phenomena in Tissues

EXCITABILITY IS THE capacity of the organism to respond by an internal modification (adaptation) to a change in the energy potential of the environment, *i.e.*, to a stimulus. Excitability is a property of all living cells, but it is highly developed in some tissues (*e.g.*, nerve and muscle) and less obvious in others (*e.g.*, bone, cartilage, and adipose tissue). Notwithstanding the considerable differences observed in the excitability of different cells and in one and the same type of cell in different species, there are laws of excitability common to all living organisms.

THE GENERAL LAWS OF EXCITABILITY

Specific irritability. Energy in all forms, mechanical, chemical, electrical, heat, light, sound, etc., can act as a stimulus. This does not mean that all changes in energy potential excite all cells; certain conditions, particular to the physiologic state of the cell, must be satisfied for a given stimulus to evoke a response. A fundamental condition is that the form of energy must be suitable for the receptor. Each cell has a stimulus, or group of stimuli, to which it responds with greater ease, *i.e.*, the response is provoked with a smaller quantity of energy than that needed with other forms of energy. This is known as the "specific irritability" of cells. For example, mechanical deformation of the skin stimulates certain cutaneous receptors, others are sensitive to changes in the temperature of the skin, and in the retina there are cells sensitive to light. It is also possible to excite a cell with a nonspecific stimulus. Thus a sensation of light can result from a blow (mechanical energy) on the eyeball. Similarly in physiologic conditions striated muscle fibers are stimulated exclusively by nerve impulses, but they can also be stimulated by an electric shock, a sharp blow, a sudden rise in temperature, and several chemical substances. Certain variations in energy potential apparently do not act as stimuli; *e.g.*, ultraviolet and infrared rays are not visible because they do not stimulate the retina, but they have been shown to evoke responses from other cells. It is difficult to state definitely that a given change in energy potential has no influence on an organism, because sometimes its effects are not easily recognized or may take some time to appear.

Electricity is the form of energy most commonly used for experimental purposes, because it is easily handled, can be accurately measured, and does not produce irreversible changes in the tissues when properly applied. Other forms of energy such as light, sound, mechanical energy, etc., must be used when studying special receptors sensitive to these stimuli.

Conditions of efficiency in a stimulus. Excitability can be measured, and its changes followed, by estimating the conditions that a stimulus must fulfill to evoke a response. Thus, if the excitability of a tissue diminishes, it is necessary to increase the strength of a previously adequate stimulus to evoke the same response.

Three parameters must be considered in a stimulus: (*a*) the intensity or strength; (*b*) the time in which the change of energy potential takes place, *i.e.*, the rate of change; (*c*) the time

during which this variation must remain at or above a certain level.

Strength of stimulus. The threshold. Whatever be the nature of the stimulus, it must be of a certain minimum strength to evoke a response. When the strength is just sufficient to provoke the minimum response, it is called the *threshold* or *liminal* stimulus. If it is weaker and does not provoke a response, it is called *subliminal.* A *maximal* stimulus evokes the greatest response possible, and a *supramaximal* stimulus is one of even greater strength. A *submaximal* stimulus provokes a response intermediate between the smallest and the greatest. The foregoing statements are valid for structures made up by several excitatory units; each unit, *e.g.*, a single nerve or muscle fiber, responds maximally to the threshold stimulus, *i.e.*, further increase in the strength of the stimulus does not increase the response (see "The all-or-nothing" law, page 776). When excitability increases, a previously subliminal stimulus may attain or surpass the threshold; on the contrary, when excitability decreases, a previously efficient stimulus may become subliminal.

The strength or intensity of a stimulus is given by the degree of variation in energy potential, *e.g.*, in an electric stimulus, it depends on the voltage; in stimulation by heat, on the rise or fall in temperature; etc. The quantity of energy should really be taken into account instead of considering only the rise or fall in potential. For example, in a mechanical stimulus (considered as the energy developed by the fall of a body) the height of the fall and the weight of the mass falling are the components that determine the strength of the stimulus. The efficiency of an electric stimulus depends on the density of current, *i.e.*, intensity of current i, expressed in amperes, in relation to the surface on which it acts; $i \times$ sq. cm. It is usual to express the intensity of an electric stimulus by the voltage; this is justified if there is no change in the stimulated surface or in the impedance of the circuit, as by Ohm's law, $i = V/R$ (V = voltage, R = resistance). Hence, when R is constant i varies as, and in proportion to, V. In the discussion that follows, the intensity or strength of an electric stimulus will be expressed in volts.

FIG. 322. Diagram of strength, slope, and duration of stimulating currents. *a*, the current is established and stopped instantaneously, and lasts a certain time at a given voltage; the threshold is reached and stimulation takes place; *b*, a current of the same type and strength, but lasting a shorter time, does not stimulate; *c*, the current lasts the same time as in *b*, but is of a higher voltage, therefore it acts as a stimulus; *d*, the current rises gradually, therefore it must rise to a higher voltage in order to reach the threshold; *e*, the current rises at a slower rate than in *d*, therefore it must rise to an even higher voltage to attain the threshold; *f*, the slope of the current is such that it can never reach the threshold.

The variable phase in the evolution of energy is of paramount importance; the constant phase is important only during a short initial period (see "The duration of the stimulus," page 773). This can be demonstrated by stimulating a muscle with a galvanic current. There is a contraction at make and another at break, but while the current flows at a constant potential there is no contraction. The rise in potential at make and its fall at break act as stimuli.

Excitation takes place at the cathode at make and at the anode at break. Anode-break excitation is often absent, *e.g.*, in freshly dissected muscle and in frog nerves with normal circulation. Conditions that depress a preparation and lower the membrane potential (see page 779) are favorable for the appearance of anode-break excitation which may evoke a repetitive response.

The rate of change in potential. Du Bois Reymond's law. Sudden variations in energy potential are more efficacious as stimuli than gradual changes. As the rate of change diminishes the rise or fall in potential must be increased in order to attain the threshold; if it is below a certain value no response is evoked however great the variation in potential (Fig. 322). Du Bois Reymond expressed this fact in the form of a law (Du Bois Reymond's law of excitation): Excitation is a function of the differential coefficient of the density of current c with respect to time t; dc/dt.
FIG. 323. Chronaxie. Strength-duration curve. $1R$, rheobase; $2R$, twice the voltage of the rheobase; C, chronaxie. (*Lapicque.*)

The duration of the stimulus. Chronaxie. A stimulus must remain at or above the threshold for a certain time, otherwise it does not evoke a response. This fact was demonstrated by the application of stimuli of very short duration, obtained by means of the ballistic rheotome, or Lucas's pendulum and spring rheotomes, or condenser discharges. At present square pulses of variable strength and duration electronically generated are used.

The strength of a stimulus and the time that it must last to excite are related in a way which is characteristic for each tissue and which can serve to define its excitability. Lapicque has given the name "chronaxie" (Greek χρονος, time, and αξια, value) to this relation, called by Waller "characteristic of excitability," and "excitation time" by Lucas. By plotting the smallest strength (voltage) of a stimulus against its duration, strength-duration curves, also called "chronaxie curves," are obtained (Fig. 323). These curves have approximately the same slope for very different tissues if the time scale is changed; this should be in seconds for "slow" tissues and in fractions of milliseconds for "fast" ones. Chronaxie curves have been obtained not only for plain and striated muscle and nerves of vertebrates, but also for invertebrates, protozoa (*Vorticella*), algae (*Spirogyra*), and sensitive plants. Chronaxie is therefore a characteristic of excitability of all cells (Fig. 324).

The excitability of a tissue can be measured by determining one point on the strength-duration curve. The excitation circuit should have a shunt with a resistance of 10,000 to 20,000 ohms, in order to minimize variations in the resistance of the tissue studied. The galvanic threshold is first determined by establishing the minimum voltage that stimulates when the current lasts an indefinitely long time. Lapicque has given the name "rheobase" (base of current) to this voltage. The minimum time that the rheobase voltage must last to stimulate is called by Lapicque the "utilization time." It is unnecessary to prolong the current longer than this utilization time because the voltage cannot be reduced however long the current
FIG. 324. Chronaxie. Strength-duration curves of animal and plant tissues. All have the same shape, but the time scale varies. (*Lapicque.*)

lasts. The utilization time is of physiologic significance, because a stimulus provokes excitation as soon as it has lasted this time. If the current is shortened to less than the utilization time, it will be necessary to increase its strength in order to obtain a response. There is a utilization time for each voltage, which is longer as the rheobase is approached and shorter as the strength of the stimulus increases. The curve approaches the axis of the strength values asymptotically. In practice, however, if the duration is shortened below a minimum, however high the voltage, there is no stimulation (Figs. 322 and 323).

The utilization time of the rheobase is difficult to determine accurately, because in this section of the curve its variation with respect to the values of strength of stimulus is minimal; therefore a small error in establishing the rheobase may result in a great difference in the time obtained. Lapicque has proposed that the time of a stimulus of twice the strength of the rheobase be determined, as the curve varies more rapidly in this section, and therefore its points can be established with greater accuracy. Lapicque also gives the name of "chronaxie" to this time, which he defines empirically as "the minimum time a current must last to obtain a threshold contraction (the minimal response) with a strength of stimulus (voltage) twice that of the rheobase."

The excitability of a tissue can be determined in practice by measuring its chronaxie. It should not be forgotten, however, that chronaxie is an empirical value; therefore comparable results will be obtained only if both the rheobase and chronaxie are measured in well-defined, standard conditions. Otherwise changes in the conditions of stimulation, rather than changes in excitability, will be measured.

There are therefore two time factors of importance in the development of the excitatory state: (*a*) the duration of the variable phase (rate of change—Du Bois Reymond's law of excitation); (*b*) the duration of the constant phase, or utilization time (Lapicque's chronaxie).

Local and propagated excitatory states. A normal tissue at rest is in condition to be excited; the stimulus changes this condition (excitability) into an excitatory state. A process is started at the point stimulated which increases very rapidly; when it has reached a certain size and covered a certain area, it spreads throughout the whole cell. These two phases are known as (a) the *local excitatory state;* (b) the *propagated excitatory state.* As soon as the local excitatory process begins to be produced by an applied current, a reaction takes place in the excitable substance and another process opposes the excitatory change. This reaction has been called "accommodation" by Nernst. The process of accommodation is slow; in myelinated nerves it has only one-hundredth to one-tenth the speed of the local excitatory state. Accommodation is therefore of little or no importance when stimuli of great strength, and consequently short utilization time, are applied; but it is important when the stimulus has a long utilization time, such as occurs with weak stimuli of a strength near the rheobase and with stimuli consisting not in a sudden but in a slow variation of energy potential.

Latent addition. A subliminal stimulus has no apparent effect, but it must have a hidden one, since a response can be obtained if a sufficient number of these stimuli are sent at adequate intervals. The effect of each successive stimulus is added to that of previous stimuli until the threshold has been attained; there has been "latent addition," as Richet called this process.

In latent addition four factors, varying in relation to each other, must be considered: (*a*) strength of stimulus, or voltage; (*b*) the duration of the constant phase, or chronaxie (it would be better to say "utilization time," since the chronaxie is the utilization time of a stimulus twice the strength or voltage of the rheobase or galvanic threshold); (*c*) the interval between the successive stimuli, or its reciprocal, the frequency of stimulation; (*d*) the number of stimuli needed to attain the threshold. By maintaining constant two of these factors, variations of the other two as functions of each other can be studied.

With constant frequency and number of stimuli, as the duration of each stimulus decreases, the voltage must increase to evoke a response. The strength-duration ratio gives a chronaxie curve. The rheobase is the minimum voltage which provokes a response with a given number of stimuli of long duration discharged at a given frequency. If this voltage is doubled, the minimum duration of each stimulus which evokes a

response when discharged the same number of times at the same frequency is the chronaxie for repetitive stimulation.

With a constant number of stimuli, each one of the same duration, as the interval between the stimuli increases (or the frequency diminishes) the voltage must be increased to obtain a response. If the interval between stimuli is lengthened excessively, the voltage will be that of the threshold for a single stimulus, because the effect of each subliminal stimulus will have completely disappeared before the following stimulus is applied. If, on the other hand, the interval is shortened beyond a certain limit, the voltage cannot be reduced, and the minimum remains constant (Fig. 325).

With constant frequency and duration of stimuli, as the voltage is diminished the number of stimuli needed to obtain a response increases. The curve that expresses the ratio of these two factors is an asymptote approaching the axis of voltage with small numbers of stimuli, and the axis of number of stimuli with low voltages. With a given voltage and duration, the product of the interval between the stimuli (or its reciprocal, *i.e.*, frequency of stimuli) by the number of intervals (number of stimuli minus 1) is a constant, which Lapicque calls "summation time." Repetitive excitability can be defined by two time factors, chronaxie and summation time; these increase and diminish simultaneously.

These observations show that the local excitatory state takes some time to develop and attain the threshold that fires off a propagated excitation. The size of this local excitation is dependent on the strength of stimulus; it starts to disperse as soon as it commences and finally disappears completely. Summation takes place when there remains a sufficient amount of the local excitatory state produced by a subliminal stimulus at the time the following stimulus is applied.

Repetitive excitability. A large number of tissues and functional systems are only slightly or not at all sensitive to a single stimulus. However great the strength and duration of a single stimulus, it may evoke no response or only a small one in this type of effector, *e.g.*, glands and smooth muscle. To obtain the full response, stimuli must be applied repeatedly with an adequate frequency and for a sufficient time. Lapicque has called this type of response "repetitive excitability." It is of great interest because the physiologic excitation of neurons takes place by repetitive stimulation.

Wedensky inhibition. When a nerve is continuously stimulated at relatively high frequency, after a time the response diminishes and eventually ceases, *e.g.*, tension developed by a muscle in tetanus (sustained contraction) subsides gradually until the muscle is completely relaxed. This is known as Wedensky inhibition. At one time it was considered as due to incomplete recovery between the successive stimuli and prolongation of the refractory period (see below), because a response can be obtained by stimulating at lower frequency. There are, however, several phenomena included under the single term of "Wedensky inhibition." One type of depression occurs after relatively prolonged stimulation; it is due to the release of an insufficient amount of chemical mediator, acetylcholine, in muscle. In this case the injection of a small amount of acetylcholine, not large enough to evoke a response, will summate its effect with that of the stimulation which has become subliminal, and the effector will again respond. In other cases depression is due to an excess of chemical mediator accumulated during excitation at high frequency, or because the mediator is not destroyed. This effect can be produced by injecting large doses of the mediator, or by

FIG. 325. Voltage and frequency of stimuli needed to obtain summation. Forty-eight stimuli of $\frac{1}{60}$ and $\frac{1}{90}$ of a chronaxie were applied to the columella muscle of the snail *Helix*. (*Chauchard, A., and B. Chauchard, Ann. de. Physiol., vol. 1, p. 6, 1925.*)

protecting it from destruction[1] (see "Chemical phenomena of neuromuscular transmission," Chap. 67).

The refractory period. As soon as the propagated excitatory state is produced, the tissue becomes inexcitable, and for a short time no response can be obtained even when a stimulus of great strength is applied. This is known as the *absolute refractory period.* It is followed by a second phase, called the *relative refractory period*, during which excitability is gradually restored. The strength of the stimulus needed to evoke a response is at first considerable; then it diminishes progressively until the normal threshold is recovered. In certain conditions a period of hyperexcitability follows the relative refractory period (Fig. 326). The capacity of response during this relative refractory period is depressed; *e.g.*, the nerve fiber conducts at lower speed an impulse that has a smaller action potential.

FIG. 326. Recovery of excitability after excitation in a nerve-muscle preparation of a frog. (*Adrian and Lucas, J. Physiol., vol. 44, p. 68, 1912.*)

The duration of the refractory period varies in different tissues and depends on the state of excitability. Bowditch was the first to observe the refractory period when studying the excitability of heart muscle. The heart has a very long refractory period, which lasts throughout the phase of contraction. In nerve fibers of the highest speed of conduction, the absolute refractory period lasts from 0.4 to 0.5 msec., and the threshold returns to normal in 2 to 3 msec. Striated muscle in the cat, stimulated through the nerve, has a refractory period of 3 msec.; when the muscle is stimulated directly this is reduced to 2.2 msec.; the muscle end-plate, therefore, prolongs the refractory period by 0.8 msec.

[1] ROSENBLUETH, A., K. LISSÁK, and A. LANARI, *Am. J. Physiol.*, **128**, 31, 1939.

Rosenblueth and his associates[1] maintain that the division of the refractory period into absolute and relative has no physiological significance; there is a *functional refractory period*, *i.e.*, the time after a conditioning stimulus during which the action potential developed by a second stimulus at the site of excitation is not of sufficient amplitude (voltage) to reach the threshold of the neighboring parts of the nerve.

The all-or-nothing law. Bowditch (1871), working in Ludwig's laboratory, showed that a frog's heart, brought to a standstill by a Stannius ligature, responded to a threshold stimulus with a maximal contraction; no greater response could be obtained by increasing the strength of the stimulus, other conditions being equal. "The reason why the heart can vary its degree of contraction must be sought in the fibers themselves and not in the changes of the stimulating agent."[2] Gotch obtained evidence showing that the changes in response of striated muscle, stimulated directly or through the nerve, with stimuli of different strengths, were due to the activation of a variable number of contractile units, each one of which gave a maximal contraction. Pratt and Eisenberger[3] gave direct and definite proof that each muscle fiber responds maximally to the threshold stimulus. They used a microelectrode and registered the response of individual fibers. They observed that when a fiber contracts it does so to the utmost of its capacity under the existing conditions (Fig. 327).

"All or nothing seems to be the motto of the heart when stimulated," was Ranvier's commentary on Bowditch's work, and this dictum includes striated muscle and nerve. The lack of relationship between size of response and strength of stimulus is easily seen in the heart because it contracts as a single unit. Striated muscle is made up of many units, which can respond separately; contraction increases with the strength of the stimulus because a larger number of units is thus excited. It must be borne in mind, however, that the response of a given unit can vary when the conditions of the tissue are changed.

Stimulation of an isolated fiber, with an electrode sufficiently large to act upon the whole

[1] ROSENBLUETH, A., *et al.*, *J. Cell. & Comp. Physiol.*, **33**, 405, 1949.

[2] BOWDITCH, H. P., *Ber. Sächs. Ges.*, **25**, 652, 1871.

[3] PRATT, F. H., and V. P. EISENBERGER, *Am. J. Physiol.*, **49**, 1, 1919.

fiber, has shown that it is possible to obtain graded contractions by increasing the strength of the stimulus. Tension developed is a function of voltage when stimuli of constant duration are used and a function of duration when the voltage remains constant. Stimulation with a very fine electrode provokes the contraction of only that part of the fiber which is near the electrode. A stronger stimulus increases the contracting area. A still stronger stimulus will produce a contraction that spreads to the whole fiber and is of an all-or-nothing character, *i.e.*, the weakest stimulus capable of producing this propagated disturbance evokes a maximal contraction. Both the local and the propagated excitation give normal strength-duration curves (chronaxie curves), but only the propagated excitation is accompanied by a "spike" potential.[1] As long as the muscle fiber remains in good condition, it is very difficult to obtain a localized response graduated in relation to the strength of the stimulus. This is made easier by the use of anesthetics, an excess of K^+, or any other agent that damages the integrity of the fiber. In physiologic conditions striped muscle, nerve, and heart give the maximal response with the minimum stimulus that can provoke a propagated excitation.

[1] The local excitatory state is also accompanied by electrical phenomena, but there is not a large "spike" potential such as is seen in the propagated excitatory state (see "Electrical phenomena of muscular activity," Chap. 67).

Adrian has pointed out that an all-or-nothing response is a consequence of a threshold and a refractory period. When the local excitatory process reaches the threshold, a propagated disturbance is initiated and excitability disappears for a short time (absolute refractory period). Therefore, even if the stimulus continues it cannot produce a greater effect because the tissue is incapable of response (Fig. 328).

FIG. 327. The "all-or-nothing law." The lower tracing registers the strength of the stimulus; the upper tracing, the response of the muscle. The height of contraction increases suddenly, *e.g.*, at *A* and *B*, when the gradual increase in strength of stimulus reaches certain levels. (*Pratt, F. H., and V. P. Eisenberger, Am. J. Physiol., vol. 49, p. 1, 1919.*)
FIG. 328. Changes in excitability produced by stimulation. When the local excitatory state *V* produced at the cathode reaches the threshold *U*, the propagated excitatory state is fired off and excitability *E* disappears completely (absolute refractory period); later excitability is gradually recovered during the relative refractory period. Persistence of *V* above the threshold cannot evoke a second impulse because excitability has been abolished.

The local excitatory state is not all-or-nothing in character. Its size depends on the strength of the stimulus, or better still on the relation between the strength of the stimulus and the excitability of the tissue. It is not followed by a refractory period and does not have a spike potential. As soon as this state attains a certain threshold size it starts a propagated disturbance, which is all-or-nothing in character, is followed by a refractory state, and has a spike potential.

Excitability of different tissues. Though all cells and tissues are excitable and there are laws common to the excitability of all of them, there are also differences between the tissues. Thus, generally speaking, tissues that respond slowly have a higher rheobase and a longer chronaxie than tissues that respond rapidly. The frog gastrocnemius has a chronaxie of 0.3 msec. and a contraction time of 0.15 sec.; gastric muscle in the same species has a contraction time of from 15 to 20 sec. and a chronaxie that varies between 30 and 100 msec.; the pigment cells (chromatophores) in the frog's skin react very slowly, and their chronaxie is 11 to 15 sec. (Table 85).

Factors that modify excitability. When studying excitability it should be kept in mind that currents of short duration excite only at the cathode; therefore only changes taking place under the cathodic electrode produce an effect. Generally speaking, rheobase and chronaxie vary in inverse direction.

Cold diminishes the threshold (rheobase) and increases chronaxie; if sufficiently intense it will abolish excitability. A change of the *acid-base equilibrium* toward the alkaline side diminishes the rheobase and increases chronaxie; one toward the acid side produces opposite effects. Alkalosis produces an increase in muscle tone and spontaneous contractions that can become convulsions; this syndrome is called tetany. In acidosis, muscles are relaxed and excitability is depressed. Excitability is also conditioned by the *ion equilibrium.* Monovalent and bivalent cations are antagonistic to each other. Variations in the ratio of $\frac{K^+ + Na^+}{Ca^{++} + Mg^{++}}$ cause changes in excitability. A relative or an absolute increase in monovalent cations lowers the rheobase (threshold) and increases the chronaxie; the predominance of bivalent cations has the opposite effect. Removal of the parathyroid glands diminishes the blood calcium (hypocalcemia); therefore the threshold of excitability is lowered and tetany occurs. Hypercalcemia, on the contrary, depresses excitability. Application of a constant electric current provokes changes in excitability which will be discussed later (see "Electrotonus").

ELECTRICAL PHENOMENA IN TISSUES

Toward the end of the eighteenth century Galvani demonstrated the existence of electrical phenomena in living tissues. He exposed the sciatic nerve of a frog and placed it on the leg muscle of another frog, having first injured this muscle. Each time the nerve closed a circuit between the undamaged surface and the injured part of the muscle, the muscles innervated by the nerve contracted. There is a difference in

FIG. 329. Galvanoscopic leg. Each time the nerve *nb* of the muscle *B* closes the circuit between the normal surface 1 and the injured surface 2, *B* contracts.

potential between the intact and the injured parts of the muscle; the nerve acts as a conductor and the electric current thus set up stimulates it. The 'galvanoscopic leg" was the first galvanometer to be invented. It was the means of registering for the first time the effects of a direct electric current (Fig. 329).

Demarcation potential and action potential. When a nerve or muscle is injured and the damaged part is joined to the intact surface by a circuit in which there is a sufficiently sensitive galvanometer, the injured part is found to be electronegative with respect to the parts that are undamaged (Matteuci, 1838). This is the injury or demarcation potential; it diminishes in approximately exponential form with distance from the injury (Fig. 330 I). It is due to the existence of an electromotive force in the intact membrane, the *membrane resting potential*, the protoplasm being negative and the external fluid positive. Injury removes the electromotive force, and there is no potential difference at the junction of protoplasm and external fluid. The demarcation potential sets up a flow of current, the demarcation current, through a considerable segment of the fiber (Fig. 330 II).

When a cell is stimulated and an excitatory state is evoked, the point stimulated becomes electronegative with respect to the parts at rest (Du Bois Reymond). A "negative variation" spreads like a wave over the whole surface of the cell (Bernstein); this is the *action potential*, or more precisely the spike potential, of the propagated excitatory state. It travels at a definite

Res., vol. 131, New York, 1947.*)
Fig. 331. Simplified diagram of cathode-ray oscillograph. *S*, stimulating electrodes, through which an induction shock, or a condensor discharge, can stimulate the nerve; *L*, electrodes of registering circuit, one terminal on the intact surface, the other on the killed end of the nerve; thus a monophasic variation is obtained. The source of electrons (cathode rays) is a Braun tube; the rays are "focused" on the fluoroscope or the photographic paper of a photokymograph. As the electrons pass between the *X* plates, the rays can be moved in a horizontal plane by changes in potential in the sweep circuit; as they pass between the *Y* plates, they can be similarly moved in a vertical plane. When the nerve is stimulated at *S* the action potential on reaching the circuit *L* provokes an oscillation of the cathode rays as they pass through *Y*. (*Erlanger, J., and H. S. Gasser, "Electrical Signs of Nervous Activity," University of Pennsylvania Press, Philadelphia, 1937.*)

speed—100 m/sec. in the fastest mammalian nerve fibers, and only a few centimeters per second in the slowest fibers.

Resting and action potentials are of very low voltage; the convenient unit of measure is the millivolt (1 mv. = 0.001 volt). Vacuum-tube amplifiers have been used to amplify potential variations of any form without distortion, thus overcoming all difficulties of registration due to the low voltage. Action currents are also of very short duration; the unit of time convenient for their measurement is the millisecond (1 msec. = 0.001 sec.). The inertia of the recording apparatus is a serious obstacle for the accurate study of these phenomena. One of the first instruments used was Lippmann's capillary electrometer. Later, Einthoven's string galvanometer became the standard instrument for the study of electrical variations in the heart (see Chap. 15, The Electrical Phenomena of Cardiac Activity). Braun's cathode-ray tube has been adapted by Erlanger and Gasser for use as an oscillograph and can register changes in potential that take place in 0.1 msec.; the results obtained are accurate to 0.02 msec. (Fig. 331).

(*Hodgkin, A. L., Biol. Rev., vol. 26, p. 339, 1951.*)

Isolated surviving nerve or muscle fibers are often used in the study of electrical phenomena of living tissues. These fibers are either surrounded by air (or another dielectric medium) or submerged in a solution of dissociated electrolytes. The former, although an artificial procedure, is a most useful one, but in the living organism excitable tissues are in an environment which is essentially a solution of dissociated electrolytes and therefore conducts electricity. A difference in potential between two points in a medium of this nature causes a flow of current from the positive to the negative pole throughout the whole medium, if it is not too extensive. If a nerve or muscle fiber surrounded by a dielectric medium is stimulated, no change is recorded in a part at rest until the disturbance reaches it. If the nerve is surrounded by a conducting medium there is a fluctuating field of current flow throughout the medium while the disturbance is being propagated; a part of the nerve that is at rest acts as a source of current flow until the propagated disturbance reaches it, as a sink of current flow while activity lasts, and again as a source when the disturbance spreads beyond it.

The resting and action potentials of single fibers can be recorded by several methods:

1. Electrodes are placed on the surface of the fiber or cell (external electrodes); the potentials recorded are reduced by short-circuiting in the external fluid, but this reduction is corrected by determining the ratio between the internal resistance of the fibers and the resistance of the external fluid[1] (Fig 332*A*).
2. A capillary electrode filled with sea water, or isotonic KCl, is introduced into one end of a fiber and pushed into it along its axis for 10 to 30 mm.; the second electrode is placed in the external fluid. The effects of damage made by introduction of the electrode do not extend beyond 10 mm. from the point of insertion. This method has been used in giant plant cells and axons of squids with fiber diameters of 200 to 500 μ[2] (Fig. 332*B*).
3. Electrodes with a tip diameter less than 0.5 μ can be introduced transversely through the membrane without damaging it; they are usually filled with 3*M* KCl in order to reduce junction potentials to a low value. The second electrode is placed in the surrounding fluid[3] (Fig. 332*C*).

The resting membrane potential has been recorded in many excitable tissues. It ranges be-
een 50 and 100 mv. Excitation reverses this
tential by 30 to 50 mv., so that the action
tential ranges from 80 to 130 mv.[1] (Table 86,
;s. 333, 334) (see "Electrical phenomena of

d capacitative membrane. The membrane can
represented by an infinite series of elements
parallel connected by intracellular and extra-
lular fluid conductors (Fig. 335). Each ele-
:nt has a condenser (c), a resistance (r), and a
ttery (*emf*) with the positive plate toward the
ter surface. The membrane acts as a rectifier,
and the current necessary to maintain a depolarization is much greater than that needed to produce an equivalent increase in membrane potential.[1] In the resting membrane there is no flow of current because all the elements are at the same potential (Fig. 335).

FIG. 334. Diagram of axon membrane potential conducting an impulse.

The effects of ions on nerve trunks, and the electrical behavior of the latter in response to applied currents, in many respects are not consistent with the core-conductor theory. The resistance of the epineurium is the cause of these phenomena.[2] If the epineural connective sheath is removed, the nerve follows closely the expectations of the theory, and restoration of the sheath reproduces the original permeability and electrical properties of the nerve.

The membrane has selective permeability, *i.e.*, certain substances pass through it more or less easily, and to others it is impermeable. The size of the particle with respect to the size of the membrane pores, and in the case of ions the electric charge, are fundamental factors in conditioning the passage through the membrane. A membrane with selective permeability which separates two electrolyte solutions (protoplasmic and interstitial fluid) is polarized; ions are distributed on its internal and external surface in an "electric double layer" (Helmholtz). In excitable tissues cations form a positively charged layer on the outside surface and anions a negatively charged layer on the inside surface (Fig. 333).

Lorente de Nó[3] postulates three fractions in the membrane potential, Q, M, and L, maintained at three concentric double layers, q-m, m-m', and m'-l; q is the most external, and l is supposed to be situated in the core. Apparently there is no potential difference

at the boundary between *q* and the external fluid, because substitution of the ions in the external fluid by sugars, or of the cations by choline, does not produce significant changes in the membrane potential. The *Q* fraction is large and rapidly restored (*Q* = quick) during the descending phase of the spike potential. The *M* and *L* fractions are smaller and are restored more slowly during the negative after potential. The *L* fraction is very sensitive to external influences (*L* = labile), such as cooling and ether anesthesia; it is small in a nerve maintained in oxygen but increases rapidly and considerably if O_2 is replaced by 5 per cent CO_2 and 95 per cent O_2.

Fig. 335. Diagram of electrical structure of excitable membrane.

Electrotonus. When a galvanic current is applied to an excitable tissue (polarizing current), part of it flows from one electrode to the other along the conductors outside the membrane, and part through the membrane and the cytoplasm, not only between the electrodes (intrapolar segment) but also spreading in pseudowavelike form in the extrapolar regions laterally to the cathode and anode (Fig. 336). Excitable tissue does not behave as a passive conductor but reacts to the applied current, and electromotive changes take place which have been called "electrotonus" by Du Bois Reymond. The potential (electrotonic potential) established by the flow of current across the membrane is a variation of the membrane potential. This potential spreads in pseudowavelike form along the extrapolar segments, diminishing exponentially as the distance from the electrodes increases.

Fig. 336. Polarization of nerve *N* with galvanic current. P_1P_2, polarizing circuit; R_1R_2, recording circuit.

Lorente de Nó[1] distinguishes several components in the electrotonic potential, E_1, E_2, E_3, E_4. Each one has characteristic electrical features, and each to a certain extent may vary independently of the others. These components are found in the cathode and anode and are related to the different fractions of the membrane potential. The E_1 component develops rapidly and does not spread far; it is a variation of the *Q* fraction of the membrane potential ("fast" electrotonus). E_2 and E_3 are variations of the *M* and *L* fractions respectively; they develop less rapidly ("slow" electrotonus) but spread more, so that at 15 mm. from the polarizing electrode the electrotonic potential is mostly "slow" electrotonus. The E_4 deflection is related to postcathodal depression (see below).

Electrotonus and excitability. Application of a constant current tends to decrease membrane polarization at the cathode and to increase it at the anode while the current is flowing; the reverse occurs when the current ceases to flow.

[1] *Loc. cit.*

This causes considerable changes in excitability during and after the flow of current. Changes in excitability are, in general, parallel to variations in the electrotonic potential. A negative variation lowers and a positive variation raises the threshold.[1] At the cathode (cathelectrotonus) during the flow of current excitability rapidly rises to a maximum, then falls gradually while the current is still flowing. After the current ceases to flow excitability is depressed below the resting level (postcathodal depression). At the anode (anelectrotonus) excitability rapidly falls below the resting level and then rises gradually. When the flow of current ceases, excitability rises above the resting level (Fig. 337).

Cathodal and anodal block. Propagation of the excitatory state (*e.g.*, conduction of a nerve impulse) can be blocked by the polarizing current both at the cathode and at the anode. Cathodal block is due to depolarization and is reinforced by repetitive stimulation. Thus, a single impulse, or a series of impulses at long intervals, may pass through a cathodal region which blocks a series of impulses of higher frequency. Anodal block is caused by an increase in polarization, and impulses arriving at the anodal region do not reinforce, but on the contrary diminish, anodal block; thus a single impulse may be stopped, but a series of impulses may pass through if delivered at a sufficiently high frequency to permit summation of depolarization produced by each impulse.

[1] Fluctuations of E_1 and E_3 produce large changes, and those of E_2 small changes, in excitability.

FIG. 337. Changes in excitability (thin line) and electrotonic potentials, *P*, produced at 6 mm. from the polarizing electrode. On the left, cathodal current; on the right, anodal current. Above, beginning of flow of polarizing current; below, end of flow. (*Lorente de Nó, R., Studies of the Rockefeller Inst. Med. Res., vol. 131, New York, 1947.*)

THE MECHANISM OF MEMBRANE POTENTIALS

The role of metabolism. Membrane potentials of excitable cells can be kept up for a time in tissues separated from the organism and in the absence of oxygen. Anoxia, however, gradually produces depolarization and the membrane potential declines. If oxygen is again available repolarization rapidly takes place and the membrane potential is restored. Even prolonged anoxia does not, however, cause complete depolarization of nerves. A residual potential remains which declines at a very slow rate, and depends on oxidative metabolism only in so far as metabolism is necessary for the maintenance of the normal structure of the fiber. This potential is probably due to differences in the concentration of ions inside and outside the fiber.

The manner in which oxidative metabolism maintains the resting potential is not known. It was usually supposed that metabolic processes acted indirectly, being necessary for the maintenance of the normal structure of the excitable substance and membrane permeability. A more direct action has also been

postulated. According to Lorente de Nó[1] the membrane potential is the result of an equilibrium between electrostatic forces of attraction in the double layer (which would collapse if these forces alone existed) and electromotive forces in the membrane which tend to separate the charged particles of opposite sign. These electromotive forces are established by electrochemical reactions dependent on oxidative metabolism. It has also been postulated that metabolic processes are necessary for the active extrusion of Na from the cells, which may leak in during rest and which enters in large quantities during activity (see below).

The role of ions. Bernstein,[2] on the basis of the fact that potassium concentration is much greater in the excitable cells than in the external fluid, and supposing the membrane to be impermeable to Na^+ and anions, attributed the membrane potential to the difference between the concentration of K^+ inside and outside the cells. Further observations have shown that this theory is inadequate, but undoubtedly the resting and action potentials depend on (*a*) the concentration of ions within and outside the cell; (*b*) the permeability of the cell membrane; (*c*) the metabolic processes which condition ionic concentrations and membrane permeability, discussed in the preceding paragraph.

The concentration of ions in cells and tissue fluids and movements of ions through cell membranes can be accurately determined. The development of sensitive micromethods of analysis and the use of radioactive isotopes have been of great value in this respect. These methods, however, do not give much information on the speed of chemical changes and therefore on the phase of a rapid physiologic phenomenon (*e.g.*, excitation) in which they occur.

Ionic concentrations and membrane permeability in the resting state. The concentration of *potassium* in excitable cells is 20 to 50 times the concentration in the external media (Ringer's fluid, sea water, plasma, or dyalized blood).[3] Most of the potassium (80 to 90 per cent) in nerve and muscle fibers is free to exchange and probably exists as free ions.[4] *Sodium* is three to fifteen times more concentrated in the external fluid than in the cells, and *chloride* five to fifty times more concentrated outside than within the cells. In excitable tissues, therefore, there is high K^+ and low Na^+ and Cl^- concentration in the cells. The deficit of inorganic anions is considerable; in muscle it is more than 120 mEq./kg. of fiber water.[1] Electrical neutrality is maintained by organic anions. Proteins and phosphate compounds are found in high concentration in vertebrate muscle, but the nature of organic anions which balance K^+ has not been established.

According to Conway[2] and his associates the size of the hydrated ions determines whether or not they can pass through the membrane. The membrane is relatively permeable to K^+ and Cl^-, and their equilibrium concentrations are in agreement with the Donnan relation: $[K]_i[Cl]_i = [K]_0[Cl]_0$. Thermal agitation and potential differences are the forces that move these ions through the membrane. Experiments with radioactive isotopes (K^{42} and Cl^{38}) have given results that, with certain restrictions, are in agreement with the Conway hypothesis. The hydrated sodium ion is larger than the hydrated potassium ion, and the resting cell membrane is relatively impermeable to it. A study of the movements of Na^+, made with a radioactive isotope (Na^{24}), has shown[3] a ratio of inward to outward flux of Na^+ that has led to the hypothesis of the existence of an active mechanism which expels from the cell sodium that leaks into it. This "sodium pump" is dependent on a metabolic process.

The magnitude of the resting membrane potential calculated from the potassium concentrations inside and outside the fiber, taking into account Cl^- and other ions, is in good agreement with the figures obtained by direct measurement. If potassium concentration increases in the external fluid, it has a depolarizing action and the membrane potential decreases proportionally to the K^+ concentration. The fall in membrane potential is such as may be expected if the membrane is permeable to K^+ and Cl^- and very little to Na^+ and other ions. There is therefore a considerable amount of evidence for the

importance of K^+ concentration for the establishment of the membrane potential.[1]

The action potential. When an excitable cell is stimulated and enters into activity, the membrane potential is reversed. The inside of the resting cell is negative to the external fluid by 50 to 100 mv.; at the height of activity it is 30 to 50 mv. positive (Table 86 and Figs. 333 and 334). This reversal is attributed to a sudden change in the membrane which becomes highly and specifically permeable to sodium during the rising phase of the spike potential. During the falling phase permeability for potassium increases and the cell loses K^+. A great deal of experimental evidence has been brought forward in support of this hypothesis:

1. The inflow and outflow of sodium have been measured in giant axons of squids by activation analysis and by means of a radioactive sodium isotope (Na^{24}).[2] There is a large increase in the inflow and outflow of sodium, with a net rise in intracellular Na^+ sufficient to account for the transfer of charge which must take place to reverse the potential.
2. It has long been known that muscles immersed in sodium-free Ringer's fluid lose their excitability (Overton). More recent work has confirmed and extended this observation, showing that nerve fibers do not conduct when submerged in a fluid free from sodium, *i.e.*, the excitatory state is not propagated along such a fiber.

[1] Lorente de Nó (*loc. cit.*) does not agree with this conclusion. He finds that anoxic depolarization and recovery in oxygen are not changed significantly by the absence of K^+ in the external fluid.

[2] KEYNES, *op. cit.*, **114**, 119, 1951; ROTHENBERG, M. A., *Biochim. et biophys. acta*, **4**, 96, 1950; GRUNDFEST, H., and D. NACHMANSOHN, *Federation Proc.*, **9**, 53, 1950.

3. If the sodium concentration in the external fluid is reduced, the resting potential increases slightly and the action potential diminishes considerably. The potential is no longer reversed on excitation when the external sodium concentration is one-third to one-sixth the normal. Moreover the maximum rate of rise of action potential is proportional to the external sodium concentration.[1]
4. Potassium inflow and outflow are increased by stimulation, and nerve and muscle fibers lose K^+. A nerve fiber loses at each impulse an amount of K^+ equivalent to that of Na^+ entering it.[2]
5. There is a considerable decrease in the resistance of the membrane during activity,[3] which falls from a resting value (in giant axons of squids) of about 1,000 ohms/sq.cm. to 25 ohms/sq. cm. during activity. Membrane conductance increases rapidly during the rising phase of the spike potential and reaches a high value in less than 0.1 msec. It then decreases but remains above the resting level during the positive phase of the action potential and the early part of the refractory period (Fig. 338). The capacity of the membrane does not change significantly during activity; it may fall 1 to 2 per cent from the resting value of 1.5 μf/sq. cm. (squid axon).

The process of excitation. When a stimulus, *e.g.*, an electric shock, is applied to an excitable tissue, the following events occur: The permeability of the membrane changes abruptly so that sodium ions enter into the cell, the membrane is depolarized, and an electrotonic potential is set up. If this local disturbance occupies a sufficiently large area, the threshold of a propagated disturbance is reached, local currents flow into the active region from the neighboring areas, which are thus depolarized, and excitation spreads along the surface of the cell, accompanied by a spike potential. Na^+ inflow takes place during the first part of the process and the membrane potential is reversed; K^+ flows out during the declining phase of the spike potential. During the recovery period the membrane is repolarized, but the cell cannot respond to stimulation (refractory period) until the process of recovery (repolarization) has reached a certain level. The role of chemical factors in excitation will be discussed in the following chapters.

CHAPTER 67

The Phsiologic Properties of Muscle

MOVEMENT

Movement is one of the most widespread of vital activities; there is no life without it. The protoplasm of the living cell is in constant movement. Its submicroscopic particles show a rapid oscillatory motion known as "brownian movement," there are fluid currents within it, and there is a continual exchange of matter between the cell and its environment. All this activity ceases when the cell dies.

Unicellular animals move from one place to another by means of the so-called "ameboid" movements, or by the activity of flagella or cilia distributed on their outer covering, or under the influence of external agents (tropisms). In animals with a more complex structure (celenterates, arthropods, worms, vertebrates) a special tissue is developed which has the property of contractile movement and which forms the muscles. These organs not only serve for locomotion but also carry out all major displacements of mass within the body.

Ameboid movements. When an adequate stimulus acts on an ameba (or a cell which has ameboid movement) a stream of endoplasm begins to flow toward part of the cell where a salient, called a pseudopod, appears. This is due to contraction of the cortical gel at the rear of the cell. After contracting the gel liquefies and is pushed forward along the central part of the cell toward the pseudopod, where it forms gel on the walls. Several theories have been proposed to explain this type of movement—differences in surface tension, or in pH, or in osmotic pressure between different parts of the cell, rhythmic contraction of the membrane, etc.—but it is not yet clear how these forces act.

Goldacre and Lorch[1] have shown that an injection of 1 to 3 per cent solution of adenosinetriphosphate (ATP) into the tail of an ameba caused contraction to accelerate, and extended wrinkling in the tail region. When ATP was injected into the pseudopod, streaming was reversed. Large amounts of ATP caused rapid putting out and retraction of many pseudopods all over the cell surfaces. These effects lasted less than 1 min. and were again observed on repeating the injection. ATP has an effect on actomyosin similar to its effect on the ameba's tail, *i.e.*, contraction of the actomyosin fiber and liquefaction of the gel (see "Physico-chemical structure of the myofibril"). Goldacre and Lorch suggest that in the tail an "organizer" produces ATP which causes folding of the polypeptide chains of the cortical gel, which thus contracts and liquefies; in the region of the pseudopod the protein unfolds and cortical gel is formed.

The leukocytes of vertebrates progress by ameboid movement at a speed of 30 to 35 μ per min., but for this they must be on a resistant surface; in a fluid medium, such as blood plasma, they have a spherical form. Temperature, saline concentration, ion and acid-base equilibriums, oxygen and CO_2 tensions, several chemical substances, and other factors in the environment condition the ameboid activity of free cells.

Ciliary movement. Cilia are permanent, threadlike protoplasmic organs inserted in the free surface of the cells of certain epithelia and over the whole surface of some free cells (ciliated bacteria and protozoa). Ciliary movement takes place in two stages: (*a*) all the cilia move together in the same direction in a sudden fast movement, like the lash of a whip; (*b*) a slow movement follows which brings the cilia back to the resting position. During the first movement the cilia become rigid, and during the second they are flexible and bend. Particles on

[1] GOLDACRE, R. J., and I. J. LORCH, *Nature, London,* **166**, 497, 1950.

the epithelial surface are displaced in the direction of the rapid movement. Ciliated protozoa progress in a direction opposite to the rapid movement, just as swimmers do. The rate of movement is increased by heat up to an optimal temperature, by alkalinization of the surrounding fluid, and by an increase in K^+ up to a certain concentration. It is decreased, or even stopped, by cold, acidification, Ca^{++}, asphyxia, and anesthesia. The movements of the cilia imply the activity of the whole cell, as is shown by its oxygen consumption, which increases and decreases with the rate of ciliary movement. When the cilia are stimulated at one point, a wave of movement is transmitted all along the epithelium. The excitatory state is not propagated by the movement of the cilia, and this movement can be stopped by cooling a stretch of epithelium without stopping the wave, which is transmitted through the cooled cells and excites the cilia of those on the further side of the block.

Tropisms. In unicellular organisms and in plants there is a particular form of movement known as tropism. An external physical force (physiotropism) or chemical substance (chemotropism) attracts (positive tropism) or repels (negative tropism) the organism or part of it. For instance, oxygen attracts some bacteria and repels others; similarly, light attracts the branches of green plants (phototropism) and gravity the roots (geotropism). Heat (thermotropism), mechanical contact (thigmotactism), fluid currents (rheotropism), or electricity (galvanotropism) also provoke this type of movement.

MUSCULAR CONTRACTION

Fundamental properties of muscle. In higher organisms there are highly differentiated, elongated cells, which have the property of diminishing one diameter and increasing the others, *i.e.*, which can shorten and thicken. These cells are the muscle fibers, and this type of movement is called "contraction"—improperly so, because only insignificant changes in volume occur during contraction and relaxation. The extremities of the fibers are attached to other structures (*e.g.*, bones), either directly or by means of fibrous formations (tendons), and when the muscle contracts these structures are moved. Muscles also form part of the walls of cavities or tubes, the diameters and capacity of which diminish on contraction of the wall muscles and increase on their relaxation.

There are three types of muscle fibers: striated, smooth or plain, and cardiac. They all have the same fundamental properties: (*a*) the capacity of responding to a stimulus, *excitability;* (*b*) the capacity to transmit the excitatory state, *conductivity;* (*c*) the capacity to shorten, *contractility;* (*d*) the capacity to recover the resting form after a force has ceased to act on them, *elasticity;* (*e*) resistance to change in shape due to internal friction, *viscosity.* Each type of muscle has distinctive structural and functional characteristics. Striated muscle is also known as "skeletal," "somatic," or "voluntary" muscle, because in vertebrates it is inserted on the bones, is originated in the somites, and is usually brought into activity by impulses from the central nervous system. Smooth muscle is sometimes called "visceral," because it forms part of the walls of viscera, or "involuntary," because it has a considerable degree of autonomy. Striated muscle will be considered first.

Structural Aspects of Striated Muscle

Microscopic structure of muscle fibers. Muscle fibers are giant cells, formed in the course of development by fusion of several mesenchymatic cells, the myoblasts. They are enclosed in a thin structureless membrane, the *sarcolemma.* Histochemical examination has shown that this membrane has no collagenous substance; therefore it is probably formed exclusively by the myoblasts, without the participation of connective-tissue cells. Microincineration shows that it is rich in silicates. The myofibrils are surrounded by a network of filaments, visible with the electron microscope, which have a tendency to unite and form continuous sheets. Each filament is about 250 A in diameter and is made up of a series of disks some 200 A high. They seem to be related to collagen and probably contribute greatly to the stability and the elastic properties of muscle.[1]

The *nucleus* of the myoblast divides several times, but the cell does not divide; thus the adult fiber has several nuclei, situated mainly under the sarcolemma. The *protoplasm* is made up

[1] Rosza, G., A. Szent-Györgyi, and R. W. G. Wickoff, *Exper. Cell Research,* 1, 194, 1950.

of two different parts, the *fibrils* and the *sarcoplasm*, which is found between the fibrils and under the sarcolemma. In the neighborhood of the nuclei, a Golgi apparatus, mitochondria, and lipid inclusions are seen; these lipid bodies are also found between the fibrils. The myoblast forms a fibril which later divides into bundles of fibrils, the *sarcostyles*. The outer layer of the sarcostyles behaves as a semipermeable membrane.

The sarcostyles are made up of segments, the *sarcomeres*. (Fig. 339, *S*.) A relatively thick, resistant, and impermeable membrane separates one sarcomere from another; it is called Krause's membrane, or the Z disk. Krause's membranes of neighboring sarcostyles are joined together and finally inserted in the sarcolemma; thus they form partitions which hold at the same level all the sarcostyles of a muscle fiber.[1] This division of the sarcostyles into segments gives the fiber the cross-striated aspect particular to this type of muscle. Observations of unstained myofibrils made with the electron microscope have shown transverse bands corresponding to this cross striation. Longitudinal striation, due to the fibrillar constitution, is common to all types of muscle.

The middle part of the sarcomere, which is dark, is known as Brücke's or the Q or A disk; it is separated from Krause's membrane by a clear, hyaline substance, called the J or I disk. Examined under the microscope by polarized light, the Q or A disks are seen to be anisotropous, but the J disk is only slightly doubly refracting; its anisotropy is about 10 per cent that of the Q disk. The ratio of Q to J in a resting fiber is 55:45. Q is rich in salts, especially in potassium chloride and phosphates; Fe is also found. Microincineration shows J to be almost free from minerals. A clear disk, the line of Hensen (*H*), divides Q into two equal parts. In a stretched fiber a fine membrane, Heidenhain's membrane (*M*), can be seen in the middle of *H*. The J disk shows a dark line about halfway between the membrane of Krause (*Z*) and the Q disk; this is Engelmann's accessory disk (*N*), which probably is an artefact. There is also another dark line close to *Z* known as the terminal disk.

[1] Doubts have been cast on the existence of Krause's membrane in the living fiber. Coupling of the contractile filaments and the myofibrils with each other and the sarcolemma has been attributed to physical forces.

Observations made with the electron microscope[1] have shown that the myofibril is made up of closely packed filaments[2] which can be separated by mechanical means in a colloid mill, or by tryptic digestion. They run the whole length of the sarcomere but do not cross the Z membrane. They are about 200 A in diameter and have nodosities or differences in densities at regular intervals of approximately 400 A. In the intact myofibril "the particles are arranged with great regularity standing in rows both cross- and length-wise, that is, associated both end to end and side to side" (Szent-Györgyi), giving the myofibril a fine cross-banding distinct from the microscopic cross striation. This tridimensional regularity in structure is not peculiar to muscle fibers, but is also found in other animal and vegetable fibers. The spaces between the different layers and particles are not uniform in the three dimensions of space, and they are small enough with respect to the wavelength of light to endow the system with the property of double

FIG. 339. Electron-microscope images of skeletal muscle fibers of toad (×20,000). (*Draper, M. H., and A. J. Hodge, Nature, vol. 163, p. 576, 1949.*)

[1] HALL, C. E., M. A. JAKUS, and F. O. SCHMITT, *Biol. Bull.*, **90**, 32, 1946; MORGAN, C., G. ROZSA, A. SZENT-GYÖRGYI, and R. W. G. WYKOFF, *Science*, **111**, 201, 1950; ASHLEY, C. A., K. R. PORTER, D. E. PHILPOTT, and G. M. HAAS, *J. Exper. Med.*, **94**, 9, 1951.

[2] In the living myofibril there are no preformed filaments; the contractile substance forms a continuous mass. The filaments appear owing to the treatment to which the muscle is submitted.

refraction. Muscle fibers are birefringent or anisotropous (Fig. 340).

Evidence obtained with the electron microscope suggests that the myofibril has a tubelike structure, the walls containing the filaments and an A substance, surrounding an aqueous core.[1]
Fig. 340. Diagram of an anisotropous fiber. Observation along the axis *a*, or any other transverse axis, will show a series of layers placed at equal distances from each other. Observation along the longitudinal axis *b* will show a series of segments with identical characteristics at regular intervals; the spacing is not the same as along a transverse axis.

During contraction the A substance in the Q disks shifts toward the Z membrane and the M band is widened, becoming the most transparent part of the fibril. The dense substance on each side of the Z membrane forms the so-called "contraction band." The sarcomere shortens to half the resting length and becomes much wider.

There are two types of striped muscle fibers, the *white* and the *red* fibers. White fibers are thick, poor in sarcoplasm, with nuclei exclusively under the sarcolemma and in large numbers near the end-plate; cross striation is regular and well marked, and longitudinal striation is not easily distinguished. The red fibers have abundant sarcoplasm, with nuclei distributed all through the fiber; cross striation is irregular and poorly marked, and longitudinal striation is outstanding. Red fibers have more myohemoglobin and less cytochrome than white fibers. There are intermediate fibers between these two types. In some animals there are muscles made up mostly of either one or the other type of fiber; in man both kinds are found in all muscles, but in certain muscles one or the other type predominates.

The Excitation of Muscle

Muscles respond to many kinds of stimuli according to the general laws of excitability. Contraction can be provoked experimentally by mechanical, thermal, chemical, and electrical stimuli, but in physiologic conditions striated muscles are excited exclusively by nerve impulses.

Innervation of muscle fibers.[1] The nerves of skeletal muscles are made up of myelinated and unmyelinated afferent and efferent fibers. The different types of fiber can be separated, in order to examine their morphologic and physiologic characteristics, by (*a*) section of the dorsal roots (deafferentation); (*b*) section of the ventral roots (elimination of somatic motor fibers); (*c*) removal of the appropriate sympathetic ganglia (suppression of visceral fibers).

There are two types of motor fibers in the limb-muscle nerves of mammals: (*a*) large fibers, and (*b*) small fibers.[2] Large fibers in the cat have diameters between 10 and 18 μ (the majority between 12 and 14 μ), a low threshold, and high velocity of conduction (around 70 m./sec. and up to 108 m./sec.). Small fibers have diameters between 3 and 8 μ (peak at 5 μ) and a high threshold, and they conduct at velocities of about 27 and 30 m./sec. (not above 50 to 55 m./sec.).[3] Certain muscles (face, larynx, infrahyoid region) receive only medium-sized fibers distributed around a single peak at about 10 μ; these muscles have few spindles and perform relatively simple actions. Muscles in the limbs and the extrinsic eye muscles have small and large fibers distributed around two peaks; these muscles have many spindles, and they take part in complex accurate movements, or in postural reflexes.[4] In man there are many small

fibers in the cervical roots but fewer in the lumbar and sacral roots.

In the frog, axons of small diameter (5 μ) innervate the same muscle fibers as the larger motor axons. Stimulation of the small fibers evokes local potentials similar to the end-plate potential (see page 793) and slowly rising, well-maintained local contractions, clearly distinguishable from the propagated contractions which involve the whole muscle fiber. With repetitive stimulation, tension up to 15 per cent of the maximal tension may be obtained. Small fibers can be stimulated reflexly, especially by stimulation of large afferent fibers, and the appreciable tension thus evoked can be maintained for prolonged periods. Impulses transmitted by the small fibers have been considered as playing a part in the maintenance of muscle tonus (see Chap. 82). Stimulation of the small fibers in the ventral roots of mammals, however, does not produce any appreciable increase in tension.[1]

In limb-muscle nerves (cat) large fibers make up two-thirds and small fibers one-third of the total efferent fibers. Large fibers pass into the muscle end-plate, which suffers degenerative changes and eventually atrophies when these fibers are cut. In vertebrates a few muscle fibers receive two nerve endings, which sometimes come from different spinal roots. Double innervation is the rule in invertebrates; usually one nerve fiber stimulates and the other inhibits the muscle fiber, as also occurs in most vertebrate smooth muscles. The small fibers innervate the intrafusal muscle fibers of the spindles.[2] The functional significance of the small fiber system will be discussed in Chap. 73 ("Proprioceptive sensibility") and Chap. 81 ("Muscle tonus").

In the frog the large efferent fibers not only innervate muscle fibers, but also give off branches to the intrafusal muscle fibers of most spindles.[3] The small nerve fibers innervate skeletal muscle fibers which have distinctive anatomical, physiologic, and pharmacologic characteristics.[4]

Afferent fibers in limb muscles have been classified into three groups in descending order

[1] Tasaki, I., and K. Mizutani, *Japan. J. M. Sc.*, **10**, 237, 1944; Kuffler, S. W., *Proc. Soc. Exper. Biol. & Med.*, **63**, 21, 1946; Kuffler, S. W., and Y. Laporte, *Federation Proc.*, **6**, 146, 1947.

[3] Katz, B., *J. Exper. Biol.*, **26**, 201, 1949.

[4] Kuffler, S. W., *Arch. d. sc. physiol.*, **3**, 613, 1949.

of diameter: groups I, II, and III.[1] The large group I fibers constitute 45 per cent of the afferent fibers of the hind-limb extensors and a smaller proportion of the flexors; they innervate the muscle spindles and Golgi tendon organs. Stimulation of the smaller fibers in groups II and III gives rise to the flexor reflex (see Chap. 69).

In the neighborhood of the muscle fiber the axon loses the myelin sheath, penetrates the sarcolemma, and ramifies in the sarcoplasm, which is abundant and has numerous nuclei in this place, known as the end-plate.

Section of the motor nerve is rapidly followed by degenerative changes and eventually by atrophy of the end-plate.

Nerves to the muscles include nonmyelinated fibers; some are afferent fibers, but the majority are postganglionic sympathetic fibers which innervate the blood vessels. No satisfactory proof has been given that the muscle fiber receives sympathetic as well as somatic innervation.[2]

When a muscle is stimulated, even after its nerve has been cut, the stimulus acts on the nerve fibers and only indirectly through these does it act on the muscle. It is therefore necessary to give time for nerve degeneration to take place if a purely muscular response is desired. Another method consists in the study of individual muscle fibers isolated in Ringer's solution. In this condition the nerve and end-plate degenerate within a few hours, but the properties of the muscle fibers remain apparently unaltered for several days. These fibers give strength-duration curves of the α type (see below, "Neuromuscular block") at whatever point the fiber is stimulated; therefore the excitability of the fiber is uniform throughout its whole length.[3]

Transmission of Excitation from Nerve to Muscle

The excitatory state is transmitted from the nerve to the muscle, but not in the opposite direction from the muscle to the nerve. In the end-plate as in the synapse there is unidirectional or irreversible conduction. This fact has great interest, not only for the understanding of

[1] Rexed, B., and P. O. Therman, *J. Neurophysiol.*, **11**, 133, 1948; Lloyd, D. P. C., and H. T. Chang, *J. Neurophysiol.*, **11**, 199, 1948.

[2] Hinsey, *loc. cit.*

[3] Ramsey, R. W., and S. S. Street, *Biol. Symposia*, **3**, 9, 1943.

muscular excitation, but also because phenomena occurring at the end-plate may throw light on synaptic transmission of the excitatory state.

End-plate delay. When the nerve impulse reaches the end-plate, there is a delay before the muscle contracts. The delay lasts 2 msec. in the frog gastrocnemius, 0.8 msec. in the cat gastrocnemius, and a slightly shorter time in very rapid muscles, such as the eye muscles. During this period electrical and chemical processes occur, and the excitatory state is transmitted from the nerve to the muscle.

Table 87. Changes in Chronaxies of Muscle and Nerve

Factor causing change	*Muscle*	*Nerve*
Curare	+	0
Sparteine	+	0
Fatigue	+	0
Strychnine	0	−
Nicotine	−	0
Veratrine	−	0
Scopolamine	+	−

+ = increase; − = decrease; 0 = no change.

Neuromuscular block. The transmission of excitation from the nerve to the muscle fiber may be blocked. The muscle then responds to direct stimulation but not to stimulation through the nerve, although the excitability of the latter is unimpaired and it conducts impulses of normal amplitude at normal velocity. Neuromuscular block was first observed by Claude Bernard (1851) when studying the effects of curare (a poison extracted from several plants of the genus *Strychnos* by Amazon Indians, who smear it on their arrows); hence the name "curarization" given to this phenomenon.

The peripheral action of curare was demonstrated by Bernard in the following experiment: A ligature was placed on the leg of a frog, leaving out the sciatic nerve, so that the circulation was suppressed without disturbing nerve connections with the centers. Curare was then injected into the animal. When paralysis was fully developed, stimulation of the sciatic nerve of the leg with normal circulation, *i.e.*, that on which curare had acted, did not provoke contraction, although the muscle responded to direct stimulation. Stimulation of the sciatic nerve of the leg in which the circulation had been suppressed, so that curare could not act on it, provoked contraction.

Curare kills by paralyzing the respiratory muscles. Death can be prevented by keeping up artificial respiration until the effect of the drug has passed off. Several alkaloids have been extracted from curare, *e.g.*, curarine and D-tubocurarine. In surgical operations when muscular relaxation is required, it can be provoked without submitting the patient to deep anesthesia by injecting a curare alkaloid, taking care to maintain adequate pulmonary ventilation.

Kühne supposed that curare acted on a receptive substance in the end-plate, which serves as a bridge between the nerve and muscle fibers. The hypothesis of the existence of a neuromuscular junctional tissue received further support from observations by Langley on the action of nicotine on striated muscle and by Elliott on the action of adrenaline on smooth muscle. Strength-duration curves, however, show only two types of excitability,[1] known as α and γ. The former is slower; it is the only one found in nerve-free parts of muscle (sartorius) and in fully curarized muscles. The latter is faster, has the same time scale as the strength-duration curve of the nerve, and is abolished by curare; it is attributed to excitation of the nerve. There is no satisfactory evidence of a third type (β) of excitability which would be even faster and correspond to the junctional tissue.

Lapicque[2] has maintained that normally the chronaxie of muscle is subordinated to that of its nerve; there is isochronism, *i.e.*, muscle and nerve chronaxies have the same value. When either muscle or nerve chronaxie is altered so that they are in a 1:2 ratio (heterochronism) the neuromuscular junction is blocked. Neuromuscular block, however, can be produced by doses of curare which do not change the excitability of muscle, much larger doses being necessary to depress muscular excitability.[3]

Neuromuscular block is observed in transmission fatigue and can be produced by several drugs (Table 87), though not necessarily by the same mechanism as that of curare and its alkaloids; *e.g.*, acetylcholine; cholinesterase inactivators such as eserine, prostigmine, diisopropylfluorophosphate (DFP), etc.; decamethonium; erythrine, an alkaloid extracted

from the seeds of the "ceibo" tree, *Erythrina crista galli;* etc.

Curare acts by antagonizing the effect of the chemical mediator, acetylcholine, although it does not prevent the release of acetylcholine at the end-plate on arrival of the nerve impulse in the body, an *action potential* develops in which two components can be separated, the end-plate potential and the spike potential (propagated potential).

End-plate potential. Normally the end-plate potential (e.p.p.) is masked by the spike potential, but it can be made evident by means of curare or its alkaloids.[1] The effect of this drug is to reduce the amplitude of the e.p.p. below the threshold of the propagated impulse so that the spike potential does not appear. The e.p.p. consists of a single monophasic wave (Fig. 341) which rises to a peak in 1 to 1.5 msec. (completely curarized frog's sartorius at 20°C.) and decays gradually, taking 2.4 to 6.0 msec. from onset to half decline.[2] The amplitude in a fully curarized muscle is 10 to 20 mv., but it is less if the dose of curare is increased, and conversely the removal of curare is accompanied by an in-

(see Chemical phenomena of neuromuscular transmission page 794).

Electrical phenomena of muscular activity. Muscle fibers, like other living cells, have polarized membranes, and activity is accompanied by electrical phenomena. Knowledge of these phenomena has advanced considerably since it has been possible to stimulate and register electrical events in single fibers, either isolated or *in situ*.

The *resting potential* of the muscle fiber of the frog at 20°C., measured with an intracellular electrode, is about 90 (75 to 105) mv., and there is not more than 0.5 mv. difference from one part of the fiber to another. Curare does not modify the resting potential. When the fiber is stimulated through its nerve, as occurs normally

[1] ECCLES, J. C., B. KATZ, S. W. KUFFLER, *J. Neurophysiol.*, 4, 362, 1941.

[2] FATT, P., and B. KATZ, *J. Physiol.*, **115**, 320, 1951.

crease in the rate of rise and amplitude until a spike is fired off. The e.p.p. spreads for a few millimeters along the fiber, decaying exponentially with time and distance from its focus in the end-plate. The e.p.p. increases with the strength of the stimulus, and by repeated stimulation at adequate intervals so that summation may take place, it may reach the threshold and a spike is fired off.

The e.p.p. is due to transient subliminal depolarization of the end-plate surface. In normal muscle during transmission of an impulse the e.p.p. is seen as an initial step of about 40 mv. occurring at the first ½ msec. of the rising phase of the action potential registered at the end-plate. A few millimeters from the end-plate the spike potential does not show this step (Fig. 341*C*).

Antagonists of cholinesterase, *e.g.*, prostigmine, increase the amplitude and duration of e.p.p. (Fig. 341*B*). Sodium and calcium deficiencies, on the contrary, reduce the e.p.p.

Minute end-plate potentials are registered in resting fibers; their amplitude is about 1 (0.4 to 2) mv., and they appear irregularly at random with occasional bursts of high frequency. They are reduced in size by small doses of curarine and increased by prostigmine. Denervation and nerve anesthetics abolish them.[1]

Spike potential. If depolarization of the membrane attains the threshold, a propagated disturbance is initiated and spreads over the surface of the whole fiber. It is accompanied by a spike potential with a reversal of about 35 mv. at its peak, which it reaches in 1 msec. It then decays and is at half-decline in approximately 4 msec. This is an "all-or-nothing" phenomenon, *i.e.*, it is not proportional to the strength of the stimulus; a threshold stimulus evokes the maximal potential.

In a normal muscle the action potential evoked by a nerve impulse and registered at the end-plate differs from the action potential registered at other parts of the muscle fiber and from that evoked by direct stimulation; its peak is lower by about 15 mv., and the descending limb does not fall smoothly but forms a "hump" attributed to the persistent action of the mediator (Fig. 341*C*).

The spike is followed by a refractory period. The velocity of spread is 2 m./sec. in the largest fibers of the frog at 20°C.; it is slowed down by cooling; the temperature coefficient Q_{10} is 2. In mammalian muscle the following figures have been found for speed of conduction in meters per second: soleus of cat, 2.85; tibialis anticus of cat, 5 to 6;[1] anterior gracilis of rat, 3.4 to 5.[2]

[1] Burn, B. D., and W. D. M. Paton, *J. Physiol.*, **115**, 41, 1951.

The action potential wave is followed after a short interval by a wave of contraction, which spreads at the same velocity as the spike. The active state on the surface is propagated inward throughout the cross section of the fiber, but the nature of the process which links excitation to contraction is as yet unknown. The active contractile state is set up very abruptly (see page 798), so it cannot be due to diffusion of a substance from the surface; it is a physical or physicochemical process released at the surface and then propagated inward.[3]

After-potentials. Before the spike has come to an end a second negative potential begins, known as the *first negative afterpotential;* it has a low voltage (5 mv.) and lasts 50 to 150 msec. A *second negative afterpotential* of about 0.2 mv., lasting up to 1 sec., has been reported. There is inconclusive evidence for the existence of a *positive afterpotential* appearing between the two negative afterpotentials, of approximately 1 mv. and lasting 250 msec.

Chemical phenomena of neuromuscular transmission. Stimulation of the motor nerve, even after section and degeneration of afferent and sympathetic fibers, causes the release of acetylcholine (ACh) at the end-plate,[4] in sufficient amounts to provoke contraction. Curare, in doses which provoke neuromuscular block, does not prevent the liberation of ACh. Acetylcholine is rapidly destroyed by cholinesterase, which is found in the end-plate—most of it within the refractory period.[5] Its effect, therefore, cannot normally spread or persist beyond a very short time. The output of ACh from active motor nerve endings depends upon the concentration of Na^+ in the external fluid. The reduction in the e.p.p. and neuromuscular block

brought about by lack of sodium or calcium is due mainly to a reduction in the output of ACh. It has been suggested that at the nerve ending ACh, rather than K^+, is exchanged for Na^+ that enters the nerve fiber during the rising phase of activity.[1]

A small dose (2 to 20 μg) of ACh injected into the artery of a muscle provokes muscular contraction with a propagated spike potential similar to that following stimulation of the motor nerve; it can also provoke contracture, *i.e.*, a mechanical response without a propagated spike potential (see Contracture).[2] Substances with anticholinesterase activity such as eserine, prostigmine, and di-isopropylfluorophosphate (DFP) increase the excitatory effect of ACh. Denervation increases sensitiveness to acetylcholine; at first acetylcholine produces mainly contraction; later the response is mainly contracture.[3] Curare, on the contrary, antagonizes the effect and raises the threshold of ACh.

Acetylcholine has a specific depolarizing effect on the end-plate, which it does not exert on other parts of the muscle fiber. Acetylcholine depolarizes even when there is no sodium in the external fluid; probably it produces a large nonselective increase in permeability and an ion sink is established at the end-plate, through which the fiber membrane becomes depolarized.[4]

Large doses of acetylcholine depress the response to direct electrical stimulation of the muscle, and to stimulation of the motor nerve; complete neuromuscular block may be produced. This effect is potentiated by cholinesterase antagonists.

Substances with anticholinesterase activity (eserine, prostigmine, DFP) may provoke muscular contraction. They augment the effect of nerve stimulation of low frequency, provoking a repetitive response to single shocks,[5] but they have a depressive effect on stimulation at high frequencies.[6] The response to direct stimulation of the muscle is not modified by cholinesterase antagonists, therefore they exert their effect on the process of neuromuscular transmission.

The strength of contraction decreases if the motor nerve is stimulated at a sufficiently high frequency (transmission fatigue); there is also a progressive decrease in the amount of acetylcholine liberated at the end-plate. In this condition eserine or another anticholinesterase increases the response of the muscle.

Potassium ions probably play a part in neuromuscular transmission. Potassium is released from muscles stimulated directly or through the motor nerve, or by acetylcholine. Curare prevents liberation of potassium by nerve stimulation.[1] In small doses potassium stimulates muscular contraction and can enhance the effects of motor-nerve stimulation and of acetylcholine. Large doses have a depressing effect. The stimulating action of potassium is not blocked by curare, but K ions have a decurarizing action. These facts have acquired special interest since the part played by potassium in excitation is becoming more fully understood (see Chap. 66).

The sequence of events taking place when a muscle is stimulated through its nerve can be interpreted as follows: The impulse arriving at the nerve endings does not cause a direct spread of electric current from nerve to muscle, but releases a mediator, acetylcholine, which raises the permeability of the end-plate membrane so that ions that do not diffuse through the resting membrane can now pass across it (depolarizing effect). The minute end-plate potentials of resting muscle are due to leakage of small amounts of acetylcholine. The depolarized area is the site of the e.p.p.; if this reaches the threshold (about 40 mv.), it stimulates the surrounding regions, local circuits are set up, and a propagated "all-or-nothing" spike potential spreads throughout the surface of the fiber. If the effect of acetylcholine is prolonged, repetitive firing will be produced as long as the e.p.p. stays above the threshold.

The end-plate can be blocked by (*a*) raising the threshold by strengthening polarization with anodal currents; (*b*) an antagonist of the mediator, such as curarine, which prevents depolarization; (*c*) persistent action of the mediator maintained by cholinesterase antagonists, *e.g.*,

[1] Fenn, W. O., *Proc. Soc. Exper. Biol. & Med.*, **37**, 71, 1937; Cicardo, V. H., *Rev. Soc. argent. de biol.*, **14**, 297, 1938; Cicardo, V. H., and J. L. Moglia, *Rev. Soc. argent. de biol.*, **16**, 149, 1940.

eserine, so that depolarization is abnormally prolonged and extended beyond the end-plate; (*d*) depolarization of the end-plate by cathodal currents.

Mechanical Phenomena of Muscular Contraction

Muscular contraction in the body is usually evoked by nerve impulses arriving at the end-plates of the fibers which make up the muscle. In order to analyze the complex phenomena which take place, muscles have been separated from the organism—in some cases, a single muscle fiber[1]—and stimulated directly by means of electric shocks. A single shock of sufficient strength, or a single nerve impulse, evokes a muscle twitch, *i.e.*, contraction followed by relaxation. This is the elementary unit of muscular activity. Repetitive stimulation of adequate frequency provokes sustained contraction called tetanus. If the resistance against which the muscle contracts is so great that it cannot shorten, tension develops and is converted into heat; this is known as an isometric contraction.[2] If the resistance is not so great, the muscle can shorten and perform work; this is known as an isotonic contraction.

A muscle twitch takes place very quickly; thus the contraction time (from the beginning of the spike potential to the peak of contraction) for the internal rectus of the eye is less than 8 msec. This can be slowed down by cooling, and at 0°C. the behavior of muscle is essentially the same as at normal body temperature, except

for the lower rate of change. Slow muscles, such as those of the toad and tortoise, have also been used to obtain valuable information; thus skeletal muscles of the tortoise take fifteen times as long as those of the frog to complete contraction; *e.g.*, at 0°C. shortening begins 90 to 100 msec. after the stimulus has been applied, takes several seconds to reach the maximum, and takes several seconds more to complete relaxation.

Fig. 343. Tension-length relations of sartorius of frog or toad. 1, at rest, positively stretched; 2, extra force developed during maximal tetanus; 3, total force of maximal tetanus (sum of 1 + 2). Length is given as fraction of standard length in body, and tension as fraction of maximum force developed (*Hill, A. V., Proc. Roy. Soc., London, s.B., vol. 141, p. 104, 1953.*)

Methods for registering the phenomena of muscular contraction must cope with their minuteness and their velocity; sensitiveness and speed are therefore essential. The use of electronic techniques, piezoelectric crystals, and ultimate recording with the cathode-ray oscillograph has made possible the registration of mechanical events with great sensitiveness and accuracy, because large amplification with insignificant inertia can be obtained.

Muscle is made up of (*a*) a contractile component, located in the A segment of the myofibril (see "Physico-chemical structure of the myofibril"); (*b*) a passive undamped elastic component in series with the contractile element, *e.g.*, tendons; (*c*) an elastic component in parallel with the two preceding components, constituted by the sarcolemma and fibroelastic tissues surrounding the muscle fibers (Fig. 342).

Elasticity. All the elastic components of muscle show the load-extension relation usually seen in biological fibers, *i.e.*, great extension with small loads which becomes less with greater ones (Fig. 343). The extensibility of the contractile component is so great that when a mus-

cle is stretched to little more than its resting length in the body, the load is borne mainly by the parallel elastic component. The behavior of the other two components (contractile and elastic in series) must be examined at lengths not greater than the normal resting length. When the muscle contracts in isometric conditions the series elastic component is stretched by the shortening of the contractile component. This extension is equivalent to 4 per cent or more of the length of the muscle at rest, depending on the length of the tendon. As the active state diminishes the contractile component becomes less capable of bearing a load or stress, and it is stretched by the series elastic component.

At rest the contractile component is not only extensible but also plastic. If a muscle is made to shorten by stimulation it remains shortened unless a load or elastic forces tend to pull or push it out. A resting muscle isolated from the body exerts a small but measurable tension at lengths down to about 60 to 75 per cent of the natural resting length in the body. If it is stretched to a given length, tension rises rapidly at first, then falls to a small value. Further stretching will again cause a rise in tension, followed by a fall to a small value. The resting muscle thus remains at any length it has been given. Its fibers are not folded but truly shortened, and if a quick stretch is applied, tension rises rapidly from the beginning; there is no delay, as there would be if slack of folded fibers had first to be taken up.

Resting muscle shortens when warmed under a constant load, or its tension rises if it is warmed while kept at constant length. Cooling produces the opposite effect. These are reversible processes and can be repeated any number of times. They are not due to excitation of the fibers, because they occur in muscles which have been made inexcitable by an excess of KCl. Muscle behaves, in this respect, like rubber. Other fibers, *e.g.*, tendon, have "normal" elasticity, *i.e.*, they lengthen on warming and shorten when cooled.

When a muscle is stretched there is an output of heat and a rise in temperature; on release heat is absorbed and the temperature falls. For a given distance of stretch, or release, the thermoelastic heat given out, or absorbed, becomes greater as the length is increased. These thermal changes are not simultaneous with the mechanical changes but show a considerable lag; they start slowly and continue after stretch or release is complete. At greater lengths thermoelastic temperature changes show a diphasic character; on release there is first an increase in temperature which appears without delay, followed by a fall in temperature. At short lengths there is only one elastic component involved, which has "rubberlike" elasticity, probably the contractile constituent of muscle; at greater lengths a second elastic component with "normal" elasticity comes into play, probably the parallel elastic component.[1]

The work done on a muscle by stretching it is much less than the heat produced, and the work done by a muscle released after stretching is less than the heat absorbed. The internal energy therefore decreases on lengthening and increases on shortening. This has been attributed to crystallization (an exothermic process) on stretching, as occurs in rubber. Changes in the birefringence of muscle suggest that crystallization increases on stretching. Stretching also increases the distance between the basic and acidic groups of the muscle protein chains; this increase would cause a shift to the alkaline side, as has in fact been observed,[2] and liberation of heat.

The stress-strain relations of a contracting muscle differ from those of a resting muscle. In a muscle in tetanic contraction tension developed by the active state is greatest at the length of the muscle at rest in the body, when the resting tension is very small. At greater lengths the resting tension, due mainly to the parallel elastic component, comes into play. The tension developed by contraction, obtained by subtracting the tension at rest from the total tension of the contracted muscle, diminishes as length increases (Fig. 343).[3]

Meyer[4] has postulated a model system which exhibits a stress-strain curve similar to the peculiar curve of contracting muscle. It consists of two spheres charged with opposite electric charges, which therefore attract each other, and rubber cylinders which when compressed compensate the attraction. Perhaps the charges in the basic and acidic groups of muscle

[3] Hill, A. V., *Nature, London*, **166**, 415, 1950.

[4] Meyer, K. H., *Proc. Roy. Soc., London, s.B.*, **139**, 498, 1952.

proteins, the attraction and repulsion forces of which vary with shifts in pH, play a part similar to that of the spheres in Meyer's model.

The latent period. After a stimulus has been applied to a muscle there is a delay before the beginning of shortening or the rise in tension. This interval is known as the latent period.
Fig. 344. Events in muscle following stimulation: *A*, opacity changes; *B*, mechanical response; *C*, course of action potential. (*Hill, D. K., J. Physiol., vol. 108, p. 292, 1949.*)

If muscle is not stimulated directly but through its nerve, part of the apparent latency is taken up by the spread of excitation along the axons (conduction time) and by the end-plate delay. "True latency," *i.e.*, that of the muscle itself, begins with the onset of the spike potential. When experimenting with a multifibered muscle, delay due to spread of excitation can be suppressed by using multiple electrodes so that all the fibers are stimulated simultaneously.

The latent period differs in different muscles; "quick" muscles have a shorter latency than "slow" muscles. Cooling prolongs the latent period and warming shortens it; the Q_{10} is about 2.1. In mammalian muscle at 37°C. it is of the order of 1 msec.

Several events occur in the course of the latent period:

1. About halfway in the latent period there is a slight lengthening or decrease in tension (Fig. 344). This initial or *latency relaxation*[1] is not observed if the muscle is not under a small initial tension. If the initial tension is decreased, latency relaxation diminishes and the phase of positive tension begins earlier. Hill[1] attributes latency relaxation to lengthening of the parallel elastic component.
2. There is an early increase in transparency, which begins at the same time as latency relaxation[2] (Fig. 344) and decreases as the muscle shortens. This is different from the increase in transparency which occurs later and is not complete until recovery has restored the muscle to its initial state (von Muralt). Changes in transparency are attributed to changes in the molecular pattern of the muscle proteins.
3. Early in the latent period, even before the onset of latency relaxation, the internal mechanical condition of the muscle changes abruptly. If it is submitted to a quick stretch, it is seen that the resistance to stretch is greater than that of resting muscle. The contractile component suddenly becomes capable of bearing a load equivalent to the maximal tension developed in an isometric contraction.[3] Resistance to stretch increases rapidly, reaching its maximum in about 1½ times the latent period; it remains at this level for a time, then diminishes gradually as relaxation sets in.
4. About halfway in the latent period, at the same moment that latency relaxation commences, an output of heat begins (see "Energetics of muscular contraction," "Heat of activation").

Shortening. At the end of the latent period the muscle begins to shorten. Speed of shortening increases rapidly and reaches its full value in about 1½ times the latent period (7 per cent of the time to maximum shortening); it remains constant in rate for a time, then falls off and is followed by lengthening during relaxation if the muscle has contracted against a load.[4] The time taken to reach full velocity of shortening is due in part to the fact that not all the fibers enter into the active state simultaneously. The active state which causes shortening, therefore, is fully developed in each individual fiber in a very

[4] *Ibid.*, **138**, 329, 1951.

short time, not more than one-tenth the time taken to develop maximum tension.

Speed of shortening against a load diminishes as the load increases (Fig. 345). The relation of speed to load can be expressed by the following equation:[1] $(P + a)v = b(P_0 - P)$, where P is the load, v is velocity of shortening, P_0 is the maximum force the muscle can exert at zero speed, and a and b are constants with the dimensions of force and velocity respectively. The maximum speed of shortening under zero load is about $4b$. The constant a is especially significant because during shortening there is an output of heat (see "Energetics of muscular contraction"), proportional to the amount of shortening, which is defined by ax (x is the distance shortened).

This characteristic relation between force and speed of shortening holds for skeletal muscle of frog, toad, and man,[2] and there is certainly a relation of this type in other muscles.

The force developed by contraction varies with the initial length of the muscle; it is greatest when the length is approximately that of the muscle at rest in the body.

If an isolated fiber of a frog muscle is allowed to shorten to less than 60 to 70 per cent of its resting length, its properties are permanently altered: it no longer lengthens in relaxation, but remains shortened; the tension developed on stimulation is less and the time for its full development is greater; there are structural alterations in the fiber, which loses the regularity of its cross striation. This is called by Ramsey and Street[3] the δ state. Similar structural changes are seen in contractures.

Relaxation. At different times relaxation has been considered as a passive or an active phenomenon. There is no heat of relaxation; whatever heat is released during the period of relaxation can be accounted for by degradation of mechanical energy (see "Energetics of muscular contraction"). Moreover, if a muscle shortens during contraction and it is not submitted to a load or tension, it does not lengthen but remains at the length to which shortening during contraction has reduced it. Relaxation seems, therefore, to be a purely passive process.[1]

Changes in volume. The volume of a muscle diminishes rapidly as soon as contraction begins and continues to decrease as contraction goes on; with relaxation the volume increases suddenly, but there is a small remaining constriction even after a single twitch, which is larger after a tetanus. After relaxation the volume again increases. Reversible changes in volume accompanying contraction and relaxation are due to mechanical compression and decompression, chiefly of water contained in the muscle. Internal pressure rises to 100 to 300 mm. Hg[2] and stops the blood flow through the muscles. The decrease in volume remaining after relaxation is due to chemical breakdown, probably of adenosinetriphosphate and creatinephosphate. Later the volume again increases, corresponding to the resynthesis of the substances broken down; if resynthesis of phosphagen and the formation of lactic acid are prevented by poisoning with iodacetate, constriction may go on increasing after relaxation.

lated so as to obtain a maximal contraction, *i.e.*, contraction of all the muscle units, gives a first response that is less than the second. The second response in turn is not as great as the third, and so on, until after a few contractions their height and duration become stabilized. This was first
Fig. 346. Mechanical and electrical response of the cat's gastrocnemius to a double induction shock on the peroneal nerve. Interval between shocks: *a*, 24 msec.; *b*, 32 msec.; *c*, 40 msec.; *d*, 48 msec. (*Cooper and Eccles, J. Physiol., vol. 69, p. 377, 1930.*)

observed by Bowditch in the frog's heart, brought to a standstill by a Stannius ligature; he called it the "staircase effect," (*Treppe*) owing to the aspect of the record obtained.

When two maximal stimuli are sent with an interval such that the second arrives before the end of the effect produced by the first, the second contraction develops a greater tension and lasts longer than the contraction produced by a single stimulus. When the second stimulus falls during the absolute refractory period left by the first stimulus, it evokes no response. As the interval between the stimuli is lengthened, the response to the second stimulus becomes greater; it reaches a maximum when the second stimulus is applied at the peak of the response to the first stimulus (Fig. 346). The first stimulus provokes shortening of the contractile component and the series elastic component is stretched. The active state, however, commences to decline and relaxation to begin before stretching is complete. The second stimulus brings the active state again to its full intensity; the contractile component shortens and commences to pull on the series component which is already stretched, and a higher tension will be developed than can be achieved by a single shock. There is no algebraic summation of the effects of the consecutive stimuli; tension developed by each one will depend on the amount of stretch already existing. This is called "wave summation," because it is the sum of two waves of contraction in the same fiber.

When the muscle is stimulated repeatedly at a frequency such that the interval between stimuli is less than the contraction time, a sustained contraction of several times the strength of the simple contraction is observed. This type of contraction is called "tetanus." When the frequency of stimulation is not so high, relaxation commences before the succeeding stimulus arrives, the contraction is not so strong, and the top of the curve shows undulations, which are more marked as the frequency decreases. This type of contraction is called "incomplete tetanus" (Fig. 347). The minimum frequency of excitation needed to produce a complete tetanus varies inversely to the contraction time. Rapid muscles need a higher frequency than slow muscles, *e.g.*, this frequency is 30 per second for the soleus of the cat, 100 per second for the gastrocnemius, and 350 per second for the internal rectus of the eye, the contraction times of which are 100, 40, and 8 msec. respectively.

Initial tension or length (within certain limits) increases the maximum tension, and the tension developed in a tetanus, in the same way as in a muscle twitch. Once stimulation has ceased, the muscle remains contracted in tetanus for a short time, which is prolonged by increasing the initial length of the muscle and the duration and (within certain limits) frequency of stimulation.

After a brief tetanus, a single supramaximal shock or an injection of acetylcholine provokes a stronger twitch than before the tetanus. *Posttetanic potentiation* disappears gradually during the following rest period. It is observed in single isolated fibers and is not suppressed by complete curarization; therefore, it is not due to recruiting of fibers but to some change in the muscle fiber which favors a higher development of tension. In slow muscles, *e.g.*, the soleus, after a short high-frequency tetanus a single shock may provoke a repetitive response followed by a period of inhibition, which may last up to 100 msec., during which the response to a single shock is considerably diminished.[1] Curare suppresses this type of posttetanic potentiation; therefore it is due to a change in synaptic transmission. The demarcation potential diminishes after a brief tetanus. A similar decrease in potential and increase in response to a single shock is provoked by an injection of KCl, facts which have led to the suggestion that posttetanic potentiation is due to mobilization of potassium.[2]

The motor unit. The axon of a motor neuron branches out in its course toward the periphery and ends in a number of muscle fibers. An individual motor neuron together with the bunch of muscle fibers it innervates is a motor unit. When a nerve impulse is transmitted along the axon, all the muscle fibers at which its branches end are stimulated and contract simultaneously. The ratio of muscle fibers to nerve fibers gives the average number of muscle fibers per unit in a muscle, but the individual units are of variable size. The units in the limb muscles, which function in the maintenance of posture and locomotion, are mainly large units, although there are also smaller ones. Muscles that take part in finely graduated movements, such as the hand and eye muscles, are made up of small units. In the cat, the innervation ratio of the soleus, a red muscle, is 1:120, and that of the extensor digitorum longus, a white muscle, is 1:165. The eye muscles of man have innervation ratios of 1:2 and 1:6. The fibers of a unit are distributed along the whole length of the muscle, not grouped in one part of it, so that when the unit contracts tension is developed not at just one point but throughout the muscle, thus making for smooth contraction.

The average tension developed by the contraction of a motor unit is measured in the following way: The corresponding dorsal root ganglia are removed, and time is given for the complete degeneration of the sensory fibers. The motor nerve is then stimulated with a maximal stimulus, and the tension developed is measured.
FIG. 347. Mechanical and electrical response of the cat's gastrocnemius to induction shocks on the popliteal nerve. Frequency of stimulation: *a*, 19 per second; *b*, 23.5 per second; *c*, 35 per second; *d*, 115 per second. This last frequency provokes complete tetanus. In *a*, *b*, and *c*, relaxation commences before the following stimulus is applied; oscillations in the mechanical record correspond to those of the electrical record. (*Cooper and Eccles, J. Physiol., vol. 69, p. 377, 1930.*)

Table 88. Number of Motor Units and Average Tension per Unit in the Cat's Muscles

Muscle	*Tension per unit, gm.*	*Number of units*
Gastrocnemius	30.1	430
Soleus	9.9	200
Semitendinosus	5.5	630
Extensor digitorum longus	8.6	330
Crureus	10.2	250

The fibers in the motor nerve are counted, and the maximum tension is divided by the number of fibers to obtain the average tension per motor unit (Table 88). Large units develop more tension than the average, and small ones less.

Muscular contraction in the organism. Adrian and Bronk[1] studied the motor nerve impulses to a muscle by means of a preparation in which the nerve was reduced to a small number of fibers and the action potentials were registered. Striated muscles normally receive nerve impulses of low frequency, which provoke a certain amount of tension, called muscle tonus. When a voluntary or reflex movement takes place, the frequency of the impulses increases and the muscles contract. The maximal frequencies observed were not sufficient to produce a complete tetanus; they were below 15 per second in the nerve of a slow muscle such as the soleus, and were not above 100 per second even with maximal stimulation in the most rapid muscles. Nevertheless a smooth contraction is obtained, because the units do not contract synchronously; there are fibers in different phases of contraction, and the oscillations of the incomplete tetanus are damped down.

FIG. 348. Duration of contraction and realizable work of forearm flexors in man. (*Adapted from A. V. Hill.*)

The strength of contraction is graded by two different mechanisms: (*a*) the frequency of the nerve impulses, which conditions wave summation and therefore tension developed by each fiber; (*b*) activation of a greater or smaller number of units (multifiber or quantal summation). A vigorous contraction throws into activity a large number, or even all, of the units of a muscle, at a high frequency of stimulation. There is also a tendency toward synchronization of the nerve volleys, and large waves appear in the electromyogram, due to the summation of the action potentials of many fibers activated simultaneously. When the frequency of the nerve volleys is not sufficient to produce a complete tetanus, the contraction becomes oscillating, as can be observed on making a great muscular effort.

[1] ADRIAN, A. D., and D. W. BRONK, *J. Physiol.*, **67**, 119, 1929.

The degree of activity, *i.e.*, the number of active motor units and their frequency of excitation, has been determined in intact human muscles by integrating the action potentials with surface electrodes. Electrical activity, thus measured, is directly proportional to the tension developed and to the speed of shortening.[1] The maximal tension that can be developed by voluntary contraction (arm flexors) remains constant over a period of months[2] and seems to be as great as the maximal tension developed by electrical stimulation.[3]

The amount of energy that can be made to yield work, *i.e.*, the realizable work, is conditioned by the speed of contraction. The force developed by contraction is a decreasing linear function of velocity; therefore maximum force is developed at zero speed. On the other hand, energy expended in maintaining the active state is greater the longer it lasts. Therefore, there is an optimum rate of contraction for each muscle or group of muscles; for the forearm flexors in man it is 2 sec. (Fig. 348).

Maximum work is obtained when (*a*) the speed of contraction is the optimum for the muscle groups in activity; (*b*) the initial length is the optimum for the development of force in the active state; (*c*) the muscles contract against a weight which is just sufficient to require the maximum development of energy, but not such that shortening will be hindered (otherwise the contraction will be in part isometric). Training raises efficiency because contraction starts at the most favorable initial length (adoption of adequate posture) and is carried out at optimum speed.

Fatigue. Sustained repetitive stimulation is followed after a time by a progressive decrease in the mechanical response of the muscle; after a period of rest the muscle recovers its capacity to respond. This may be due to failure of (*a*) trans-

[1] LIPPOLD, O. C. J., *J. Physiol.*, **117**, 492, 1952; BIGLAND, B., and O. C. J. LIPPOLD, *J. Physiol.*, **123**, 214, 1954.

[3] MERTON, P. A., *J. Physiol.*, **123**, 553, 1954.

mission of excitation from the nerve to the muscle fiber, *transmission fatigue*, or (*b*) the contractile mechanism, *contraction fatigue*.[1]

Transmission fatigue is produced by prolonged stimulation of the motor nerve at a sufficiently high frequency (*e.g.*, 60 per second for 1 hr.). Direct stimulation shows there is no loss in the contractile capacity of the muscle, even when its response to nerve stimulation is considerably reduced. In this type of fatigue the acetylcholine output per impulse diminishes, and the response is improved by acetylcholine or cholinesterase antagonists. Small doses of curare, which raise the threshold to acetylcholine, have a greater depressor effect on fatigued muscle (with a low acetylcholine output) than on fresh muscle (with a normally high acetylcholine output). Nerve and muscle excitability diminish during fatigue because of an increase in the rheobase.

The excitability of the muscle fiber itself is also depressed by repetitive stimulation. This has been demonstrated in single isolated muscle after degeneration of the nerve in the following way: The fiber is stimulated at a frequency high enough to produce complete tetanus. After a short time, tension begins to fall off and incomplete tetanus (oscillating response) replaces complete tetanus. A little later only every other stimulus provokes a response, and as time passes the fiber responds to every third, fifth, tenth, twentieth stimulus. This is a Wedensky-inhibition phenomenon attributed to lengthening of the refractory period.[1]

If the frequency of stimulation is low (less than 30 per second), there will be no transmission fatigue and the progressive fall in the mechanical response will be due to contraction fatigue. Contraction time lengthens. Relaxation becomes slower and less complete as fatigue progresses (Fig. 349). The amplitude of the isotonic contraction diminishes, because shortening is progressively reduced and relaxation is incomplete. If the load is increased, fatigue develops more rapidly (Fig. 350). Conversion of chemical energy into tension becomes less efficient, and the $Tl:H$ ratio diminishes (T = tension, l = length, H = heat). Metabolic products, *e.g.*, lactic acid, accumulate and their elimination hastens recovery. Energy-producing substances, *e.g.*, glycogen, diminish, and fatigue occurs very rapidly if the energy stores have been depleted, or the recovery processes are inhibited, *e.g.*, in muscles intoxicated with moniodoacetate (see "Chemical phenomena of muscular contraction"). A completely fatigued muscle goes into contracture (fatigue cramp).

In maximal voluntary effort of the whole body, *e.g.*, in running, the supply of oxygen is the factor limiting performance (see Chap. 47); the onset of fatigue is due to failure of the contractile mechanism (contraction fatigue). Maximal voluntary contractions of a single small muscle (adductor of the thumb) are also limited by the blood supply; fatigue does not seem to be caused by failure of neuromuscular transmission be-

min 0 2 4 6

Fig. 349. Fatigue. Isotonic contractions of a muscle-nerve preparation of the gastrocnemius of the toad, stimulated by submaximal induction shocks at the rate of 85 per minute. At first the height of contraction gradually increases and then decreases. Relaxation is incomplete after a time, and after 3 min. 30 sec. there is marked contracture.

[1] Ramsey and Street, *loc. cit.*

cause there is no change in the action potentials evoked by maximal shocks delivered to the nerve.[1]

Contracture. In certain conditions the development of tension and shortening are kept up for a long time, although there is no tetanus, *i.e.*, no summation of the effects of repetitive stimulation. This particular form of contraction is known as contracture. It is a reversible process, and therefore differs from cadaveric rigidity and from rigidity due to coagulation of the muscle proteins. In contracture there is an increase in the metabolism of muscle, heat production is considerably greater than at rest, and there are glycolysis and lactic-acid formation. The fibers in contracture are electronegative with respect to the resting fibers. A contracture differs from normal contraction in two ways: (*a*) there is no propagated excitatory disturbance, with a corresponding spike potential, whether the whole fiber or only part of it is in contracture; (*b*) the intensity of contracture is graded in respect to the strength of the stimulus; it is not an all-or-nothing phenomenon.

Experimental contractures can be produced in isolated or intact muscles in many ways. Repetitive supramaximal stimulation produces a contraction followed by incomplete relaxation, the degree of contracture being dependent on the strength of the stimulus. After 100 stimuli have been sent at a frequency of 30 per minute, the contracture falls off. This is known as "Tiegel's contracture" and is due to a prolonged mobilization of energy following stimulation. Mosso observed it on stimulating the muscles of the forearm in man. It is not of reflex origin as it has been obtained after anesthetizing the brachial plexus.

Heat (45 to 50°C.), high pressure, and mechanical stimulation can produce contracture. Acids also provoke contracture, which rapidly passes on to an irreversible rigidity. A large number of drugs produce contractures (chloroform and other anesthetics, veratrine, aconitine, Ba, Ca, etc.). Other drugs, such as nicotine, acetylcholine, and quaternary ammonias, provoke contracture only in denervated muscles.

a

b

Fig. 350. Voluntary contractions of the flexor muscles of the middle finger of the right hand, registered by Mosso's ergograph. *a*, weight lifted, 4 kg.; the height of the contraction diminishes progressively; *b*, weight lifted, 2 kg.; the height of contraction diminishes at first and then remains at a constant level (steady state) during the 8 min. of the experiment.

[1] Merton, P. A., *J. Physiol.*, **123**, 553, 1954.

In most cases a so-called "contracture" observed in the intact organism is not a true contracture, but an increase in muscle tonus or a prolonged tetanus, due to an increase in the frequency of nerve volleys. In certain conditions it is possible to obtain a true contracture, called "idiomuscular contracture" by Schiff. Ranson[1] has described a "myostatic contracture" which is observed in cases of rupture of the muscle tendon, tetanus, and prolonged immobilization in a plaster cast. This is not a true contracture but is rigidity due to structural alterations in the affected muscles.

Chemical Phenomena of Muscular Contraction

Muscle is a machine for converting chemical energy into mechanical energy. Energy is stored in certain substances in the muscle, which on disintegrating release energy by processes called exothermic or exergonic reactions. Moreover, "in the process of contraction the muscle machine itself undergoes chemical and physical changes."[2] In order to understand how muscle functions, therefore, it is necessary to study (*a*) its physicochemical architecture, and (*b*) the metabolic processes of contraction.

Physicochemical structure of the myofibril. Proteins make up about 20 per cent of the muscle substance, and four-fifths of its solids; carbohydrates, lipids, organic crystalloids, and inorganic salts make up the rest.

There are several water-soluble proteins in muscle; the main ones are the *myogens* and *mvoalbumin*. The latter seems to play a part in the building up of other muscle proteins during embryonic development. The insoluble fraction contains those which are most important from the functional point of view; the principal ones are (*a*) myosin, (*b*) actin, and (*c*) actomyosin.

Myosin constitutes 40 per cent of the total protein and about 8 per cent of the muscle substance. Its molecular weight is 840,000. X-ray diffraction studies have shown that myosin molecules consist of long chains of polypeptides, joined to each other by side chains so as to form a grid, which in turn is joined to other grids by other side chains (Fig. 351). The distance between the grids is the same as that between the chains in a grid; therefore, along two axes the spaces between the components of the molecule are the same. In the longitudinal axis the spacing is different; the "links" of the chain are not of the same length as the space between grids and chains. The myosin molecule is thus a uniaxial optical system, therefore anisotropous or birefringent (crystalline birefringence)[1] (Fig. 340). The chains can be more or less extended. In a stretched myosin fiber (Astbury's β type) the length of one segment in the longitudinal axis is 10.2 A. When the fiber is not stretched it folds (Astbury's α type) and the segmental length is reduced to 5.1 A. In the resting muscle fibers myosin is probably in the α and partly in the β configuration. In contraction it folds even more, taking on Astbury's supercontracted state.

Fig. 351. Diagram of a myosin molecule. The principal chains are joined together by side chains forming grids.

Myosin particles, or micellae, are 23 A in thickness and 2,300 A in length.[2] In suitable dilution, myosin shows flow double refringence because the elongated particles are placed

[1] Ranson, S. W., *J. Neurol., Neurosurg. & Psychiat.*, **8**, 304, 1928.

[2] Dubuisson, M., *Proc. Roy. Soc., London, s.B.*, **137**, 63, 1950.

[1] Structures composed of units with tridimensional regularity are crystals. Myosin and other fibrous proteins are dispersed in a liquid medium; they are therefore called "liquid crystals."

[2] Weber, H. H., *Proc. Roy. Soc., London, s.B.*, **137**, 50, 1950. According to Mommaerts, the particle measures 30 by 1500 A.

lengthwise in the direction of flow and have a tendency to lateral association, forming swarms of micellae. Anisotropy of myosin is due, therefore, not only to its molecular structure (crystalline double refraction) but also to the orientation of its micellae (form double refraction). The electron microscope shows the formation of a network of long threads. Myosin is one of a family of fibrous proteins, which includes keratin, epidermin, fibrinogen, fibrin, etc.

Myosin acts as an enzyme, splitting off the terminal phosphate of adenosinetriphosphate (ATP).[1] Attempts to separate this adenosinetriphosphatase activity from myosin have been unsuccessful. It is dependent on the presence of free SH groups in myosin and is inhibited by Mg^{++} at pH 6.5 to 7. Actomyosin, however, is active as ATP-ase at pH 7, and both Mg^{++} and Ca^{++} promote this activity. Myosin, in the presence of salts, binds ATP; Mg^{++} enhances this activity. In resting muscle prevailing dissociation of COOH groups of its constituent amino acids gives myosin a negative charge, but adsorption of Mg^{++} neutralizes this charge; ATP adsorbed by myosin, however, gives it a negative charge, which increases as ATP is taken up and decreases as ATP diminishes.

Myosin also acts as a deaminase, splitting off the amino groups of adenosinemonophosphate (AMP). This enzymatic activity is independent of the ATP-ase activity.

Actin, isolated by Straub, forms 12 to 15 per cent of the total protein in muscle. It has a molecular weight of 70,000. It exists in two forms, globular G-actin and fibrous F-actin. One can be converted into the other by a reversible process of polymerization-depolymerization. G-F transformation does not take place in a salt-free medium. Hydrogen ion is the most potent activator of polymerization, which takes place readily at pH 6, but other ions also condition the process. There is an optimum concentration for each salt; thus NaCl and KCl provoke polymerization at $0.1M$ concentration, but at high concentrations the process is reversed. Mg ion and ATP are necessary factors for G-F transformation, which does not take place in their absence. Polymerization has been followed with the electron microscope. Small globules of molecular dimensions first unite into larger ovoids 100 A in width and 300 A long; these are then joined end to end and form long filaments with a periodic cross striation at 300-A intervals.

[1] Engelhardt, W. A., and M. N. Ljubimowa, *Nature, London*, **144**, 669, 1939.

X-ray diffraction diagrams of muscles are the sum of the patterns given by extracted F-actin and myosin separately, and the two are oriented parallel to each other and to the muscle-fiber axis.[1]

Actomyosin. Myosin and F-actin in appropriate conditions of ionic equilibrium unite to form an F-actomyosin-ATP complex, a colloid of high viscosity. This complex contains 1 part of actin to 2.5 to 3 parts of myosin. The SH groups of myosin must be free for it to unite with F-actin.

If a thread of F-actomyosin is suspended in $0.05M$ KCl, and ATP (0.015 per cent) is added, the thread shortens and narrows very rapidly. Shrinking (syneresis of colloids) is due to loss of hydration water from the particles; in this case it takes place so quickly that it simulates contraction, except that the thread does not become shorter and wider like the muscle fiber, but simply shrinks. If, however, the actomyosin thread is stretched so that its micellae tend to be oriented along its axis, when ATP is added it does not shrink but becomes shorter and wider. The reaction is reversible, and the thread swells and stretches when the ionic strength is increased and ATP is added. Szent-Györgyi and his associates have shown that muscle fibers (rabbit's psoas) extracted with 50 per cent glycerol at 0°C. can be kept at low temperatures almost indefinitely without losing their contractility. If these fibers are submerged in muscle juice, or in a solution of KCl, Mg Cl_2, and ATP at the concentrations in which these substances are found in muscle juice, they contract. K^+ can be replaced by Na^+, but Mg^{++} cannot be replaced by Ca^{++}, and ATP is entirely specific; no other substance produces its effect. An increase in the concentration of KCl, Mg, ATP or a shift in pH will provoke dissociation of F-actomyosin into its components, and the fiber relaxes. A shift in concentration of $0.02M$ KCl is sufficient to dissociate or unite the two proteins.

The state of actin in the resting muscle is not known. Straub believes it is in the form of G-actin, which on excitation is converted to F-actin. Szent-Györgyi believes it is in the form of F-actin, but dissociated from myosin. The electron microscope shows filaments in the myofibrils running through the whole length of the sarcomere from one Z membrane to another.

[1] Astbury, W. T., *Nature, London*, **160**, 388, 1947.

These have been interpreted as made up of F-actomyosin or F-actin and myosin lying side by side. The A segment, however, contains more substance than the I segment; therefore Szent-Györgyi considers that the filaments are probably made up of F-actin, and that myosin is located only in the A segment which is the contractile part of the sarcomere. If this were so, "only half of the actin filament could take part in contraction, while the other half would merely act, so to speak, as a tendon for the contractile part,"[1] *i.e.*, would form part of the series elastic component.

Szent-Györgyi has suggested the following sequence of events to explain contraction and relaxation: The wave of excitation disturbs the ionic equilibrium so that conditions favorable to the union of actin and myosin ATP are created. F-actomyosin ATP in its extended state is unstable and tends to dissipate its thermodynamic potential, going into an energy-poorer shorter form. Dephosphorylation of ATP to ADP would bring about dissociation of actin and myosin and relaxation. During the period of recovery ATP is resynthesized and adsorbed by myosin. There is, however, no conclusive evidence as to whether hydrolysis of ATP is associated with contraction or with relaxation. The adequacy of this theory has been subject to criticism from other points of view, *e.g.*, the theoretically derived energetics of the system. "There still remains the bare mechano-chemical fact that actomyosin does somehow contract when acted on by ATP in the presence of physiological concentrations not only of ATP but of the cations K and Mg as well."[2]

Other proteins in muscle are the X globulin; tropomyosin, which is a prototype of myosin, perhaps one of the units from which the myosin filament is made; para-myosin; contractin appearing in contracting muscle; Y protein, which becomes strongly bound to the muscle stroma in contracted muscle; and N protein, a lipid-protein-nucleic acid complex showing negative birefringence, thus having the properties of the substance in the I band which extinguishes the positive double refraction of F-actin or actomyosin in this band.

Myohemoglobin (MHb) is found in higher concentration in red fibers (700 to 800 mg. per cent) than in white fibers; it increases after birth and decreases a little in senility. Its molecular weight is approximately 16,800, *i.e.*, that of one of the four units which make up hemoglobin. Evidence obtained from x-ray diffraction diagrams suggests it is a flat molecule made up of four parallel chains 54 A long, situated in the same plane; the width of the molecule is 37 A and its thickness between 9 and 14 A. This structure is similar to that of one of the four layers of hemoglobin. The affinity of myohemoglobin for oxygen is greater than that of hemoglobin and less than that of the cytochrome–cytochrome oxidase system; at 40 mm. Hg oxygen partial pressure, hemoglobin is only 38 per cent saturated, while myohemoglobin is 60 per cent saturated. The relative affinities for oxygen are such that myohemoglobin acts as an oxygen carrier, taking O_2 from the blood and giving it up to the muscle enzyme system.

Glycogen is found mainly in the anisotropous substance in close association with myosin. The total amount of glycogen in a resting muscle is approximately 500 mg. per cent; red fibers have two-thirds to three-fifths the glycogen content of white fibers. Glycogen diminishes in the course of contraction and falls to about 100 mg. per cent in a fatigued muscle; when the glycogen store has been exhausted, the muscle goes into contracture. Glycogen is rapidly restored during the period of recovery after exercise (see Chap. 41, Carbohydrate Metabolism). Hexoses, trioses, and several phosphoric esters of these sugars, and lactic and pyruvic acids are steps in the breaking down of glycogen, a process that sets free energy employed in muscular activity.

Phosphocreatine, also called creatinephosphate or phosphagen, acts as a phosphate donor on being split into creatine and phosphate. Creatinephosphoric acid is a stronger acid than phosphoric acid, therefore alkali is set free by this breakdown. More important still, a great amount of energy is liberated, from 10,000 to 12,000 cal. per mol. This is an "energy-rich" phosphate bond, to use a term employed by Lipmann, in contrast with others, such as hexosephosphate, which are "energy-poor," as on their being split only 3,000 cal. per mol is set free.

Adenosinetriphosphate or adenylpyrophosphoric acid (ATP) is also an important phosphate donor and acts as a coenzyme in phosphorylation reactions. The pyrophosphate is the active "energy-rich" bond. On being split, it gives one

[2] Sandow, A., *Ann. Rev. Physiol.*, **11**, 297, 1949.

phosphate and adenosinediphosphate (ADP); in a second stage, another phosphate is set free and *adenosinemonophosphate* (AMP) or adenylic acid is formed (see "Intermediary carbohydrate metabolism," Chap. 41).

Diphosphopyridine-nucleotide functions as a hydrogen acceptor or coenzyme (cozymase I) to dehydrogenases acting on trioses. *Triphosphopyridine-nucleotide* (cozymase II) acts as a hydrogen acceptor in other reactions, *e.g.*, the oxidation of hexosemonophosphate to phosphohexonic acid (see Chap. 34).

Approximately fifty *enzymatic activities* have been found in muscle extracts (see Chap. 34), but the existence of an enzyme in minced muscle does not necessarily mean that it plays a part in the living fiber; it only suggests that it may do so. Moreover, it has been proved that certain chemical reactions that take place in minced muscle do not occur in the intact fiber.

The following are the main enzyme systems found in muscle:

1. *Cytochrome–cytochrome oxidase*, found in higher concentration in white than in red fibers (see Chap. 34).
2. *Flavoproteins* (Warburg's yellow respiratory pigment), the prosthetic group of which is flavindinucleotide (see Chap. 34 and "Vitamin B_2," Chap. 49).
3. *Dehydrogenases:* for lactate, hydroxybutyrate, succinate, malate, isocitrate, tartrate, glycerophosphate, glycero-aldehyde phosphate, triose phosphate, and glutamate.
4. *Adenosinetribhosphatases.* The ATP-ase activity of myosin inhibited by Mg^{++} with an optimum at pH 9, and of Mg actomyosinate with an optimum at pH 7, have already been mentioned. Another adenosinetriphosphatase has been extracted from muscle. It is independent of myosin and is activated by Mg^{++} but not by Ca^{++}.[1]
5. *Phosphorylase*, which activates the reversible hydrolysis (phosphorolysis) of glucose-1-phosphate (Cori's ester) in the synthesis and breakdown of glycogen (see Chap. 41). *Isophosphorylase* catalyzes the 1:6 linkages in the formation of glycogen.
6. *Phosphopherases, i.e.*, enzymes that catalyze transfer of phosphate from one compound to another (Parnas), such as *hexokinases* which transfer phosphate from ATP to glucose giving glucose-6-phosphate (Robison's ester) and to fructose giving fructose-6-phosphate (Neuberg's ester).[1] Another enzyme analogous to but different from hexokinase, activated by Mg^{++} and Mn^{++}, catalyzes the following reaction: glucose-1-phosphate + ATP ⇄ glucose-1:6-diphosphate + ADP.[2] Phospherases also transfer phosphate from creatinephosphate to ADP and AMP, and from ATP to Neuberg's ester giving fructose-1:6-diphosphate (Harden and Young's ester).
7. *Myokinase*, which dismutates ADP, activating the following reaction: 2 ADP ⇄ ATP + AMP.
8. *Phosphoglucomutase*, which catalyzes intramolecular transfer of phosphate from C^1 to C^6. Glucose-1:6-diphosphate, formed by the enzyme reaction mentioned above, acts as the prosthetic group of the enzyme. P is taken up by the enzyme from C^1 and returned to C^6 of the glucose-1-phosphate substrate,[3] as has been shown by means of radioactive P.[4] The reaction can be formulated as follows: glucose-1-phosphate + glucose-1:6-diphosphate ⇄ glucose-6-phosphate + glucose-1:6-diphosphate.
9. *Phosphohexose isomerase*, which catalyzes the equilibrium found in resting muscle between Robison's ester (70 per cent) and Neuberg's ester (30 per cent). The mixture of the two esters is known as Embden's ester.
10. *Aldolase*, which catalyzes the reversible cleavage of fructose-1:6-diphosphate into glyceraldehyde-3-phosphate and dihydroxyacetone phosphate.

Metabolic processes. When there is an adequate oxygen partial pressure in the muscle (aerobiosis), oxidation is ultimately the main source of energy. When the muscle contracts internal pressure is developed which is sufficiently high (100 to 300 mm. Hg) to suppress the blood flow through the capillaries. There is

satisfactory evidence not only that blood flow decreases during strong sustained contraction of human muscles,[1] but also that mechanical hindrance produced by rhythmic contractions reduces blood flow.[2] A condition of relative oxygen insufficiency (anaerobiosis) is set up, and phosphorolysis seems to be the main source of energy. Immediately after contraction has ended the blood flow increases considerably and the oxygen supply is greater than in the resting condition.

Aerobic processes. Respiratory metabolism. Muscle oxygen consumption increases considerably on contraction, and the increase is proportional to the activity developed. All those factors which condition development of tension in contraction also have an influence on oxygen consumption; *e.g.*, the length or tension of the resting muscle (initial length) conditions the resting oxygen consumption and the excess oxygen consumption due to activity.

The excess oxygen consumption of activity begins early in contraction. The first blood that can be obtained from a muscle after contraction has begun shows that there is an increased reduction of hemoglobin; therefore the muscle takes up more O_2. Millikan[3] has used a photometric method to follow the changes in oxygen saturation of myohemoglobin in the muscle fiber of the cat's soleus contracting *in situ*. Myohemoglobin begins to lose oxygen within the minimum time (200 msec.) in which the decrease can be registered after the commencement of contraction; within the first second this process has reached its maximum velocity. Desaturation of myohemoglobin probably starts even earlier. The soleus has a contraction time of 100 msec.; therefore if the increase in oxygen consumption begins during the phase of contraction, it must do so in a much shorter time than that recorded by Millikan. D. K. Hill[4] studied the oxygen consumption of the frog sartorius at 0°C., in order to decrease the velocity of the reactions; nearly all the excess O_2 consumption in this condition took place after the contraction phase had ended. The excess oxygen consumption persisting after activity has ceased has been called the "oxygen debt" by A. V. Hill. Recovery of the initial resting condition requires the energy set free by oxidation, and although the oxygen consumption diminishes rapidly after activity has ended, it remains for a long time above the resting level.

Stannard[1] has observed that sodium azide and other inhibitors of the cytochrome system suppress oxidations due to activity without altering the resting oxygen consumption. Therefore there is more than one enzyme system that takes part in the oxidation processes of muscle. Several other facts are in agreement with this. Thus if the oxygen partial pressure is diminished so that it falls below 50 mm. Hg in venous blood (hemoglobin 85 per cent saturated), the oxygen consumption of the resting muscle in the dog decreases by one-third; a further reduction in O_2 partial pressure, down to 20 mm. Hg, has no effect. Therefore there is an enzymatic system that needs an O_2 partial pressure of more than 50 mm. Hg, while another remains active at much lower O_2 pressures.

Anaerobic processes. Muscle can contract in an atmosphere free of oxygen (anaerobiosis). The ratio of tension developed to initial heat is the same as in aerobiosis. The capacity to perform work is nevertheless considerably diminished. In aerobiosis the frog sartorius can contract at a rate of 23 per minute without showing signs of fatigue for more than 10,000 contractions; in anaerobiosis (the muscle being kept in oxygen-free Ringer solution) this same rhythm of contraction soon produces fatigue; a steady state can be kept up for a long time only if the frequency of contraction is not more than 5 or 6 per minute.[2]

In the course of his studies on fermentation, Pasteur[3] saw that yeast, when it cannot freely oxidize the sugar it uses for its nutritive processes owing to lack of oxygen, continues to live by obtaining energy from other exothermic chemical reactions, such as the formation of alcohol from sugar. This change to anaerobic fermentation when there is a deficiency of oxygen is known as the "Pasteur reaction." In muscle kept in anaerobiosis, glycolysis occurs, glycogen diminishes, and lactic acid is formed (it would be more correct to say lactate, as the lactic acid

is almost completely dissociated); lactic fermentation, therefore, takes place.

Fletcher and Hopkins's[1] classic work showed that in a resting muscle in aerobiosis there is very little lactic acid (0.015 gm. per cent). In anaerobiosis lactic acid increases gradually to 0.2 or 0.3 per cent, a process that can be speeded up and increased to 0.3 or 0.5 gm. per cent, by making the muscle contract by any means whatever—simple contraction, tetanus, heat, chloroform, etc. In the course of recovery, in an atmosphere of oxygen, lactic acid accumulated in anaerobiosis diminishes considerably (down to 0.07 gm. per cent). Meyerhof[2] studied the variations in muscle glycogen and lactic acid in relation to oxygen consumption. In aerobiosis glycogen diminishes without lactate being produced, and in both the resting and the active muscle the oxygen consumed corresponds to the amount needed to oxidize the glycogen that has disappeared. In anaerobiosis lactic acid is formed in quantities corresponding to the glycogen decrease. If the tissue is placed in oxygen after a period of anaerobiosis, lactic acid disappears and glycogen is resynthesized. Oxygen consumption in these conditions is greater than before the period of anaerobiosis, but the excess oxygen consumption (oxygen debt) would be sufficient to oxidize only one-fifth to one-fourth of the lactic acid that disappears, and glycogen increases in such quantities as if three-fourths to four-fifths of the lactic acid removed had been converted into glycogen. This series of chemical reactions, glycogen → lactic acid → glycogen, is known as the "Pasteur-Meyerhof cycle."

Several facts were discovered later that added considerably to the knowledge of the chemistry of muscular contraction:

1. In anaerobiosis a hexosemonophosphate accumulates, which was named "lactacidogen" by Embden, because it was thought to be the lactic acid precursor.
2. Fiske and Subbarow[3] and simultaneously the Eggletons[4] found a labile organic phosphorus compound, which disintegrates when the muscle contracts. This is phosphocreatine, called "phosphagen" by the Eggletons, because it is a source of the phosphate that appears on muscular contraction. During recovery in oxygen, phosphagen is totally resynthesized from creatine and phosphate. In anaerobiosis only 30 per cent of the phosphagen is resynthesized.
3. Lundsgaard[1] demonstrated that muscular contraction can take place without the formation of lactic acid in animals intoxicated with monoiodacetic acid. Iodacetate blocks especially the triosephosphate dehydrogenase. The intoxicated muscles contract for a short time, and when all the phosphocreatine has been disintegrated they enter into contracture. The drug does not modify the ratio of tension developed to heat production.
4. Myosin has adenosinetriphosphatase activity which splits off the terminal phosphate of ATP, thus breaking an energy-rich bond and releasing 11,000 cal./mol of phosphate. Myokinase catalyzes the reconstruction of this bond by the conversion of 2ADP into ATP and AMP. ATP is also resynthesized by the transfer of phosphate from creatinephosphate to AMP and ADP.

Chemical reactions that accompany muscular contraction. Glycogen breakdown is of primary importance in the process of liberating energy for muscular contraction. In the first stages phosphorolysis is the principal mechanism; oxidation takes place only in the final phases (see Intermediary Carbohydrate Metabolism, Chap. 41).

1. Glycogen is split by phosphorolysis into glucose-1-phosphate (Cori's ester). The reaction is activated by phosphorylase. Phosphorolysis does not entail a transfer of energy.
2. Glucose-1-phosphate is transformed to glucose-6-phosphate by intramolecular phosphate transfer; phosphoglucomutase with glucose-1:6-diphosphate catalyzes this reaction, as was explained in a previous paragraph.
3. Fructose-6-phosphate (Neuberg's ester) is formed by intramolecular rearrangement, so that an equilibrium of 70 per cent Robison's ester and 30 per cent Neuberg's ester is main-

tained in the resting muscle; phosphohexose isomerase catalyzes this equilibrium.

4. A further phosphorylation transforms fructose-6-phosphate to fructose-1:6-diphosphate (Harden and Young's ester); ATP again acts as a phosphate donor, with Mg^{++} activating the reaction.
5. Hexosediphosphate splits into two phosphorylated three-carbon-atom groups, probably dihydroxyacetone phosphate and 3-phosphoglyceraldehyde; aldolase catalyzes this reaction.
6. 3-Phosphoglyceraldehyde is phosphorylated and then oxidized to 1:3-diphosphoglyceric acid; a dehydrogenase activates this reaction and diphosphopyridine-nucleotide acts as hydrogen acceptor. The 1:3-diphosphoglyceric acid is dephosphorylated (ADP acting as phosphate acceptor) and converted by intramolecular phosphate transfer into 2-phosphoglyceric acid. Enolase activates the loss of H_2O, and phosphopyruvic acid results, which by dephosphorylation (ADP being the phosphate acceptor) gives pyruvic acid.

Lactic acid

In a second phase pyruvic acid may follow one of two paths, according to the availability of oxygen. If there is oxygen deficiency (anaerobiosis), pyruvic acid accepts H_2 from reduced DPN and lactic acid is formed; this is a reversible reaction, catalyzed by a special dehydrogenase. In the organism lactic acid passes into the blood and in the liver is reconverted into glycogen, which by glycogenolysis is transformed into glucose, which is taken back to the muscle by the blood and there synthesized into muscle glycogen, which on being broken down again gives lactic acid. This series of reactions is known as the "Cori cycle." If, on the contrary, there is abundance of oxygen (aerobiosis), pyruvic acid is oxidized to CO_2 and H_2O, possibly along the path known as the tricarboxylic acid or citric acid cycle (see Chap. 34).

Creatinephosphate is disintegrated into creatine and phosphate, a highly exothermic reaction; the phosphate is taken up by ADP, and the reaction is catalyzed by a specific enzyme and Mg^{++}. This is a reversible process, and in the course of muscular contraction, there is first disintegration and then resynthesis of creatinephosphate. The resynthesis is an endothermic (endergonic) reaction; it therefore needs outside energy, which is obtained from glycolysis or oxidation. In monoiodacetic-acid intoxication the inhibition of these exothermic reactions prevents the reconstruction of phosphocreatine.

It is not yet possible to state exactly what chemical reactions take place in the living muscle fiber, nor in what order they come; neither can we correlate precisely chemical reactions and energy changes. From the facts known it seems that some process approximating the following sequence takes place in the living muscle: With the onset of contraction, there is a sudden and considerable increase in the need of oxygen, which causes a relative deficiency of oxygen and therefore a condition of anaerobiosis; this produces a "Pasteur reaction," *i.e.*, anaerobic fermentation. Anaerobic chemical reactions have been demonstrated in the course of the first minute of contraction in mammalian muscle with normal circulation: lactic acid, hexosemonophosphate, and more slowly inorganic phosphate increase, while glycogen and creatinephosphate diminish rapidly and adenosinetriphosphate more slowly.[1] Oxygen supply soon improves owing to vasodilatation and the opening of capillaries that are closed in the

[1] FLOCK, E. W., D. S. SINGLE, and J. L. BOLLMAN, *J. Biol. Chem.*, **129**, 99, 1939.

resting muscle. A steady state is then established, during which lactic acid concentration in muscle returns to the resting value, owing principally to diffusion into the blood. Hexosemonophosphate and more slowly ATP and inorganic phosphate also return to the resting values. Glycogen and phosphocreatine remain low. This steady state can be kept up for a long time. When glycogen is exhausted, the muscle enters into a lasting contracture (fatigue cramp). Oxidation reactions are the principal source of energy; anaerobic processes are probably emergency reactions set in motion when there is oxygen deficiency, *i.e.*, at the beginning of contraction.

Changes in acid-base equilibrium during contraction. Chemical reactions in muscle produce rapid shifts in the acid-base equilibrium. In order to follow them, their velocity can be diminished by cooling. In frog muscle at 0°C., as soon as contraction begins there is a shift toward the alkaline side. Then there is a shift in the opposite direction, attributed to disintegration of ATP. A progressive alkalization follows, due possibly to phosphocreatine disintegration; this takes place mostly when the muscle is already relaxed. Finally there is a prolonged acidification, attributed to lactic acid formation, because it is more marked in anaerobiosis and does not take place in muscles intoxicated with monoiodacetate.[1]

Owing to the delay with which these shifts are recorded, it is impossible to correlate them with the mechanical. chemical, or thermic phenomena of contraction. "No present method is nearly rapid enough, nor probably sensitive enough to record changes of pH suspected to occur in a single contraction."[2]

ENERGETICS OF MUSCULAR CONTRACTION

In the resting muscle, as in all living tissues, there is a continuous evolution of energy. Activity causes a considerable increase in the mobilization of energy, because muscle is a machine which converts chemical energy into mechanical energy. Energy evolved can be measured as heat, but the amount of heat produced in a muscle twitch is very small, about 3 μcal per gm. Heat production of muscle is a complicated phenomenon; to analyze it, it is usually necessary to record it as a function of time, but a twitch, even in a cooled muscle, is a very rapid event; *e.g.*, in frog's skeletal muscle at 0°C. heat begins to appear about 10 msec. after the stimulus has been applied, reaches its peak in 30 to 40 msec., and is complete in about 400 msec. The recording instruments should, therefore, be highly sensitive and very rapid. Hill[1] has developed a thermopile of palladium-gold and iron with a very rapid galvanometer which can register with a sensitivity of 10^{-5}°C. and a time lag as small as 1.5 to 4 msec. The mechanical events (shortening or tension) can be recorded simultaneously.

Heat is produced in the course of muscle activity in two main phases: (*a*) during the mechanical response, *initial heat;* (*b*) after mechanical response, *recovery heat.*

Initial heat.[2] Heat produced during the mechanical response in a single twitch is composed of two parts: (*a*) heat of activation, and (*b*) heat of shortening; the observed heat is the sum of the two. If the stimulus is sustained, *i.e.*, in a tetanus, a third component appears, (*c*) heat of maintenance.

Heat of activation is calculated by subtracting from the observed heat the heat of shortening. It is rather less than the maximum heat of shortening and is not dependent on the length at which the muscle is stimulated or changes in length thereafter, or on the load, or on work done. It begins during the latent period of the mechanical response well before shortening or the rise in tension commences; thus the latent period of activation heat is about 10 msec. in the frog's muscle at 0°C., and the mechanical latency is 20 to 25 msec.; in the tortoise's muscle the respective figures are 60 msec. and 90 to 100 msec. The heat of activation starts at a maximum rate, then diminishes in rate continuously as contraction proceeds.

Heat of shortening begins when the muscle commences to shorten and is proportional to the amount of shortening. If the muscle does not shorten, the heat observed is equal to the heat of activation. Heat of shortening is not dependent on the load, speed of shortening, or work done.

The total energy liberated in a muscle twitch can be expressed as $E = A + W + ax$, where A is the activation heat, W is the work, and ax is the heat of shortening. This relation is true for the whole contraction and for any part of it.

[1] HILL, D. K., *J. Physiol.*, **98**, 467, 1940. DUBUISSON, M., *Proc. Roy. Soc., London, s.B.*, **137**, 67, 1950.
[2] HILL, A. V., *Proc. Roy. Soc., London, s.B.*, **137**, 40, 1950.

[1] *Ibid.*, **136**, 228, 1949.
[2] *Ibid.*, **136**, 195, 220, and 242, 1950; **137**, 268 and 330, 1951.

The rate at which energy is liberated, in excess of activation heat, in a muscle twitch and in a maintained tetanic contraction is a decreasing linear function of the load. This should be connected with the characteristic relation between force and velocity discussed above (see "Shortening," under "Mechanical phenomena of muscular contraction").

Heat of maintenance in a tetanic contraction is the sum of the heat of activation produced by each one of the successive shocks of the stimulus.

Heat produced during relaxation is equivalent to the mechanical energy which disappears at the same time. If the muscle is without load or tension no heat is produced after shortening is ended. The process of relaxation itself, therefore, is not accompanied by the production of heat.[1]

Recovery heat. Heat continues to be produced after the mechanical response is ended at a low rate and for a long time. The absence of oxygen does not modify the output of initial heat, but diminishes considerably the heat of recovery. In the presence of oxygen total recovery heat is about equal to total initial energy as heat and work together.

Contraction may be regarded as due to entropy changes as in the shortening of rubber, or to changes in potential energy resulting from chemical reactions. In an entropy cycle the strength of intermolecular attractions should decrease during contraction, while in a potential energy cycle they ought to increase; observations in muscles suggest that they do decrease.[2] There are, however, fundamental objections to the entropy theory. If shortening is due to muscle passing from a state of low entropy to one of high entropy, as in the retraction of stretched rubber, the heat of shortening should be negative. This is not so, since heat is given out during shortening; therefore, from the thermodynamic point of view, entropy is decreased by contraction. When rubber shortens, if it does work, the heat absorbed is greater in proportion to the work done, while in muscle heat of shortening is not affected by work.[3]

Efficiency. Mechanical efficiency is the ratio of the energy equivalent of work performed to the total energy mobilized (see Chap. 47). The gross efficiency of the whole organism is 17 to 20 per cent, *i.e.*, less than one-fifth of the total energy spent can be recovered as work; the rest is given off as heat. The maximum efficiency of a muscle twitch or a tetanic contraction is approximately 40 per cent, according to results obtained with accurate myothermic methods.[1] Previous determinations had given lower figures.

SMOOTH MUSCLE

Smooth muscles are made up of elongated, spindle-shaped cells, with a central nucleus and a thin membrane. The fibers are much shorter than those of striated muscle. Each one has its origin in a single mesenchyme cell, or in an ectodermal cell (piloerectors, iris). They are not multinucleated giant cells as are the striated muscle fibers. The protoplasm is differentiated into slender fibrils which have no transverse striation, but in the adductor muscle of the clam regular segments repeated periodically at intervals of 1100 A have been observed by means of the electron microscope. In some smooth muscles, the fibrils pass from one cell to another; the protoplasmic bridges endow these muscles with some of the characteristics of a syncytium. Myosin, which differs slightly from striated-muscle myosin, is the principal constituent of the fibrils and gives the cell the property of birefringence, its anisotropy being similar to that of the A or Q disk. Microscopic examination of living smooth-muscle cells, in tissue cultures, has shown a displacement on contraction of the peripheral protoplasm (Roskin's kinoplasm) toward the perinuclear region. The middle part of the fiber is thickened and its volume diminishes; therefore the interfibrillar space increases. The protoplasm loses its transparency, becomes cloudy, and stains more deeply, a sign of condensation.

Smooth muscle forms membranous structures, sheets, or ribbons, such as the nictitating membrane, the retractor penis, and the piloerectors; in other cases it forms part of the walls of cavities or ducts, such as the bladder, the uterus, the digestive tract, the ureter, the blood vessels, etc. Smooth muscles do not constitute a homogeneous group; they have the property of contractility in common, but excitation and conduction vary considerably from one muscle to another. Bozler[2] distinguishes two types of smooth muscle:

[1] *Ibid.*, **136**, 220, 1950.

[2] Bozler, E., *Biol. Symposia*, **3**, 95, 1941.

1. *Multiunit smooth muscles*, which are similar to striated muscle. They are made up of motor units and are usually activated by motor nerves. The nictitating membrane, the piloerectors, and the muscles of the blood vessels belong to this group.
2. *Visceral smooth muscles*, which are similar to cardiac muscle. They are syncytial in character and have a well-developed automatism, being less dependent on the nervous system than the previous group. Among these are the muscles of the intestinal tract and the uterus.

Innervation. Smooth muscles are innervated by sympathetic and parasympathetic postganglionic fibers. These are fine, nonmyelinated fibers, with the exceptions of those from the ciliary ganglion which have a myelin sheath up to their ending in the intrinsic musculature of the eye. The nictitating membrane and the piloerectors are innervated exclusively by the sympathetic and the ciliary muscle by the parasympathetic; in these muscles the nerve impulses produce contraction. Most smooth muscles have a double innervation; one of the nerves has a stimulatory, and the other an inhibitory, effect. These smooth muscles resemble the muscles of invertebrates, which also have excitatory and inhibitory innervation. They differ from striated muscles, which receive only excitatory impulses, inhibition being due to the suppression of the central excitatory state (central inhibition).

Each fiber of the ciliary muscle has a nerve ending, but in the majority of smooth muscles not all the fibers are innervated.[1] The cells that are not innervated are stimulated indirectly, perhaps by the chemical mediator, sympathin or acetylcholine. The motor units in the multiunit muscles are not so well defined as those in striated muscle. Stimulation of an axon going to a striated muscle provokes contraction in a definite number of muscle fibers, namely, all those innervated by the peripheral branching of the axon; section of the nerve fiber suppresses the activity of these same muscle fibers. Consequently there is a constant ratio between the responses to stimulation of a fixed fraction of the nerve and of the whole nerve, whatever the frequency of stimulation. In the nictitating membrane, on the contrary, as frequency of stimulation increases, a larger number of muscle fibers respond.[1] This may be due to the liberation of a greater amount of chemical mediator (sympathin) by the more frequent stimulus and therefore the activation of a larger number of muscle fibers.

[1] CANNON, W. B., and A. ROSENBLUETH, "Autonomic Neuro-effector Systems," Macmillan, New York, 1937.

Nerves have a twofold action on the smooth muscles: (*a*) nerve impulses liberate chemical mediators and thus have a stimulatory or inhibitory effect; (*b*) nerves also have a "trophic" action, which is made manifest by denervation, *e.g.*, nerve degeneration sensitizes the nictitating membrane, and other adrenergic effectors, to adrenaline. This effect is due to the suppression of a direct action of the nerve on the muscle fiber, because when only a few fibers of the nerve going to the nictitating membrane are cut, only the units that have lost their innervation are sensitized.

The effects of several chemical substances are of great physiological, as well as pharmacological or therapeutic, interest (see Chap. 84). They can be classified into three groups: (*a*) sympathicotropic; (*b*) parasympathicotropic; (*c*) musculotropic. The first two act on the receptors for the sympathetic and parasympathetic chemical mediators and produce the same effects as these. The third group of substances acts directly on the muscle fiber; among these is the extract of the posterior hypophyseal lobe.

Excitation and conduction. The excitability of smooth muscle is remarkable for (*a*) its slowness—chronaxies are very long, *e.g.*, 3 to 5 msec. for the stomach of the frog and 1.5 sec. for the blood vessels in the web of the frog; (*b*) its instability—many factors can change it.

From the standpoint of excitation and conduction, smooth muscles are not a homogeneous group of effectors. Certain muscles, *e.g.*, the nictitating membrane, the piloerectors, and the nonpregnant uterus of the cat in anestrus give little or no response to direct electric stimulation. Stimulation of the nerve provokes a response after a long latent period. Neuromuscular delay is about 30 msec. in the nictitating membrane and 40 msec. in the piloerectors; mechanical latency is approximately 150 msec. A single shock may be followed by a single electrical and mechanical response, similar to a slow twitch, lasting ten to fifteen times as long as the twitch of the soleus, which is a "slow" striated muscle.

[1] ROSENBLUETH, A., and D. M. RIOCH, *Am. J. Physiol.*, **106**, 365, 1933.

More frequently a rhythmic response is observed; repeated contractions with the corresponding electric potentials at a rate of one or two per second produce an effect resembling an incomplete tetanus. Adrenaline provokes a similar response. A propagated excitatory wave,
FIG. 352. Rhythmic contractions of the isolated duodenum of the rabbit. *Ac.*, acetylcholine 4×10^{-6}; *Ad.*, adrenaline 5×10^{-6}. Lower line, time in minutes.

with a spike potential, followed by a retractory period has not been satisfactorily demonstrated in this type of muscle; neither do they follow the all-or-nothing law. The nerve impulse does not stimulate the muscle fibers directly—their electrical excitability is far too low for that—but releases a chemical mediator. This mediator acts directly on the contractile element of the muscle fiber; it does not evoke a propagated disturbance such as is observed in striated muscle, which spreads throughout the fiber and provokes contraction. Contraction is graded in relation to the strength of the stimulus, *i.e.*, to the amount of mediator which is released; it is not therefore an all-or-nothing response.

Other smooth muscles respond to direct electric stimulation, *e.g.*, intestinal muscle, the ureter, the cat uterus during estrus, and the rabbit uterus. The response to local stimulation is propagated throughout the muscle accompanied by a spike potential; it is followed by a refractory period and is an all-or-nothing phenomenon. In the uterus in estrus spontaneous rhythmic waves of contraction, which are very prominent, also spread throughout the uterine horn. Stimulation of the nerves to these muscles evokes contraction or relaxation, according to the nerve and muscle, and the condition of the latter. Thus the nonpregnant uterus of the cat not in estrus always responds to stimulation of the hypogastric nerve with relaxation. In the rabbit, stimulation of nerves distributed to limited regions of the uterus provokes contraction which does not spread throughout the muscle. The vagus nerve and its chemical mediator, acetylcholine, have a predominantly excitatory effect on the motility of the intestine, evoking or enhancing rhythmic contractions and propagated contractions (peristalsis). The sympathetic, and adrenaline, have a predominantly inhibitory effect[1] (Fig. 352). Electrical excitability, spontaneous activity and conduction are not dependent on ganglion cells or nerve fibers. They have been observed in muscles after the nerves have been cut and have degenerated, and in intestinal strips in which subsequent serial section showed there were no nerve cells. Moreover a 1 per cent solution of cocaine suppresses all nervous activity but does not modify conduction or rhythmic contractions.

Rosenblueth,[2] on the basis of transmission and activation, divided smooth muscles into two classes, which differ from those of Bozler: (*a*) muscles in the first class, *e.g.*, the nictitating membrane and the piloerectors, have short fibers, there is no conduction, and the chemical mediator acts directly on the contractile substance, without an intermediate propagated disturbance which spreads excitation throughout the muscle fiber; (*b*) muscles in the second class have long fibers, and the mediator evokes a propagated process which acts on the contractile substance.

Contraction of smooth muscle. Contraction of smooth muscle can be studied *in situ* by registering the movements of the viscera of which it forms part, or in isolated strips submerged in an adequate saline solution (*e.g.*, Ringer's or Locke's), in which they survive and respond for many hours. Contraction in response to stimulation of the nerve, an electric stimulus, or a chemical substance, is very slow and frequently rhythmical. The contraction time of a single twitch is 10 to 15 times that of slow striated muscles. Relaxation is even slower, but can be speeded up by an inhibitory stimulus. The maximum tension developed in contraction increases with the resting length up to an optimum, as in striated muscle; but this optimum initial length varies considerably and is influenced by the previous condition of the muscle.

[1] The effects of nerve stimulation and of the chemical mediators on the sphincters are opposite to those they have on the wall muscles.

[2] ROSENBLUETH, "The Transmission of Nerve Impulses at Neuroeffector Junctions and Peripheral Synapses."

Repeated stimulation provokes fatigue; contraction and relaxation are shortened, and finally there is complete relaxation instead of contracture such as occurs in fatigued striated muscles.

When a smooth muscle is stretched it lengthens, at first rapidly and then more slowly, taking a long time to reach the final length, owing to internal friction or "viscosity." Tension also increases on stretching, but after quickly arriving at a maximum, it decreases slowly following an exponential curve, similar in its time course to that of relaxation. This release of tension without change in length gives great "plasticity" to smooth muscles, a property of value in visceral functions. The distention of a cavity with walls made up of smooth muscle, by the increase of its contents, at first raises the internal pressure, and then, without any change in its capacity, the pressure falls because of the release of tension in the muscles. Sudden distention can produce a greater and more lasting increase in the internal pressure, because it acts as a stimulus and provokes contraction of the wall muscles.

Tonus. This is an outstanding feature of smooth muscle, but the term is used for several different conditions. Evans defines it by the ratio $F:L$, in which F is the stretching force and L the length of the muscle. It varies considerably from one moment to another and there is no constant ratio between tension and length, such as is observed in striated muscle. Tonus is originated in several different ways: (*a*) it can be due to asynchronous activity in different parts of the muscle; (*b*) it can be produced by nerve impulses of very low frequency (2 per second); (*c*) it can arise in the muscle fiber itself, a fact proved by the tonus observed in strips of muscle free from nerve cells. Tonus in smooth muscle is therefore not an exclusively reflex phenomenon, which can be suppressed by denervation, like the tonus of striated muscle.

Conditions that modify the activity of smooth muscle. Excitability, conduction, and contraction of smooth muscle are subject to considerable variations due to the influence of different factors. An increase in *temperature* diminishes excitability and tonus; between 45 and 50°C. relaxation is complete, the thermic contracture seen in striated muscle at a temperature of 45°C. is not observed. Cold increases tonus and prolongs the survival of smooth muscle with all its properties for several days. *Acidity* produces relaxation and quiescence in smooth muscle; in striated muscle it provokes contracture. *Alkalinity* increases tonus and spontaneous rhythmic activity. *Ionic equilibrium* plays an important part in the activity of smooth muscle. A decrease in the total concentration of salts increases excitability and the amplitude of rhythmic movements; an increase has the opposite effect. K^+ in adequate concentration increases tone and contractions; Ca^{++} has opposite and antagonistic effects to K^+. The whole response of smooth muscles is conditioned by the K:Ca ratio.

The *previous activity* of the muscle has considerable influence on the response to a subsequent stimulus. A contracted muscle or one that is in a condition of high tonus will relax when excited by a stimulus that in other conditions would provoke contraction. The condition of the muscle can also modify the effects of nerve stimulation. Thus stimulation of the vagus usually produces an increase in tonus and in the rhythmic movements of the intestine, but an inhibitory effect may be observed if, when the nerve is stimulated, there is already a high degree of activity. The sympathetic, which usually inhibits, can stimulate the relaxed intestine.

Hormones exercise considerable influence on the activity of smooth muscles. For example, the uterus of the cat in estrus has rhythmic contractions and responds to electric stimulation with a propagated contraction; during anestrus there is little or no activity and it is difficult to obtain a response to electric stimulation. The injection of estrogen in a cat in anestrus induces in the uterus the conditions peculiar to estrus. Estrone injections in women increase the tonus and diminish the amplitude of the spontaneous contractions of the uterus; progesterone has the opposite effect.

Chemical phenomena. Smooth muscle has a chemical structure similar to that of striated muscle. Myosin is the principal protein, but it is not the same myosin as that of striated fibers. Glycogen is found in a concentration of about 150 mg. per cent. Inorganic phosphate makes up half the total P; a large quantity of P is bound in nucleoproteins. Creatinephosphate is found in a quantity approximately one-tenth that of striated muscle. There is less potassium than in striated muscle; the Na:K ratio is 1:1.5 instead of 1:5. There is no stable basal condition in smooth muscle because tension, length, and rhythmic contractions are subject to

almost continuous variations. Oxygen consumption rises and falls with the activity of the muscle; there is, therefore, no strictly basal oxygen consumption. Oxidative reactions are necessary for the maintenance of tonus, and a smooth muscle relaxes if placed in a nitrogen atmosphere or if cyanide is added to the fluid in which it is submerged. Oxygen restores tonus which has been lost in anaerobiosis. If a smooth muscle is stretched, length, tonus (resistance to stretching), and oxygen consumption increase.[1] If it shortens, *e.g.*, in the course of isotonic contraction provoked by histamine, oxygen consumption diminishes,[2] but not if the muscle contracts against a resistance and tension is developed on shortening. Oxygen consumption varies in the same direction as tonus in the intestinal muscle maintained in isometric conditions. Stretching increases oxygen consumption to a greater or lesser degree, according to the resistance opposed to stretching and the changes caused in rhythmic movements. The transitory increase in tonus which can be provoked by histamine or acetylcholine is accompanied by an increase in oxygen consumption. The decrease in tonus caused by atropin, and in certain conditions by adrenaline, is accompanied by a decrease in oxygen consumption.[3] These facts show that in smooth muscle, at all events in those of Bozler's visceral type, there is a close relationship between tonus (resistance to stretch) and metabolic activity.

In anaerobiosis glycolysis occurs and lactic acid accumulates. After a period in anaerobiosis oxygen consumption rises above the initial level (payment of oxygen debt), lactic acid diminishes, and glycogen increases. Phosphocreatine (phosphoarginine in invertebrate muscle) diminishes in anaerobiosis and is resynthesized during a subsequent period of aerobiosis.

Smooth muscle has the same fundamental properties as striated and cardiac muscle, but its reactions have not the constancy and uniformity observed in other kinds of muscle, because it does not form a homogeneous group and because it is conditioned by a large number of external factors. Its importance resides in the part it plays in visceral functions.

CHAPTER 68

The Conduction of the Nerve Impulse

THE NERVOUS SYSTEM transmits the excitatory state from one part of the organism to another. One of the aspects of this function, transmission within the neuron, can be studied in the axons that make up a nerve. Transmission from cell to cell through the synapse will be studied later.

Conduction along the axon is of two different types: (*a*) the so-called trophic influence, which irradiates from the perikaryon and maintains the structural and functional integrity of the fiber; (*b*) the nerve impulse, or propagated excitatory disturbance. Very little is known about the nature of (*a*) (see Chap. 65). With respect to (*b*), two different properties are usually considered in a nerve fiber: excitability, or the capacity to respond to a stimulus, and conductivity, or the capacity to transmit the excitatory state. Two different processes can, in fact, be distinguished, the *local excitatory state* and the *propagated excitatory state*, but both are phases of the same phenomenon. Excitation and conduction are produced by the same fundamental processes in all the axons that have been examined, but there are important quantitative differences between different types of fiber even in the same species.

In physiologic conditions a neuron is stimulated exclusively by a receptor, another neuron, or a physicochemical change in the nerve center. The axons that form part of a nerve do not stimulate each other; they are insulated conductors, and this insulation would have to be suppressed for the excitatory state to spread laterally from one axon to another. The excitatory state is thus propagated in an orderly way; impulses from different receptors are transmitted to the appropriate centers, are recognized and localized, although neighboring axons may be transmitting impulses from other receptors to other centers. In like manner the motor units are stimulated separately and only by the central excitatory state.

The excitatory state of one fiber, however, has a certain influence on the excitability of neighboring fibers. This was first seen in unmyelinated fibers of invertebrates and was later observed in the sciatic nerve of the frog[1] and the peroneal nerve of the cat.[2] The action potential of the conducting fiber produces electrotonic currents in neighboring fibers and thus provokes alternating changes in the threshold. At first there is depression (anelectrotonus), followed by an increase of excitability (catelectrotonus) which coincides with the ascending phase of the spike potential of the conducting fiber, and finally a second period of depression (Fig. 353). These rapidly alternating states are sometimes followed by a more prolonged lowering of the threshold. Rosenblueth suggests that the early changes are due to electrical, and later ones to chemical, factors, among which potassium probably plays an important part. When two axons are stimulated simultaneously the speed of conduction is less than when one alone is stimulated, because the impulses progress into parts of the fibers in which the excitability is depressed by the anelectrotonus produced by the action potential of the neighboring fiber. When two fibers are stimulated successively, the speed of conduction decreases in the one stimulated first and increases in the other; thus there is a tend-

[1] MARRAZZI, A. S., and R. LORENTE DE NÓ, *J. Neurophysiol.*, 7, 83, 1944.

[2] ROSENBLUETH, A., *Am. J. Physiol.*, **140**, 656, 1944.

ency to synchronization of the impulses conducted in the several fibers of the nerve.[1]

The local excitatory state. A nerve is excitable in all its length. At a stimulated point a local excitatory condition arises, which has the following features: (*a*) the size depends on the strength of the stimulus, and does not respond to the "all-or-nothing" law; (*b*) it diminishes as the distance to the locus of stimulation increases, following an exponential curve; (*c*) it decreases gradually at a velocity defined by a constant that is directly proportional to the chronaxie; (*d*) it is not followed by an absolute refractory state; (*e*) the effect of a subsequent excitation can be added to it. When this local state has developed to a sufficient size and extended over a certain area, a propagated disturbance, the nerve impulse, is fired off and transmitted in both directions along the whole neuron (see Chap. 66).

Fig. 353. Interaction of nerve fibers. Changes in the excitability of a fiber (thin line) when an impulse is conducted by a neighboring fiber are superimposed on the spike potential of the conditioning fiber. (*Marrazzi, A. S., and R. Lorente de Nó, J. Neurophysiol., vol. 7, p. 83, 1944.*)

[1] Katz, B., and O. H. Schmitt, *J. Physiol.*, **97**, 471, 1940.

The nerve impulse. The propagated excitatory state is also called the nerve impulse. It is accompanied by metabolic phenomena such as an increase in respiratory exchanges and in heat production, the liberation of acetylcholine, changes in the permeability and the electrical properties of the membrane, and several electrical potentials. The latter have been the subject of a vast amount of work, which has yielded results of great value for the understanding of nerve physiology.

ELECTRICAL PHENOMENA OF THE NERVE IMPULSE

Electrical potentials that occur when a nerve is stimulated and conducts an impulse have been registered with great precision. Adrian and his associates have recorded electrical potentials in a single axon by dissecting a nerve and cutting it down until only one or a few fibers were left,[1] or by stimulating a receptor connected with a single afferent fiber.[2] Erlanger and Gasser[3] have made a remarkable contribution to nerve physiology by the use of the cathode-ray oscillograph. The potentials registered in a nerve are the sum of the individual axon potentials. Close to the point stimulated, all the fibers enter simultaneously into activity, but as the impulse is conducted along the nerve important changes occur, mainly because of differences in the conduction velocities of the fibers. The analysis of these potentials has given much valuable information on the properties of nerve fibers.

Local potential. When a nerve is stimulated by a brief electric shock, an electrotonic potential is produced which should not be mistaken for the shock artefact. This potential extends beyond the point where the electrode is in contact with the nerve. Its intensity is proportional to the strength of the stimulus. It diminishes as the distance to the electrode increases, following an exponential curve, and it decays, also exponen-

[3] Erlanger, J., and H. S. Gasser, "Electrical Signs of Nervous Activity," University of Pennsylvania Press, Philadelphia, 1937.

tially, with a time constant that is characteristic for each type of nerve fiber. The local potential is due to depolarization, and its intensity, spread, and decay correspond in space and time to the local excitatory state provoked by the same stimulus.
FIG. 354. Action potentials of phrenic nerve. *a*, single stimulus; *b* and *c*, repeated stimulation at rates of 180 and 350 per second. There is a marked positive after-potential in *b*, which is even more marked in *c*. Time, 20 msec. (*Erlanger, J., and H. S. Gasser, "Electrical Signs of Nervous Activity," University of Pennsylvania Press, Philadelphia, 1937.*)

"Spike" propagated potential. When the local potential reaches a critical level (the threshold) it increases suddenly, and a "spike" potential is transmitted along the nerve together with the propagated excitatory state. The electrotonic potential and the spike are independent of each other and vary in different ways under the influence of several factors. Thus cold does not change the electrotonic potential, but prolongs the duration of the spike potential. The spike potential is an "all-or-nothing" phenomenon, *i.e.*, its size is not dependent on the strength of the stimulus, but on the condition of the nerve. It is the best sign of a conducted impulse. The voltage is approximately 100 mv.; the ascending phase lasts 1.5 msec. in unmyelinated axons and 0.3 to 0.4 msec. in the most rapid myelinated axons of vertebrates. The descending phase is more prolonged, but it is not easy to mark exactly where it ends, because it overlaps other potentials, known as after-potentials (Fig. 354).

After-potentials. The spike is followed by a *negative after-potential.* It begins during the descending phase of the spike. Its amplitude is only 3 to 5 per cent that of the spike. It lasts approximately 15 msec. in the fastest fibers of mammals and 50 to 80 msec. in slower fibers.

A *positive after-potential* then follows. It is composed of two elements, sometimes called the "first positive" (P_1) and the "second positive" (P_2) after-potentials. The amplitude of this potential is only 0.2 per cent that of the spike in the fastest fibers and 1.5 to 4 per cent in slower fibers. Its duration varies from 40 to 60 msec. in fast fibers to more than 1,000 msec. in slow fibers.
FIG. 355. Action potentials of a C fiber of a frog intoxicated with veratrine. The first spike, which is scarcely visible, corresponds to other fibers of higher conduction velocity. The well-marked spike corresponds to the C fibers. *a*, normal nerve, showing pronounced positive after-potential; *b*, veratrine increases the negative after-potential, which begins to mask the positive after-potential; *c*, at a later stage the negative after-potential is so great that it has completely masked the positive after-potential. (*Erlanger, J., and H. S. Gasser, "Electrical Signs of Nervous Activity," University of Pennsylvania Press, Philadelphia, 1937.*)

After-potentials differ in the different types of fibers and they are considerably modified

by changes in the activity of the fiber or its environment:

1. *Repeated stimulation*, such as that which produces tetanus, increases the positive after-potential (Fig. 354*b* and *c*), which lasts more than 1 min. after stimulation has ceased.
2. *An increase in pH* shortens the duration of both negative and positive after-potentials. It diminishes the size of the negative after-potential and increases that of the positive one. A more marked alkalinization can suppress the negative potential, but it must be considerable to diminish the positive potential.
3. *Shifts in the electrolyte equilibrium* modify the after-potentials. Thus an increase in K^+ and a decrease in Ca^{++} depress the negative potential, and increase and shorten the positive potential. An increase in bivalent cations, or a decrease in monovalent cations, produces the opposite effects on the after-potentials.
4. *Veratrine* produces a great increase in the size and duration of the negative potential (Fig. 355), which can be larger even than the spike. Narcotics, on the contrary, depress the negative after-potential.
5. All the potentials, including the spike and resting polarization potentials, diminish in *asphyxia* and *anoxia* and recover their size when oxygen is restored. Asphyxia has a considerable effect on the after-potentials, which can disappear in anaerobiosis, but they reappear with a size two to three times the normal one when oxygen is again given.

These facts and others to be mentioned below prove that the after-potentials form part of the mechanism of the recovery of excitability. "Spike potentials can be called the messages of the nervous system; the after-potentials indicate the willingness to receive those messages for transmission."[1] All these different potentials overlap and give the composite action potential. Gasser has analyzed this potential and made a diagram of the different potentials which theoretically would give the potential registered (Fig. 356).

FIG. 356. Analysis of the combined action potential of a nerve impulse. (*Erlanger, J., and H. S. Gasser, "Electrical Signs of Nervous Activity," University of Pennsylvania Press, Philadelphia, 1937.*)

EXCITABILITY CYCLE OF THE AXON

The conduction of a nerve impulse modifies the excitability of the axon and its capacity to transmit the excitatory state. These changes can be studied by sending a second impulse at varying intervals after the first conditioning impulse and registering the action potentials, which will show the condition of the fiber.

As soon as a propagated excitatory state has been produced, *i.e.*, from the beginning of the spike, the excitability of the fiber is suppressed. The *absolute refractory period* lasts until the spike is nearly over; a second response is not obtained before the descending limb of the spike has almost reached its foot.

The recovery of excitability takes place not suddenly but gradually. Total inexcitability is followed by a period of depressed excitability.

[1] GASSER, H. L., *Harvey Lect.*, **32**, 169, 1937.

i.e., the *relative refractory period*, during which a strong stimulus produces a second spike of much smaller amplitude conducted at low speed. As the interval between the two stimuli is increased, the threshold diminishes and the voltage of the spike and the speed of conduction increase. The most excitable fibers of mammals have an absolute refractory period of 0.4 msec. and a relative refractory period of 3 msec.; but 1 msec. after the beginning of the spike a second stimulus already produces a spike of 85 to 90 per cent the voltage of the first spike (Fig. 357).

The activity of the axon is discontinuous because of its absolute refractory period. The conduction of nerve impulses should be compared to the action of a machine gun, not to that of a stream of water. The duration of the absolute refractory period puts a limit to the number of impulses that can be transmitted in a given time. Theoretically 2,500 impulses per second could be carried by the most rapid fibers, and almost 1,000 per second with a nearly normal voltage at the normal speed. The fact is that such high frequencies can be kept up only for a very short time. In physiologic conditions motor fibers transmit impulses at rates of 5 to 50 per second, exceptionally at 100 per second. Afferent fibers transmit at rates of 10 to 100 per second, and very exceptionally at higher rates up to 450 per second. There is therefore an ample margin of safety, and impulses of normal voltage are transmitted at the maximum speed at the normal frequencies of discharge of neurons and receptors.

The relative refractory period is followed by a phase of hyperexcitability during which there is a low threshold and a high speed of conduction. Later there is a period of hypoexcitability, with a high threshold and low speed of conduction. Hyperexcitability begins 3 msec. after the commencement of the spike in the most rapid fibers of mammals, reaches its peak in 3 to 10 msec., and is replaced by hypoexcitability in 12 to 18 msec. Hypoexcitability is most marked at 25 to 35 msec. and lasts altogether 60 to 80 msec. Hyperexcitability coincides with the negative after-potential and hypoexcitability with the positive after-potential. Factors that modify the after-potentials also modify the excitability of the axon. Thus veratrine increases and prolongs the negative after-potential; it also accentuates and prolongs the period of hyperexcitability.

In normal conditions, when stimuli are repeated at frequencies of 50 to 300 per second, the impulses are transmitted during the phase of hyperexcitability produced by the preceding stimulus, but repeated stimulation increases the positive after-potential and the phase of hypoexcitability. The importance of this fact is made evident in the following experiment: A nerve is submitted to moderate asphyxia so that the spike is not modified but the negative after-potential is considerably depressed. If it is then stimulated at a frequency that produced a sustained tetanus when the nerve was in normal condition, it will transmit impulses at this frequency for only a very short time.
Fig. 357. Action potentials of phrenic nerve stimulated twice at varying intervals. The height of the second spike indicates the degree of recovery of the fiber, which is almost complete in the topmost record. In the lowest record the second stimulus sent during the absolute refractory period has produced a notch at the foot of the descending limb of the first spike, but no second spike. Time in msec. (*Erlanger, J., and H. S. Gasser, "Electrical Signs of Nervous Activity," University of Pennsylvania Press, Philadelphia, 1937.*)

CONDUCTION OF THE NERVE IMPULSE

The nerve takes an active part in the conduction of the nerve impulse. The stimulus does

not act like the charge of gunpowder that sends off the bullet in a cartridge, but like the spark that lights a train of gunpowder and initiates a combustion transmitted along all its length as the powder is burned up. In other words, it begins a process that is propagated along the nerve. If all the energy of the nerve impulse were originated by the stimulus and the nerve were merely a passive transmitter of this energy, as occurs with sound, the strength of the impulse would diminish as it progressed, and on arrival at its destination, it would be inversely proportional to the length of the path it has traveled. The nerve impulse does not diminish in size as it progresses along the nerve; its energy remains constant. Moreover, if it passes through a region where the properties of the axon have been depressed, its size (as given by the voltage of the spike) and its speed diminish, but on reentering a normal part of the nerve it recovers both size and speed.

Adrian[1] was the first to demonstrate this type of conduction. Later Davis and his collaborators[2] gave conclusive proof of "conduction without decrement." A length of 10 to 12 cm. of the peroneal nerve of the cat can be obtained where there is no branching off and where the nerve thus has a uniform diameter. It is placed in a box, divided into four chambers (Fig. 358). In the first chamber (*A*) the nerve is in contact with stimulating electrodes. In the second chamber (*B*) alcohol vapors are admitted to narcotize the segment of nerve it contains. Three leads (1, 2, and 3) record the action potentials at different distances from the stimulated point. The third chamber, which contains lead 4, separates the second chamber from the fourth, where air circulates and lead 5 records the action potential. Lead 6 is on a crushed portion of the nerve. The nerve can conduct impulses of normal voltage during several hours. At a given moment alcohol vapors are let into *B*, and as narcotization progresses the action potentials at 1, 2, and 3 diminish in the same degree (Fig. 359). The action potential at 5 remains normal; at 4 it may be slightly diminished, because alcohol may leak from *B* to *C*. When narcotization has reduced the action potential in *B* to about 70 per cent of its original size, the potentials at *D* also diminish a little because some of the axons are completely blocked by the alcohol in *B* and can no longer conduct impulses.

Kato and his collaborators[1] demonstrated this same fact in a single axon of a Japanese toad. A stimulus

FIG. 358. Registration of action potentials from different parts of a nerve narcotized with alcohol vapor. *A*, chamber filled with pure air where stimulating electrodes are placed; *B*, chamber filled with alcohol vapor; *C*, chamber preventing leakage of alcohol vapors from *B* to *D*; *D*, chamber filled with pure air; 1 to 6, leadoff electrodes; *G*, string galvanometer. Black segments in nerve indicate where it has been crushed. (*Davis, H., et al., Am. J. Physiol., vol. 76, p. 448, 1926.*)

was sent to a nerve, reduced by dissection to a single axon, and produced a maximal contraction ("all-or-nothing" law). A segment of the nerve was narcotized, and the threshold rose progressively until all conduction was suppressed. Up to that moment maximum responses were obtained. As long as the impulse could pass through the narcotized segment, it recovered its normal strength on arriving at the normal part of the axon.

These experiments can be interpreted in terms of the train of gunpowder. The narcotized segment of the nerve is like a stretch of the train that has been dampened. Combustion and transmission of the spark progress at lower speed, but once the spark reaches the dry powder it will again spread at the previous high rate. If the dampening is excessive the powder will not light and the spark will not be transmitted any further, as when in a nerve the impulses are blocked by a deeply narcotized segment.

A partial or complete block can be provoked in several ways (anesthetics, cold, etc.). A partial block can transmit impulses of low frequency but not at high frequencies because the recovery period is prolonged (Wedensky inhibition). A complete block stops the propagated impulse, but beyond the block Hodgkin has recorded a potential change (the "extrinsic potential"), which is an electrotonic potential provoked by the "spike potential" above the block. When the extrinsic potential rises to approximately 10 per cent of the spike, the impulse "jumps the block"; a spike potential is produced and is propagated along the axon beyond the block.

The nerve impulse is transmitted along the whole length of the axon including its branches at the highest speed possible, according to the "all-or-nothing" law. When an axon is stimulated simultaneously in two different points, the impulses thus started travel toward each other and when they meet cannot progress any farther because of the refractory state each one leaves in its wake.

FIG. 359. Action potentials along a nerve narcotized by alcohol vapors. (*Davis, H., et al., Am. J. Physiol., vol. 76, p. 448, 1926.*)

Saltatory conduction. In muscle fibers and unmyelinated nerve fibers local circuits spread the active state to the adjoining parts of the membrane, and conduction is apparently continuous. Lillie suggested in 1925 that in myelinated fibers excitation and the processes which maintain the propagated action potential take place only at the nodes of Ranvier; the internodes act as a unit, and conduction "jumps" from one node to the next ("saltatory" conduction).

Agents which stimulate or affect conduction, *e.g.*, electrical stimulation, blocking by electric polarization, ions, narcotics, etc., have a stronger effect at the nodes than in the internodal regions. Moreover, larger action potentials can be obtained from the nodes than from the internodal segments.[1] These facts can, how-

[1] ERLANGER, J., and E. A. BLAIR, *Am. J. Physiol.*, **110**, 289, 1934; **124**, 341, 1938; TASAKI, I., *Am. J. Physiol.*, **127**, 211, 1939; TASAKI, I., and T. ever, be interpreted as due to the insulating properties of the myelin sheath which do not obtain at the nodes. Satisfactory evidence of saltatory conduction is now available. If current can enter and leave the axon only at the nodes (the myelin sheath acting as an insulator), the
FIG. 360. Tracings of action-potential records obtained at a series of positions along one nerve fiber; diagram of nerve fiber on the right shows position where record was taken. R_1R_2, etc., nodes of Ranvier. (*Huxley, A. F., and R Stämpfli, J. Physiol., vol. 108, p. 315, 1949.*)

current in the axon at a given moment will be the same at all points of the internode. Huxley and Stämpfli[1] demonstrated this by recording in a single isolated fiber at different points of an internode the current in the external fluid, which is equal and opposite to that in the axis cylinder. Conduction time was found to be almost constant in the internode and to increase stepwise as each node was passed. The amplitude of the action potential diminished as it progressed along the internode and increased stepwise at the node (Fig. 360). The following experiment, in which conduction is blocked by increasing the external resistance, gives a very clear demonstration of the part played by the nodes: A single myelinated fiber is placed so that two adjacent nodes lie in Ringer's fluid but the internodal segment between them is in an air gap. Water evaporates on the surface of the internode, and the external conducting path becomes highly resistant. In these circumstances an impulse is not conducted through the gap, but if the nodal regions are joined by a bridge of Ringer's fluid, the impulse jumps the air gap. In myelinated fibers the local circuits go from one node to the next, the longitudinal current returning along the fluid outside the insulating myelin sheath. This mechanism increases velocity of conduction by making the local circuit act at a considerable distance ahead of the active region. Internodal length is proportional to the diameter of the fiber, and speed of conduction is proportional to fiber diameter. The fastest fibers are the thickest and have the longest internodal length.

An important objection to the theory of saltatory conduction consisted in the statement that there are no nodes in the spinal tracts made up of thick, myelinated, fast-conducting fibers. Many years ago, Cajal[1] had described "strangulations" in the fibers of tracts in the central nervous system, and lately nodes with morphologic characteristics similar to Ranvier's nodes have been described. Dyes enter the fiber at the nodes, and branching takes place only at the nodes. There is a linear relation between the diameter of the fiber and internodal spacing, thicker fibers having greater internodal distances.[2] Tasaki,[3] measuring the threshold in the dorsal tract of the spinal cord of frogs, found that at regular distances of 200 to 400 μ there were sensitive spots, while midway between them the fibers were almost insensible to stimuli four times the strength of the threshold for the sensitive places.

Fatigue. High-frequency stimulation for a sufficiently long time provokes signs of fatigue in nerves: the amplitude (voltage) of the spike potential is reduced, conduction velocity diminishes, and the refractory period is prolonged. Fatigue develops simultaneously along the whole length of the nerve, and recovery takes place at the same rate all along it. Connection with the soma is not necessary for recovery from fatigue caused by high-frequency stimulation. If the blood supply to the nerve remains intact, re-

covery is not greatly impaired following section up to the time when conduction fails owing to the process of degeneration.[1] A certain degree of recovery can take place in conditions of anoxia, but in the absence of oxygen fatigue develops more rapidly.

The mechanism of conduction of the nerve impulse. Local circuits are established by current flowing out from the region at rest into the adjacent depolarized zone. The inactive area is thus depolarized, becomes active, and exerts a similar influence on the neighboring parts of the membrane which are still at rest. The spike potential normally not only is of sufficient strength to produce this effect, but has an ample margin of safety, *i.e.*, it surpasses the threshold. For example, in the giant fiber of the squid conductance begins to increase when the spike is about halfway up the ascending limb (see Fig. 338, Chap. 66); in this case the spike has twice the threshold voltage. An even larger margin of safety (about five times) has been observed by Tasaki and Takeuchi in single-fiber preparations of the frog. If the properties of the nerve are depressed by anesthetics or in any other way, the spike is diminished and the impulse is blocked.

The role of sodium and potassium ion exchange in the genesis of the action potential and the propagated excitatory state, in this case the conduction of the nerve impulse, has been discussed in Chap. 66.

Chemical factors in conduction. Acetylcholine has been attributed an important part in the intracellular spread of excitation, similar to its role of chemical mediator at the synapse and nerve endings in myoneural junctions. This ester has been extracted from all types of nerves in many species, but the concentration differs considerably from one nerve to another. Thus the ventral spinal roots of the cat yield 12 to 22 μg per gm. of fresh weight, and sympathetic cholinergic nerves 18 to 40 μg per gm.; on the other hand, the dorsal roots and sympathetic postganglionic (adrenergic) fibers yield only very small amounts (less than 0.25 μg and 1.5 μg respectively).[2] Cholinesterase (an enzyme that accelerates the hydrolysis of acetylcholine) has also been found in nerves. In the giant axon of the squid it is concentrated near the surface, *i.e.*, in the proximity of the excitable membrane. Here again there are considerable differences in the concentration of the enzyme found in different nerves; thus the ventral roots have twice the cholinesterase activity of the dorsal roots. Another enzyme has been found which catalyzes the synthesis of acetylcholine (choline acetylase).[1] This enzyme also is found in higher concentration in the ventral roots than in the dorsal roots or the optic nerves, which have only 1 to 3 per cent the choline acetylase activity of the motor nerves.

Nachmansohn,[2] on the basis of a large number of facts collected by himself and his coworkers, supposes that acetylcholine is released from an unknown precursor by the flow of current from the inactive regions of the nerve set up by the local circuits provoked by the spike potential. The acetylcholine thus released probably acts on a "receptor protein"; it depolarizes the membrane, and a new local circuit is established. Acetylcholine is immediately destroyed by the action of cholinesterase. It is resynthesized during the recovery period by the action of choline acetylase and combined to an inactive precursor, from which it is released when the nerve is stimulated.

Inactive precursor (AC)

Spike potential: Inactive precursor (AC) → AC

Choline acetylase: A + C → Inactive precursor (AC)

Cholinesterase: AC → A + C
Liberation and inactivation of acetylcholine must take place within a very short time, because nerves can transmit more than 1,000 impulses per second. Nachmansohn and his associates have found that the concentration of cholinesterase is such that inactivation of acetylcholine could be completed in the stipulated interval.

This theory has been vigorously opposed,[3] but several of the most telling arguments against it have been answered.

1. The theory postulates that accumulation of ACh blocks conduction of the nerve impulse. Nerves, however, can be submerged for a long time in isotonic solutions of ACh (protected from hydrolysis by an anticholinesterase) without being blocked. This phenomenon is due to the fact that the nerve membrane is impermeable to ACh. Thus, nerve fibers were submerged in ACh labeled with N^{15}, and no labeled ACh was later found in the extruded axoplasm.[1] Acetylcholine (0.01 to 1 μg) injected into the axoplasm of giant axons of the squid prevents the development of the excitatory state under the stimulating electrode and blocks the conduction of an impulse which has arisen at some other point of the fiber. Inexcitability and block thus produced are reversible phenomena, because acetylcholine diffuses and is diluted in the axoplasm. The same effects are produced by eserine and prostigmine in 1 to 2 sec. after injecting 5 to 10 μg of these cholinesterase inhibitors. Eserine applied externally also blocks the axon, but prostigmine does not because it cannot pass through the membrane. The membrane is also impermeable to D-tubocurarine, which does not block conduction when applied externally but does so when injected into the axoplasm. This substance has only a weak anticholesterine activity, but it is very active on axonal conduction; it has been suggested that curarine probably exerts its effect by substrate competition with ACh for the "receptor protein" in the membrane.[2]
2. Cholinesterase inactivators, such as eserine, DFP, etc., according to Nachmansohn and his associates, block nerve conduction, and there is close parallelism between cholinesterase activity in the nerve and capacity to conduct impulses. This has been denied by several workers who find that cholinesterase can be inactivated in the nerve without blocking it, and that much higher concentrations of DFP and other anticholinesterases are needed to produce nerve block; in this case other enzyme systems are inhibited, *e.g.*, respiratory metabolism is depressed. It seems, however, that a considerable degree of cholinesterase activity (30 to 40 per cent of the normal value) must have remained or been recovered in experiments in which complete inactivation was supposed to have been obtained.[1]

TYPES OF NERVE FIBERS

The action potential of a nerve changes as it is transmitted away from the stimulated point. In the phrenic nerve the height of the spike diminishes and its duration increases, but the surface covered by the spike does not vary; therefore the total electric energy remains constant (Fig. 361). In other nerves, such as the sciatic and the saphenous, there are more complex variations. At a certain distance from the stimulated point, waves appear on the descending limb of the spike, which farther on has two more peaks (Fig. 362). This variation is due to the different speeds of conduction of the individual axons in the nerve. The impulse, therefore, does not arrive at a point some distance from the site of stimulation exactly at the same moment in all the fibers. Dispersion increases as the distance traveled is greater and the speed of conduction more varied.

Erlanger, Gasser, and Bishop,[2] classified the axons into three major groups, A, B, and C, according to the speed of conduction. Group A is made up of five subgroups: α, β, γ, δ, and ε (Fig. 363).

In a dorsal spinal root there are axons with speeds from 0.5 to 100 m. per sec.; the ventral roots have fibers with speeds of 2 to 100 m. per sec. The phrenic nerve is made up exclusively of α fibers and the sciatic of all types of fibers. The saphenous nerve has a large number of unmyelinated, slow-conducting C fibers; section of the corresponding dorsal spinal roots, peripherally to the root ganglion, causes degeneration of 80 to 90 per cent of these fibers, which are therefore afferent in nature. The remaining 10 to 20 per cent are postganglionic sympathetic axons. There are also A fibers in this nerve, of which 54 per cent belong to the α and β types, 11 per cent are γ, 25 per cent are δ, and 10 to 15 per cent are ε.

If an arbitrary value of 100 is given to the

FIG. 361. Action potentials of phrenic nerve. The leads were placed at 14.5, 44, and 85 mm. from the stimulated point. (*Erlanger, J., and H. S. Gasser, "Electrical Signs of Nervous Activity," University of Pennsylvania Press, Philadelphia, 1937.*)

most rapidly conducting fibers, the following values correspond to the fastest fibers in each group: α, 100; β, 60; γ, 40; δ, 25; B, 10; C, 2. In mammals the fastest α fibers conduct at 120 m. per sec. In the bullfrog the following are typical values (in meters per second): α, 41 to
FIG. 362. Action potential of the saphenous nerve of the cat. The record was taken at 6 cm. from the stimulated point. (*Gasser, H. S., Proc. Assoc. Res. Nerv. Ment. Dis., vol. 23, p. 48, 1943.*)

47; β, 22 to 28; γ, 15 to 19; δ, 12 to 13; B, 11 to 17; C, 0.8 to 1.5. In each class there are fibers of different speeds of conduction grouped around an average, but the slowest in each class are not as rapid as the tastest in the lower class. The fibers of the various classes differ from each other in other respects besides the speed of conduction.

Internodal length, speed of conduction, spike potential, excitability, and other properties of the axons are related to their diameter. There is almost a linear relation between velocity and diameter ($V \propto D$), between spike potential and diameter ($P \propto D$), and between spike potential and velocity ($P \propto V$).[1] During fetal and postnatal growth this relation also exists. In the saphenous nerve of the cat the speed of the fastest fibers is 11 m. per sec. 4 days after birth, and 80 to 90 m. per sec. in the adult. Throughout the period of development speed of conduction increases proportionally to the growth in thickness of the fibers. Excitability is also related to fiber diameter and speed of conduction; the threshold increases as the diameter and speed of the fibers diminish. The finest fibers have long chro-

[1] LASSER, H. P., and H. GRUNDFEST, *Am. J. Physiol.*, **127**, 393, 1939; HURSCH, J. B., *Am. J. Physiol.*, **127**, 131 and 140, 1939.

naxies, but there is no simple relation between chronaxie and speed of conduction. Within a group the fastest fibers have the shortest chronaxies; there is an increase in chronaxie on passing from A to B and another from B to C. The refractory period is longer as the diameter diminishes. The period of latent addition (summation time) is 0.2 msec. in all the fibers, except in C fibers, in which it is 2.5 msec.

The action potentials differ in the different groups. All fibers have a spike and after-potentials. The A fibers in mammals have a second positive after-potential only when stimulated repeatedly; in amphibians usually there is no positive after-potential. The B fibers of mammals and C fibers of amphibians have a spike and a positive after-potential, but no negative after-potential.

B fibers are the most susceptible to asphyxia. Of the A fibers the δ and ϵ are the first to be blocked by asphyxia; the last are those of greater diameter. The C fibers are the most resistant to anoxia. Cocaine applied locally anesthetizes C fibers first, and then the myelinated fibers in the same order as asphyxia. Compression first blocks the α fibers, while considerable pressure must be applied to block the finest axons (Table 89).

Fiber type and function. The α fibers are motor fibers of striated muscles and afferent fibers of proprioceptive receptors; somatic movement is therefore served by the fastest fibers. The cutaneous receptors are innervated by fibers in the remaining A subgroups and by C fibers. No group of fibers is exclusively assigned to one type of receptor, nor is a receptor served exclusively by one type of fiber, with the exception of the proprioceptive receptors just mentioned. Tactile impulses are conducted by δ and β fibers. Pain is transmitted by C fibers, and also by myelinated fibers of several diameters. Temperature impulses are conducted by fairly thick myelinated fibers and also by very slender, possibly unmyelinated fibers (see "Conduction of sensory impulses in afferent fibers," Chap. 74). Preganglionic sympathetic fibers belong to group B. Postganglionic fibers are unmyelinated C fibers, except those of the ciliary nerve, which are myelinated and belong to group B.

FIG. 363. Fiber-size spectrum. Map of all the medullated fibers in the ninth dorsal root (above) and in the ninth ventral root (below) of the bullfrog. (*Erlanger, J., and H. S. Gasser, "Electrical Signs of Nervous Activity," University of Pennsylvania Press, Philadelphia, 1937.*)

Fibers in the spinal cord. Myelinated fibers of all sizes and unmyelinated fibers have been found in the white tracts of the spinal cord.

Propriospinal fibers, i.e., those which arise and end within the spinal cord, have been studied after cutting the cord above and below a certain

segment, so that all ascending and descending fibers arising in the spinal ganglia or higher nerve centers degenerate.[1] There are large numbers of these fibers, which are myelinated and of all sizes. In the dorsal columns small fibers, 1 μ in diameter, predominate, but in the ventrolateral columns there are many large α fibers.

Ascending fibers are also of varied sizes. The spinothalamic tracts are made up mainly of fine fibers; most of the fibers in the dorsal ascending tracts are of intermediate size and conduction velocity (70 m. per sec.). The spinocerebellar tracts are formed by thick fast-conducting (120 m. per sec.) fibers.

Descending fibers come from the frontal cortex (pyramidal tract) and from subcortical nuclei, *e.g.*, the rubrospinal, vestibulospinal, and reticulospinal tracts. The pyramidal tract is made up of fibers of many sizes; in man and the apes the largest fibers have the highest conduction velocity (α fibers), but in other animals (*e.g.* the cat) the fastest pyramidal fibers conduct at about 65 m. per sec. Rubrospinal and vestibulospinal fibers are large α fibers. The refractory period, the ratio of diameter to velocity, and other properties are similar to those of peripheral fibers.[2]

THE METABOLISM OF NERVE

The structural and functional integrity of nerves is dependent on metabolic processes. A nerve separated from the organism and deprived of oxygen can, however, conduct impulses for a relatively long time. In these conditions the nerve is gradually depolarized and the membrane potential declines.[1] Activity, *i.e.*, the conduction of impulses, accelerates the process of disintegration. If the period of anoxia is not excessively prolonged, when oxygen is again available the nerve is repolarized and the membrane potential is restored. Inhibitors of respiratory metabolism, *e.g.*, cyanide, have the same effect as anoxia.

Heat production. The resting nerve of the frog at 20°C. has a heat output of 4.14×10^{-3} cal. per gm. per min., *i.e.*, 70 μcal. per gm. per sec.; an amount approximately the same as that of the resting muscle.[2] In a nitrogen atmosphere heat production diminishes gradually in the course of 3 to 4 hr. to 25 per cent of normal and remains at this level for a long time. When the nerve is again placed in oxygen, heat production increases to above the resting level; the excess heat produced is equivalent to 15 or 20 per cent of the amount that would have been put out during the period of anaerobiosis if oxygen had

[1] GERARD, R. W., *Am. J. Physiol.*, **92**, 448, 1932.
[2] BERESINA, M., *J. Physiol.*, **76**, 170, 1932.

been available. The nerve can therefore accumulate an oxygen debt, but the greater part of the energy exchanges that take place in anaerobiosis are not performed at the expense of this debt.

Oxygen consumption. The resting nerve takes up oxygen in amounts corresponding to the heat produced. Oxygen consumption varies consider .ɔly in different species and under different conditions (Table 90).

Table 90. Oxygen Consumption of Isolated Nerves

Amphibians have a seasonal variation, with greater oxygen consumption in times of activity (spring and summer) than in those of quiescence (hibernation). Cold diminishes heat production, and when this has fallen to 20 per cent of the normal figure, impulses are no longer conducted. Decalcifying agents (citrates) and thyroid feeding increase heat production. The Q_{10} (15 to 25°C.) is 2.2 in the frog. The RQ varies from 0.77 to 0.80.

CO_2 output. During anoxia there is a continuous output of CO_2, which is due not simply to the accumulation of acid metabolites, but to its production by oxidation of carbon. During the first 2 hr. of anoxia, CO_2 output diminishes to 50 per cent of the amount produced in aerobiosis and then drops to 10 per cent. The excess oxygen taken up during the recovery after anaerobiosis is more than can be accounted for by the CO_2 output. There seems to be an "oxygen reserve" that releases oxygen in anaerobiosis and is restored during aerobic recovery.

Metabolic changes accompanying activity. The heat production of the nerve is greater when it conducts impulses than when it is at rest.[1] At the beginning of stimulation there is a rapid increase. The methods now in use permit the detection of this increase only after many
Fig. 364. Heat production of frog's nerve. The preparation was kept in oxygen during and after an almost maximal stimulus lasting 12 sec. (heavy black line). (*Hill, A. V., "Chemical Wave Transmission in Nerve," Cambridge University Press, 1932.*)

impulses have traveled down the nerve. It is not possible to say whether this excess heat is produced by the activity of the fiber or by its recovery. When stimulation ceases heat production rapidly diminishes, but during the first 20 sec. it is still considerably above the resting level; it remains above this level for 30 to 40 min. (Fig. 364).

The following phases can be distinguished in the excess heat produced by activity: (*a*) *initial heat,* produced while the nerve is conducting impulses; (*b*) *delayed heat,* produced at a high rate for a short time after stimulation has ceased, and then at a low rate for a long time.[2] The velocity of production of initial heat is 5,000 times the velocity of production of delayed heat, but as the first lasts only a short time it represents a very small part of the total excess heat. Initial heat is 3 to 4 per cent of the total heat if the stimulus lasts only a short time; *e.g.,* with 280 stimuli per second at 15°C. it is 10.5 per cent, and at 24°C. it is 8.8 per cent. When stimulation is prolonged, initial heat may be

[1] Downing, A. C., R. W. Gerard, and A. V. Hill, *Proc. Roy. Soc., London, s.B.,* **100,** 223, 1926.

[2] Hill, A. V., *Proc. Roy. Soc., London, s.B.,* **111,** 106, 1932; **113,** 345, 1933.

15 per cent of the total, because there is relatively less delayed heat.

As the frequency of stimulation increases, the heat production also increases, but only up to a certain level. The effect of an impulse is added to the effects of the preceding impulses, but the size of each impulse diminishes as the frequency increases, thus compensating the increase in number of the stimuli (Fig. 365). When the frequency is below 50 per second a steady state can be kept up indefinitely; with higher frequencies heat production gradually falls off after having reached its peak. The intervals between the impulses in this case are not long enough to allow a sufficiently complete recovery to maintain a constant heat production. The total electrical energy increases with the frequency, but the action potential of each impulse is smaller, because of incomplete recovery during the abbreviated interval. The total excess heat production due to the activity is 50 to 100 per cent that at rest; in muscle contraction the excess heat is several hundred times the resting heat production.

Oxygen consumption increases in the active nerve in relation to heat production. The excess O_2 consumption is kept up for a long time after stimulation has ceased.

In anoxia heat production by the active nerve diminishes gradually until it disappears completely. As long as heat is produced the relation between initial and delayed heat is normal, but sometimes there is relatively more delayed heat. Nerve differs from muscle in this respect because anoxia reduces considerably the delayed heat of muscle. The CO_2 output continues, as occurs in the resting nerve kept in anaerobiosis, but the oxygen debt can be greater. The asphyxiated nerve recovers its properties in oxygen and also on the addition of a H acceptor, such as *m*-dinitrobenzene.

Metabolic processes in nerve fibers. The chemical processes in nerve are similar to those of muscle. There are the same enzyme mechanisms of oxidation-reduction; several dehydrogenases and the cytochrome–cytochrome oxydase system have been found. Adenosinetriphosphatase has been found in giant axons of squids; in the sheath there is 100 times the ATP-ase activity of the axoplasm.

The isolated nerve has free glucose, which diminishes gradually and disappears in the course of several hours in the resting condition; oxygen consumption is not related to this consumption of glucose. Glycogen, hexosephosphate, and lactic acid do not show considerable changes during rest. The stimulated nerve consumes glucose at the same rate as the nerve at rest. In anoxia lactic acid accumulates in amounts equivalent to the glucose that has disappeared; on adding glucose, more lactic acid is formed. In aerobic recovery glycogen is not resynthesized, nor is lactic acid oxidized; therefore, although glycolysis occurs in the nerve, the Pasteur-Meyerhof cycle does not take place.
Fig. 365. Relation between total heat per second (solid line) or total action current (broken line) and frequency of stimulation. (*Gerard, Hill, and Zotterman.*)

Phosphocreatine is disintegrated during rest in anaerobiosis, with a consequent increase in phosphate; at first this takes place at a fast rate, and later more slowly. Phosphocreatine is resynthesized during aerobic recovery. Inhibition of glycolysis by monoiodacetate accelerates phosphocreatine disintegration; but an increase in glycolysis does not spare phosphocreatine. In a stimulated nerve these same processes take place at a faster rate.

The resting nerve sets free ammonia both in aerobiosis and in anaerobiosis, and stimulation doubles its production. Deamination of oxidized proteins might be the source of NH_3, but this is doubtful, because it is still produced in anaerobiosis when oxidation of protein by the oxygen reserve has ceased. Another probable source is the disintegration of adenylpyrophosphate, which occurs in nerve.

The significance of the acetylcholine cycle has already been considered.

Relatively large amounts of thiamine have been found in myelinated nerves. There is a progressive decrease of this vitamin as degeneration progresses after a nerve has been cut. Deficiency of thiamine causes degenerative

processes in peripheral nerves and in the white tracts of the spinal cord. Vitamin C (ascorbic acid) has also been found in nerves, but its significance is as yet unknown.

The trophic influence of the perikaryon is probably a metabolic one, *i.e.*, it is implemented by chemical reactions. An axon separated from its cell body does not suffer from dystrophia due to inactivity, because stimulation does not delay degeneration but accelerates it, probably by speeding up the consumption of substances normally supplied by the perikaryon. A nerve can be compressed during several weeks without provoking degeneration, although all impulses are blocked. Normal conduction is reestablished in 1 to 2 hr. after compression has ceased.

The facts known about the metabolism of nerve at rest and during activity cannot yet be coordinated into a consistent theory explaining the metabolic and energy processes responsible for the maintenance of the specific properties and function of the nerve fiber, *i.e.*, excitability and conduction of impulses.

CHAPTER 69

Conduction in the Nerve Center

THE ELEMENTARY REFLEX

Transmission of excitation from one neuron to another is conditioned by two processes, the *central excitatory state* and the *central inhibitory state*,[1] which interact to coordinate the response of effectors to stimuli applied on the receptors. Conduction of an impulse along a neuron is to a certain extent an automatic process, because once the threshold for the propagated excitatory state has been attained, the whole neuron is excited. New possibilities arise in the synapse: excitation can be transmitted to a large number of neurons or to only a few; resting neurons can be excited, or the activity of those in a state of excitation can be suppressed. Synaptic transmission is, therefore, of fundamental importance in nervous activity, and the reflex is the primary act of integration, the functional unit of the nervous system, because in every reflex at least one synapse is involved.

The reflex arc. The structural base of the reflex is the reflex arc, made up of (*a*) the *receptor*, an organ that receives, and is excited by, the stimulus; (*b*) the *afferent neuron*, which transmits the excitatory state to the center; (*c*) the *synapse;* (*d*) the *efferent* or *motor neuron*, which transmits the excitation to the periphery, or responds by ceasing to discharge impulses, if the afferent volley is of an inhibitory, instead of an excitatory, nature; (*e*) the *effector*, in which the nerve impulse evokes a response adapted to the stimulus (Fig. 318).

The *two-neuron reflex arc*, with only one synapse, was first described by Cajal, who showed that some of the dorsal-root fibers end directly on the motor cells of the ventral horn; many of these fibers are collaterals of fibers in the dorsal column. Dorsal-root section and subsequent observation of the degenerating synaptic terminals (knobs, *boutons*, or end-feet) have given further proof of the existence of these two-neuron arcs. Lloyd's[1] work on conduction and synaptic transmission of stretch reflexes (monosynaptic reflexes) has confirmed the conclusions of the histologists. There are relatively few two-neuron arcs; in the lumbar segments of the cat, less than 10 per cent of the afferent fibers end directly on a motor neuron. These are α fibers of low threshold and high speed of conduction. They innervate receptors situated in the muscle and end on spinal motor neurons, which discharge impulses provoking a myotatic or stretch reflex in the muscle in which the receptor is located.

The great majority of reflex arcs, including those of all the cutaneous reflexes, are *multineuron reflex arcs*, having one or more *connector* or *internuncial neurons* between the afferent and efferent neurons.

The reflex arc described as a chain of neurons is a useful abstraction, but it does not really exist. An afferent neuron innervates more than one receptor and makes connections with more than one motor or internuncial neuron, and the latter receive endings from more than one centripetal or internuncial neuron. Thus when a single receptor is stimulated many neurons may enter into activity and provoke the response of several effectors. This is known as the *principle of divergence*. On the other hand, stimulation of different receptors may provoke a response through the same motor neuron which acts as a final common path. This is known as the *principle of convergence*.

Stimulation of a receptor or of an afferent

[1] Sherrington introduced the term *central excitatory state* (c.e.s.) to describe the enduring excitatory condition set up by a centripetal volley, without reference to its precise nature. The *central inhibitory state* (c.i.s.) is an enduring effect produced by a centripetal volley antagonistic to the c.e.s.

[1] LLOYD, D. P. C., *J. Neurophysiol.*, **6**, 316, 1943.

nerve does not produce contraction or relaxation in a single muscle, but in a group of muscles, which act synergically to produce a movement. The nervous system of higher animals is not organized in anatomical segments but in movement patterns and in visceral reactions. "The simplest spinal reflex 'thinks,' so to say, in movements, not in muscles" (Jackson).[1]

Fig. 366. Receptive field of the scratch reflex in the spinal dog. The figures give the relative strength of the threshold stimulus in different parts of the field. *lr*, last rib. (*Sherrington, C. S.*, "*The Integrative Action of the Nervous System,*" *Yale University Press, New Haven, 1926, p. 221.*)

Elementary reflexes. All vertebrates show certain typical reflexes, which consist in stereotyped responses to specific stimuli applied to definite receptive fields. One group of reflexes produces movement of the whole or part of the body; they are called *phasic reflexes*. An important group of these are defensive reactions, the object of which is to remove the nocuous stimulus or withdraw the body from its influence. The simplest is the *flexion reflex*, *i.e.*, flexion of the limb on which the painful stimulus acts. Another group of reflexes serves to maintain the equilibrium of the body and its posture; these are the *postural reflexes*. The simplest of these is Sherrington's *stretch*, or *myotatic*, *reflex*, which consists in the localized contraction of a muscle in response to stretching. If there is an excessive pull, the shortening ceases and is replaced by a lengthening of the muscle; this *lengthening reaction* is also of reflex origin but is produced by central inhibition, not by excitation. The *extensor thrust* is also a postural reflex; it consists in a sharp and brief extension of the limb on the application of pressure to the plantar surface, or on stretching the foot muscles by separating the toes, as occurs when the weight of the body is placed on a foot. This reflex is not restricted to one muscle or to part of a muscle, as in the case of the stretch reflex, but involves all the extensors; it forms part of Magnus's positive supporting reaction (see "Postural reflexes," Chap. 81). If the stimulus is such that it causes pain, the response is a flexion reflex instead of an extensor thrust.

These reflexes have the afferent and efferent limbs of the arc in the same spinal segment; they are *segmental*, or *short*, *reflexes*. In others, the neurons of the arc occupy several segments; they are *intersegmental*, or *long*, *reflexes*. The scratch reflex observed in the dog is an example of this last type of reflex. It consists in rhythmic alternate flexion and extension of the hind limb when a stimulus is applied to a saddle-shaped area of the skin extending from between the shoulders to the sacral region (Fig. 366).

Recent work tends to show a fundamental similarity between the processes of intraneuronal and synaptic transmission, but conduction in the reflex arc differs in many respects from conduction in the nerve. The main characteristics of conduction in the reflex arc will now be discussed.

THE LAW OF FORWARD DIRECTION OF CONDUCTION

When a nerve fiber is stimulated, at whatever point the stimulus acts, the propagated excita-

[1] Quoted by Sherrington, C. S., *Brain*, **54**, 1, 1931.

tory state spreads in both directions and the whole neuron is excited. On the other hand, transmission of excitation through a synapse takes place in only one direction and always in the same sense, *i.e.*, from the axon endings of one neuron to the dendrites or perikaryon (the soma) of the neuron with which these endings connect. This fundamental difference between intraneuronal and interneuronal conduction has been called by Sherrington the "law of forward direction of conduction." Irreciprocal conduction at the synapse is one of the most important physiologic foundations of the neuron doctrine.[1]

Bell-Magendie law. Bell (1811) observed that mechanical stimulation of the ventral spinal roots provoked muscular contraction, an effect that did not follow stimulation of the dorsal roots. A short time afterward (1822), Magendie demonstrated that section of the dorsal roots suppressed sensibility but not motility in the corresponding segments, and he confirmed Bell's finding that stimulation of the ventral root has motor effects. This fact is now known as the Bell-Magendie law. The ventral roots do not carry centripetal impulses; an experimental antidromic[2] stimulus is not transmitted to the dorsal roots or to the spinal tracts. On the other hand, antidromic conduction, *i.e.*, transmission of centrifugal impulses, has been demonstrated in the dorsal roots.

Antidromic conduction. The following are some of the most important facts demonstrating antidromic conduction in the dorsal roots:

1. Stimulation of the peripheral end of a cut dorsal root or of a cutaneous nerve provokes vasodilatation, called by Bayliss "antidromic vasodilatation." The phenomenon has been observed in the cat's paw, rabbit's ear, etc., and in man (Foerster).
2. Stimulation of the central end of the cut vagus nerve produces reflex hypotension, which persists after removal of the sympathetic, *i.e.*, of vasomotor nerves (Bayliss).
3. Mustard oil, or any other irritating substance, when applied on the skin, provokes vasodilatation and other symptoms of inflammation. This effect is suppressed by anesthetizing the skin with cocaine, or by cutting the dorsal roots peripherally to the ganglion, or by denervation of the skin, after the nerves have degenerated, but not before (Bruce).
4. Toennies[1] has registered (by means of a cathode-ray oscillograph) impulses traveling in the dorsal roots after stimulation of a cutaneous nerve (the internal saphenous) in the cat. A flexion reflex is provoked and at the same time there is a centrifugal discharge of impulses in the ipsilateral and contralateral dorsal roots. About one-third of the α fibers and some δ fibers are involved in this activity, which has all the characteristics of a reflex discharge.[2] The central reflex time is 3.5 to 4.5 msec. in the ipsilateral and 4.2 to 6.5 msec. in the contralateral fibers. Summation, facilitation, afterdischarge, and inhibition are observed. Asphyxia quickly suppresses the reflex and antidromic discharges.

The neurons that conduct these antidromic impulses have not yet been identified. There are two possibilities: (*a*) impulses are conducted antidromically by the sensory ganglionic neurons; (*b*) impulses are conducted by spinal neurons, which send out their axons in the dorsal roots to the periphery, or to the spinal ganglion, where they connect synaptically with the sensory neurons. Section of the dorsal root between the ganglion and the spinal cord does not produce degeneration in all the fibers of the proximal end (the end near the cord); 12 to 15 days after the operation intact fibers are found, even when the ganglion has been removed. Some doubt has been cast on the significance of this observation by the facts that the dorsal roots send out collaterals to the neighboring roots and that there are recurrent fibers of the ventral roots that join the dorsal roots; the undegenerated fibers found after section of a dorsal root could belong to either of these groups. No synapses have been found in the spinal ganglia, and there is a 1 : 1 proportion between the cells in a ganglion and the fibers it sends to the spinal cord. It is therefore difficult to admit that there are any fibers in the root other than those coming from the sensory ganglion cells.

Bruce's experiments, just referred to, and those of Lewis on the "triple response" of the blood vessels of the skin following trauma have suggested the "axonic reflex" hypothesis. According to this hypothesis, an

[1] Reverse or antidromic conduction will be discussed later.

[2] Stimulation of a ventral root causes an excitatory state propagated to the periphery, where it produces motor effects, and toward the spinal motor centers, *i.e.*, in a direction opposite (antidromic) to that of physiologic impulses.

[1] Toennies, J. F., *J. Neurophysiol.*, **1**, 378, 1938; **2**, 515, 1938.

[2] The following discussion will be understood better after reading the rest of the chapter, in which the characteristics of a reflex discharge are considered.

axon branches out at the periphery and innervates the skin and the blood vessels. A stimulus applied to the cutaneous branch or to the nerve trunk spreads throughout the neuron and therefore to the vascular branch, thus producing vasodilatation. This is not a true reflex—there is no *interneuronal* conduction—but a pseudoreflex produced by *intraneuronal* spread of excitation. The long latency (several seconds) and duration (several minutes) of antidromic vasodilatation suggested that a chemical mediator released at the nerve endings was responsible for this phenomenon.[1] Acetylcholine (Wybauw), histamine (Kwiatkowski), and an unknown substance, perhaps identical with the central synaptic transmitter,[2] have been considered as the chemical mediator. Experiments made on antidromic vasodilatation in the denervated rabbit's ear have shown that vasodilatation provoked by acetylcholine is suppressed by atropine and potentiated by eserine, but that atropine has no influence on antidromic vasodilatation and eserine diminishes it. Small doses of histamine produce vasodilatation, which is suppressed together with other effects of histamine by antihistamine drugs, such as mepyramine, which have no effect on antidromic vasodilatation. Acetylcholine or histamine cannot therefore act as mediators of antidromic vasodilatation in this case.[3] In others, however, histamine is released by antidromic impulses. Thus, antidromic stimulation of the dorsal roots corresponding to the hind limb in dogs provokes vasodilatation in the skin which is suppressed by antihistaminics (mepyramine, antistine, pyribenzamine).[4]

Fibers conducting Toennies' antidromic impulses are not recurrent collaterals of neighboring roots, because no peripheral degeneration was seen after cutting the rootlets in which they had been registered. A large number of neurons are involved in this phenomenon. Also Toennies has shown that afferent impulses, such as are produced by lightly tapping the skin, diminish considerably when they are preceded by an antidromic discharge. These facts suggest that the same neurons take part in afferent and antidromic conduction. Antidromic discharges may be due to interaction between neighboring fibers in the dorsal spinal tracts[5] facilitated by the abnormal condition of the cord produced by experimental conditions. Interaction between peripheral myelinic fibers made hyperexcitable has been observed,[1] also in the recently cut and cooled spinal cord.[2]

There is as yet no completely satisfactory explanation of "antidromic" conduction in the dorsal roots.

[5] BARRON, D. H., *J. Neurophysiol.*, **3**, 403, 1940.

THE LATENT PERIOD

There is a certain delay between stimulation of a receptor or an afferent nerve and the reflex motor response. This delay is called the "latent period" of the reflex. It is due to the time taken for the impulse to travel from the receptor, or the point on the afferent fiber which has been stimulated, to the nerve center, for activation of the center, transmission along the motor fiber, and finally activation of the effector. The time left after deducting peripheral conduction times of the afferent and efferent paths is known as the *central reflex time.*

Eccles and Sherrington[3] have measured the central reflex time of the flexion reflex (Table 91).

Table 91. Latent Period of the Flexion Reflex

	Msec.
Afferent nerve, conduction time, 13.8 cm. at 31.6 m. per sec	4.4
Efferent nerve, conduction time, 19.5 cm. at 93 m. per sec	2.1
Total peripheral conduction time	6.5
Total latent period	10.4
Central reflex time	3.9

In the spinal cat it was usually 3 to 5.5 msec., for a reflex provoked by a single stimulus. The latent period was usually shorter after a strong stimulus than after a weak one. This difference was due exclusively to reduction of the central reflex time, because the conduction of the impulses along the nerve fibers is an "all-or-nothing" phenomenon. When two successive stimuli were sent at an optimum interval, the central reflex time was reduced to 0.5 msec. The central reflex time is the sum of the *central conduction time, i.e.*, the time taken by the impulse to travel along the fibers in the nerve center, and the *synaptic delay*, the time spent in transmitting the excitatory state from one neuron to another.

[1] ROSENBLUETH, A., *Am. J. Physiol.*, **132**, 119, 1941.

[2] RENSHAW, B., and P. S. THERMAN, *Am. J. Physiol.*, **133**, 96, 1941.

[3] ECCLES, J. C., and C. S. SHERRINGTON, *Proc. Royal Soc., London, s.B.*, **107**, 511, 1931.

Synaptic delay. Lorente de Nó[1] has measured the synaptic delay in the motor nucleus of the third cranial nerve. He stimulated the motor neurons directly by means of a fine electrode introduced into the gray substance of the nucleus and the presynaptic fibers in the longitudinal bundle (Fig. 367). The maximum delay was found to be 0.8 to 0.9 msec., but under certain conditions it could be reduced to 0.5 to 0.6 msec. Renshaw[2] has measured this delay in the motor nuclei of the spinal cord, using a fine electrode placed in the ventral horns and recording the action potentials in the ventral root. A single stimulus of sufficient strength produces two spikes in the action potential. The first spike is due to the discharge of the motor neurons stimulated directly; the second is less synchronized and is due to stimulation of the motor neurons through the internuncial neurons. The interval between the spikes varies from 0.6 to 1 msec., but can be reduced to 0.1 to 0.3 msec. by increasing the strength of the stimulus or sending two stimuli separated by an adequate interval. The synaptic delay in other neurons has also been found to be 0.5 to 1 msec.

The synaptic delay in sympathetic ganglia is much greater than in the central nervous system. Stimulation of preganglionic fibers to the superior cervical ganglion provokes discharges from the ganglion cells after a synaptic delay of about 2 msec. when the fibers stimulated belong to the Aδ group, which end on large neurons, and of about 5 msec. when they are finer fibers of the B group, which end on medium-sized neurons.

[1] LORENTE DE NÓ, R., *Am. J. Physiol.*, **111**, 272, 1935.
[2] RENSHAW, B., *J. Neurophysiol.*, **3**, 373, 1940.

The so-called "synaptic delay" includes the conduction time along the fine terminal branches of the axons. This conduction time must amount to something, because the branches do not follow a straight line in their course, and it is well known that conduction velocity is low in slender fibers. The synaptic delay, in a strict sense, must therefore be even shorter than the times given.
FIG. 367. Diagram of Lorente de Nó's experiment for determination of synaptic delay. *O.N.*, motor nucleus of the third nerve; *COL*, colliculi; *MED*, medulla oblongata; *P*, pons; III *N.*, oculomotor nerve; IV*v*, fourth ventricle; *C1*, *C2*, *M*, and *F*, stimulating electrodes; *f*, fibers of longitudinal bundle; 1, motor neuron of the oculomotor nerve; 2, 3, 4, and 5, internuncial neurons. (*Lorente de Nó, R., Am. J. Physiol., vol. 111, p. 272, 1935.*)

Lloyd[1] distinguishes the *synaptic delay* from the *nuclear delay*. The latter consists in the interval between the arrival at the synapse of the *first* presynaptic impulse and the beginning of postsynaptic activity. Synaptic delay is the interval between the arrival at the synapse of the *last* presynaptic impulse necessary to provoke transmission and the beginning of postsynaptic activity. When all the impulses arrive almost simultaneously, as occurs in the nucleus of the third cranial nerve in the conditions of Lorente de Nó's experiment, nuclear and synaptic delays have approximately the same duration, and the synaptic delay is fairly constant. On the other hand, when the impulses arrive asynchronously, dispersed in time owing to the different speeds of conduction and different lengths of the presynaptic paths, as occurs in spinal reflexes, the nuclear delay is much greater than the synaptic

[1] LLOYD, D. P. C., *Physiol. Rev.*, **24**, 1, 1944.

delay. The distinction between nuclear and synaptic delays is important, because in most cases neurons are excited by a barrage of asynchronous impulses from internuncial neurons. In the interval between the first and last impulses that arrive at the surface of the neuron, the central excitatory state is built up.

Fig. 368. Diagram of motor neuron pool. Only two afferent fibers, *A* and *B*, have been drawn. In *a*, impulses traveling along *A* stimulate motor neurons α and β; those along *B* stimulate motor neurons β and γ. On simultaneous excitation of *A* and *B*, the β neurons are occluded. The subliminal fringe has been eliminated so as not to complicate the figure. In *b*, impulses from *A* stimulate motor neurons α above the threshold, so that they discharge impulses, and motor neurons β subliminally; impulses from *B* stimulate motor neurous γ which discharge, and motor neurons β subliminally. On simultaneous stimulation of *A* and *B* the subliminal c.e.s. provoked in the β neurons summates and these also discharge. (*After Sherrington, C. S., Proc. Roy. Soc., London, s.B., vol. 105, p. 332, 1929.*)

THE PRINCIPLE OF CONVERGENCE. THE FINAL COMMON PATH

Afferent fibers are more numerous than efferent fibers. Thus in the cat the average number of all the fibers in the dorsal roots of one side is 535,000, and that of the ventral fibers is 115,000; the proportion of ventral to dorsal fibers is 1:4.65.[1] Similar figures have been observed in other species. The predominance of sensory fibers is even more marked in the cranial nerves, owing to the great cephalic receptors of vision, hearing, taste, and smell. All sensory fibers can provoke reflexes; therefore several of them must *converge* to the same motor center. The anatomic structure of the neuron, with many synapses on the soma and only one axon to discharge the impulses, makes for convergence.

Many physiologic facts concur with these structural features to prove that impulses conducted by different sensory neurons converge to a *final common path*. The reflex contraction of a muscle, *e.g.*, the tibialis anticus, can be obtained as part of the flexion reflex, by stimulation of several afferent nerves (Table 92). The maximum reflex tension obtained in each case is less than the maximum tension obtained by tetanic stimulation of the motor nerves. No afferent path stimulates maximally all the neurons innervating the muscle; the center is distributed, or fractionated, among several sensory paths. On the other hand, the sum of all the reflex tensions gives a much higher figure than the maximal tension obtained by a motor tetanus. Therefore each motor unit must respond to more than one afferent neuron.

Occlusion. The principle of convergence is also demonstrated by the phenomenon known as "occlusion." Simultaneous stimulation of two afferent nerves, concurring in a reflex, produces a smaller reflex tension than the sum of the tensions obtained by the separate stimulation

[1] Duncan, D., and L. L. Keper, *J. Comp. Neurol.*, **64**, 303, 1936; **68**, 479, 1938; Holmes, F. W., and H. A. Dewenport, *J. Comp. Neurol.*, **73**, 1, 1940.

of each nerve. For example, simultaneous stimulation of both plantar nerves provokes a reflex tension of 1.81 kg. in the tibialis anticus; if each is stimulated separately, reflex tensions developed are 1.57 and 1.58 kg. respectively; the difference between the sum of these tensions

Table 92. Fractionation of the Motor Center; Occlusion (Tibialis anticus. Maximum motor tension 2,160 gm.)

Afferent nerve stimulated	*Tension of maximal reflex tetanus, gm.*	*Reflex tension expressed as percentage of maximal motor tetanus*

Source: Creed *et al.*

(1.58 + 1.57 = 3.15) and that obtained by simultaneous stimulation (3.15 − 1.81 = 1.34) gives the amount of occlusion. The "occluded" neurons respond maximally to both afferent nerves; occlusion is due to overlap of the areas in the motor center stimulated by the afferent neurons (Fig. 368*a*). Occlusion is conditioned by (*a*) the structural organization of the nerve centers, *i.e.*, the anatomic proximity of the afferent path endings; (*b*) physiologic factors, such as frequency of stimulation (occlusion increases with frequency of stimulation), fatigue, spinal shock, and anesthetics, which reduce the spread of excitation and therefore diminish occlusion.

SUMMATION AND FACILITATION

The central excitatory state produced by a centripetal volley resembles the local excitatory state produced by a stimulus applied to a nerve or muscle fiber: (*a*) it takes some time to develop and decays following an exponential curve; (*b*) it spreads decrementally from the locus of excitation; (*c*) if it covers a sufficient area and attains a critical level (the threshold), a propagated impulse is fired off, which is transmitted over the whole postsynaptic neuron and is followed by a refractory state. For this threshold to be attained it is necessary that several synaptic endings, placed near each other on the cell surface, should discharge within a very short time (see "Synaptic transmission," below). The latent period, extension, and intensity of the c.e.s. are dependent on the strength of the afferent volley. If a weak volley, which produces only subliminal excitation, is repeated, a reflex response may be evoked; the effects of the second volley are added to those of the first, and the passage of the impulse provoked by the second stimulus is facilitated. This is known as *temporal summation.* Lorente de Nó's work on the oculomotor nucleus has deprived this type of summation of all importance in the building up of c.e.s. at an individual synapse (see further on). If two weak volleys converge to the same neuron pool along different paths, there may be summation of the subliminal c.e.s. elicited by each one of them, and a reflex response will be observed. This is known as *spatial summation.*

Subliminal fringes. A strong afferent volley impinging on a motor neuron pool stimulates a few of the motor neurons maximally and others submaximally. The active neurons are surrounded by others excited subliminally, which form a "subliminal fringe" around the "discharging zone" (Fig. 368*b*). Neurons situated at a greater distance are not affected by the afferent volley and remain quiescent (Fig. 369). If the strength of the stimulus is increased, a larger number of fibers in the afferent nerve are excited, the area of c.e.s. is enlarged, quiescent neurons are "recruited" into the subliminal fringe, and neurons from the subliminal fringe enter into the discharging zone. Lloyd[1] has shown that the afferent volley must attain considerable size before the motor neurons pass from the subliminal fringe to the discharging zone. Further progressive increase in the strength of the afferent volley causes a rapid increase in the discharging zone ands ubliminal fringe, and a linear relation is established between the two.

When an afferent nerve is stimulated, both types of summation (temporal and spatial) may occur, because the nerve is made up of many fibers with different conduction velocities, which

[1] Lloyd, D. P. C., *J. Neurophysiol.*, **6**, 111, 1943.

converge to a neuron pool by paths of different length.

Spatial summation. (Fig. 368*b*.) For spatial summation to occur, the convergent volleys must impinge on the neuron pool simultaneously or with only a short interval between them. If
FIG. 369. Diagram of activation of a motor neuron pool. (*Creed et al., "Reflex Activity of the Spinal Cord," Oxford University Press, New ork, 1942, p. 122.*)

the interval is progressively increased, the reflex response diminishes and will eventually disappear if it is the result of summation in a subliminal fringe (Fig. 370). The nucleus of the third cranial nerve is particularly suitable for demonstration of the phenomena of summation.[1] The motor neurons can be stimulated directly or through the longitudinal bundle (Fig. 367), and synchronized volleys can be sent with little or no temporal dispersion. Two volleys sent by different paths produce a maximum effect when they are simultaneous; the effect diminishes as the interval between the volleys increases, and there is no summation when the interval is 0.5 msec. or more. In sympathetic ganglia spatial summation has been demonstrated by stimulation of convergent preganglionic fibers. In this case also, the convergent volleys must arrive at the ganglion simultaneously or with a minimum interval for summation to occur.

Temporal summation. This type of summation consists in the accumulation of the effects of successive impulses which arrive at a neuron along the same afferent fiber. Lorente de Nó has examined the possibilities of temporal summation in the nucleus of the third cranial nerve. The summation interval for successive stimuli applied directly to the neurons was from 0.1 to 0.2 msec., equivalent to the absolute refractory period of the afferent fiber. Therefore temporal summation at an individual synapse does not play a part in building up c.e.s.

In sympathetic ganglia, conditions differ. A period of hyperexcitability follows the refractory state of the ganglionic neuron; therefore a second subliminal volley that arrives at the synapse during this period of supernormality may provoke a response, *i.e.*, the first volley has facilitated the effect of the second.

The latent period of the response to the second stimulus can be reduced to a minimum equivalent to the synaptic delay (0.3 to 0.4 msec.), by adjusting the strength of the first stimulus so that it is just below the threshold, and applying the second stimulus after
FIG. 370. Reflex tension in relation to interval between stimuli. Response of tibialis anticus measured in grams of tension (ordinates) when two nerves are stimulated at varying intervals. To the right of zero, the lateral gastrocnemius nerve is stimulated first; to the left of zero, the median gastrocnemius nerve is stimulated first. Abscissas, time in milliseconds. (*Creed et al., "Reflex Activity of the Spinal Cord," Oxford University Press, New York, 1942, p. 32.*)

an interval that is neither too short nor too long (6 to 8 msec.). The second volley thus arrives at the motor neuron pool when the c.e.s. produced by the first is at its peak (Fig. 371). The central reflex time taken from the application of the first stimulus to the reflex response corresponds to the nuclear delay.

[1] LORENTE DE NÓ, R., *Am. J. Physiol.*, **111**, 272 and 283, 1935; **112**, 595, 1935; **113**, 505 and 524, 1935.

Internuncial "barrage." Spatial summation of subliminal c.e.s. plays an indispensable part in intercellular transmission. In Lorente de Nó's experiments on the nucleus of the third cranial nerve, it was possible to excite the motor cells by a single stimulus only when other paths converging to the nucleus were intact and transmitted impulses that maintained a certain level of subliminal c.e.s. Internuncial neurons have thus two functions: (*a*) they form links in the reflex arc and serve as channels of distribution of afferent impulses; (*b*) they maintain a subliminal c.e.s. by constant bombardment of the cells on which their axons end. Two fundamental types of circuits assure this continuous action of the neurons.[1] In one type (Fig. 372*M*), the impulses arrive at the center temporally and spatially dispersed, because they travel along paths in which different numbers of synapses are interposed. In the second type (Fig. 372*C*), the neuron chains form a closed circuit. In this case the recurrent impulse is retarded by the synaptic delay sufficiently to assure its arrival after the end of the refractory period left by the previous impulse. The circuit of excitation is interrupted by the summation of hypoexcitability left by successive impulses, and the neurons no longer respond to the afferent impulses.

FIG. 371. Diagrammatic representation of c.e.s. in motor neuron pool (ordinates) plotted against time (abscissas). Above: a single volley sets up a c.e.s. which attains the threshold T_1 after a latent period of 1. Below: the second stimulus is applied at varying intervals after the first. The latent period is shortest (3) when the interval is such that the second volley reaches the center at the peak of the c.e.s. elicited by the first. (*After Eccles, J. C., and C. S. Sherrington, Proc. Roy. Soc., London, s.B., vol. 107, p. 511, 1931.*)

AFTER-DISCHARGE

The motor response of a reflex persists for a much longer time after the afferent volleys have ceased than the time taken by the last stimulus to travel along the reflex arc. In some cases the maximum effect is observed after stimulation of the receptor has ceased. After-discharge may be due, in part, to stimulation of receptors by the effects of the reflex, but this is not the only and necessary mechanism of this phenomenon, as it is observed in the flexion reflex despite deafferentation of the limb by section of the corresponding dorsal roots. After-discharge is produced by repetitive firing of the motor center.[2]

Repetitive stimulation is the rule in a normal nervous system. The receptors send, along the afferent neurons, repetitive impulses that vary in frequency and duration according to the strength of the stimulus. Internuncial neurons keep up a continuous "barrage" of impulses on the neurons placed "downstream" in the chain, and the motor neurons discharge repetitively on the effectors. Prolonged activity of the internuncial neurons (interneuron reverberation) is, therefore, one of the mechanisms that cause after-discharge.

FIG. 372. Types of circuits: *M*, multiple chain; *C*, closed circuit of neurons. (*Lorente de Nó, R., J. Neurophysiol., vol. 1, p. 207, 1938.*)

[1] LORENTE DE NÓ, R., *J. Neurophysiol.*, **1**, 207, 1938.
[2] *Ibid.*, **2**, 402, 1939.

The following observations demonstrate repetitive firing of motor neurons due to activity of internuncial neurons:

1. Repeated stimulation of a motor nerve at a lower frequency than 50 per second produces an incomplete tetanus, the oscillations of which have the same rhythm as the stimulus. Repeated stimulation of an afferent nerve at the same frequency also produces incomplete tetanus, but the oscillations of the electromyogram have a greater frequency than the rhythm of stimulation. The motor neurons discharge several times for every afferent impulse. Thus contraction is smoother, the oscillations are less marked, and a complete tetanus is obtained with lower frequencies of stimulation than those necessary to produce it by excitation of the motor nerve.
2. A single stimulus produces action potentials in the afferent roots which last 1 to 2 msec. The electrical activity of the ventral root when thus reflexly aroused can last 25 msec. An electrical record of the spinal cord taken at the same time shows that the activity of the motor neurons lasts as long as the internuncial neurons are active.

After-discharge can, however, be observed where there is no activity of internuncial neurons. Thus, in sympathetic ganglia (which have no internuncial neurons) strong stimulation at relatively high frequency (60 per second) of the preganglionic fibers is followed by postganglionic discharges that persist at a falling rate for some time (27 msec.) after the presynaptic volleys have ceased.[1] Bremer and his associates[2] have examined, in the spinal frog and toad, the intense prolonged reflex after-discharge of "tonic" muscles. They found that it was more marked after deafferentation and transection of the cord, *i.e.*, when only the lower lumbosacral segments remained active. In these conditions reflex reinforcement was not possible, and interneuron reverberation was reduced to a minimum. This work coincides with that of Rosenblueth and his associates[3] in concluding that self-sustained activity of neuron aggregates is an important mechanism of after-discharge.

INHIBITION

Suppression or prevention of activity in an effector by the action of the nervous system is known as inhibition. More than a hundred years ago (1845), the Webers demonstrated that stimulation of the vagus nerve stopped the heartbeat. For the first time suppression of activity, instead of an increase in it, was seen to follow stimulation of a nerve. Later the inhibitory effects of the splanchnics and other visceral nerves were observed, and the inhibitory nerves of invertebrates were discovered. In all these instances inhibition takes place in the innervated structure; there is *peripheral inhibition.*[1]

In somatic movements, suppression of activity (*i.e.*, inhibition) in the antagonistic muscles is as important as stimulation of the activity of the protagonists for accurate and smooth performance of movements. There are, however, no inhibitory nerves to somatic muscles in vertebrates. Centrifugal stimulation of a nerve passing into a muscle provokes contraction only; there is no peripheral inhibition. Inhibition of somatic activity is exclusively a central process, the counterpart of the central excitatory state, which Sherrington has called the "central inhibitory state" (c.i.s.). This central inhibitory state is made evident only by suppression of the central excitatory state.

Characteristics of inhibition. Inhibitory effects can take place with great rapidity, and the inhibited muscle relaxes at the same speed at which it contracts. The central latency of inhibition, however, is as variable as that of the central excitatory state.

Inhibition is graded in intensity. The degree of inhibition depends on the relative proportions of c.e.s. and c.i.s. This can be demonstrated in the crossed-extension reflex in the following way (Fig. 373): A cutaneous nerve of a limb is stimulated centripetally. Ipsilateral flexion and contralateral extension are thus provoked. Contraction of an extensor (*e.g.*, the quadriceps) in the contralateral limb is registered. When the reflex is fully developed, a cutaneous nerve of the extended limb is stimulated, and the quadriceps will be seen to relax immediately. The degree of relaxation is much greater than that observed by merely suppressing stimulation of the cutaneous nerve on the flexed limb for the same

[1] The mechanism of peripheral inhibition will be discussed in Chap. 84, because in the vertebrates all inhibitory nerves are visceral nerves.

length of time as the inhibitory stimulus has been applied. The amount of inhibition, *i.e.*, the number of motor units inactivated, will depend on the strength of the inhibitory stimulus and the amount of potential c.e.s. present. If the inhibitory stimulus is weak, no apparent effect may be registered; if, on the other hand, it is strong and the c.e.s. present is weak, complete inhibition may occur. After-discharges are particularly sensitive to inhibition, and a weak inhibitory stimulus, which has no effect while the excitatory stimulus is active, may quickly suppress contraction due to after-discharge.

Convergence and summation of inhibitory impulses are observed in conditions similar to those which produce convergence and summation of excitatory impulses. A weak stimulus, which does not provoke manifest inhibition, may nevertheless produce latent or subliminal inhibition which can be made evident by repetitive stimulation, or by stimulation of afferent paths that converge to the same center. A motor center is fractionated among the afferent paths with respect to inhibition in the same way as with respect to excitation. Moreover, a subliminal fringe of inhibition surrounds the pool of completely inhibited neurons. Occlusion is observed in the inhibited neurons just as in active neurons.
Fig. 373. Crossed-extension reflex in the decerebrate cat. Reflex contraction of the quadriceps in response to stimulation of the peroneopopliteal nerve of the opposite side at the rate of 48 stimuli per second. In *a*, three stimuli are dropped. In *b*, three stimuli are applied to an ipsilateral cutaneous nerve, and inhibition is produced. (*Liddell, E. G. T., and C. S. Sherrington, Proc. Roy. Soc., London, s.B., vol. 95, p. 90, 1923.*)

The time course of inhibition is as variable as that of the c.e.s.. but inhibition can last for a considerable time. Thus inhibition of the knee jerk (contraction of the quadriceps) may last for 2 sec. after a single shock to an ipsilateral cutaneous nerve. In the experiment recorded in Fig. 374, reflex contraction of the tibialis anticus was inhibited by a conditioning stimulus. The inhibitory effect increased to a maximum, which was reached between 30 and 80 msec. Then it diminished, but even after 200 msec. there was a considerable degree of inhibition. In this experiment several afferent fibers of a multineuron reflex were stimulated; therefore the inhibitory impulses arrived at the motor center by several paths dispersed in time and space, and a c.i.s. was kept up for a long time.

Fig. 374. Inhibition of the reflex contraction of the tibialis anticus by a conditioning stimulus. Ordinate, tension in grams developed by the muscle. Abscissa, interval in msec. between the stimuli. The arrow marks the tension developed when no conditioning stimulus preceded the second stimulus. (*Eccles, J. C., and C. S. Sherrington, Proc. Roy. Soc., London, s.B., vol. 107, p. 548, 1931.*)

The exact nature of the process of inhibition is not known, but several observations have shown there are two mechanisms of inhibition, which have been called *indirect inhibition* and *direct inhibition.*

Indirect inhibition. Conduction of an impulse (the propagated excitatory state) is followed by a prolonged subnormal phase during which the threshold is raised; this phase coincides with the positive after-potential. Its long duration facilitates summation of successive subnormal phases produced by repetitive stimulation, and the neuron becomes progressively less excitable. If subnormality is sufficiently pronounced, the neuron will not respond and im-

pulses that impinge on it will appear to be inhibited. This is known as indirect inhibition.

The simplest case in which this occurs is the so-called "silent period" of the knee jerk. This is a two-neuron reflex; the arc is formed by large α afferent fibers from the dorsal roots which end directly on motor neurons. If the electrical activity of the rectus femoris is registered, small asynchronous oscillations due to "tonic" contraction will be recorded. A tap on the knee tendon provokes extension of the leg accompanied by a short series of ample oscillations in the electrical record. Electrical activity is then suspended for a few milliseconds (the "silent period") before the asynchronous waves reappear (Fig. 375). The "silent period" can be registered with greater accuracy in a single motor unit activated by rhythmic tonic impulses. A single stimulus applied to an afferent nerve provokes a reflex discharge interpolated in the "tonic" rhythm, followed by a period of complete inactivity. The silent period is longer when the "reflex" impulse comes close to the preceding "tonic" impulse. An antidromic volley has the same effect as the conditioning afferent stimulus; therefore the silent period is due to a change in the excitability of the motor neuron. Moreover, summation of subnormal phases and positive potentials corresponding to successive antidromic volleys prolongs the silent period.

Fig. 375. Electromyogram of the rectus femoris muscle of a human subject. At the signal the tendon is tapped, and a knee jerk follows. There is a silent period, during which the electrical activity of the muscle is suspended; when it is renewed the oscillations are more ample. Time in milliseconds. (*Lindsley, Am. J. Physiol., vol. 109, p. 181, 1934.*)

This type of inhibition, due to the previous activity of the neuron, has also been demonstrated in the internuncial neurons of the spinal cord by means of the flexion reflex. Two afferent volleys are sent along the same cutaneous nerve. Response to the second volley will be facilitated or inhibited according to the relative strength of the volleys and the interval between them. Inhibition of the second stimulus is most marked when a weak stimulus is followed by a strong one after an interval of at least 16 msec. in order to avoid facilitation. Hughes and Gasser[1] have recorded the electrical activity of the spinal neurons following stimulation of afferent fibers, comparing the results with the motor response. The nature of the response could be predicted by the record of the spinal-cord potential. If the positive after-potential was small, facilitation occurred; if the positive after-potential had a high voltage, inhibition in proportion to the size of the positive after-potential was observed.

Direct inhibition. Indirect inhibition is the consequence of previous activity in the neuron, but in certain cases inhibition occurs in neurons that can be considered as having been quiescent. There must, therefore, be another mechanism of inhibition. Lloyd[2] has demonstrated what is known as direct inhibition, in the two-neuron reflex arc. Internuncial neurons played no part in this case; inhibition took place at the synapse of the afferent dorsal root and the spinal motor neuron. A segmental reflex was evoked by stimulating the first sacral dorsal root, and the motor discharge in the corresponding ventral root was recorded. A conditioning volley was sent along the sixth lumbar dorsal root of the same side. When the volleys were synchronized, or the conditioning volley preceded the test volley by a short interval, inhibition was observed. Maximum inhibition was obtained with an interval of 0.7 msec. between the volleys; afterward inhibition decayed exponentially, but with a threshold volley the inhibitory effect lasted up to 7 or 8 msec. If the conditioning volley arrived at the synapse after the test volley, no inhibition was observed; therefore, in this case, after the c.e.s. was established it could not be suppressed by a subsequent inhibitory impulse.

Afferent inhibitory fibers are large, low-

[1] Hughes, J., and H. S. Gasser, *Am. J. Physiol.*, **108**, 307, 1934.

[2] Lloyd, D. P. C., *J. Neurophysiol.*, **4**, 184, 1941.

threshold, high-speed α fibers which come from proprioceptive receptors in a muscle and end on the motor neurons of its antagonists.[1]

FATIGUE

Prolonged repetitive stimulation is followed by progressive decrease in the response. This is not inhibition but fatigue. Inhibition is the rapid suppression of activity by another stimulus, while in fatigue the afferent path loses control of the motor neurons without the concurrence of another stimulus.

Phasic reflexes are easily fatigued; in the spinal cat the flexion reflex begins to diminish in less than 1 min. Postural reflexes are less susceptible to fatigue.

The motor unit is not the site of fatigue; it can give a full response to direct stimulation, or to a reflex impulse that arrives through another afferent path, after it has ceased to respond to a given impulse. Fatigue does not reside in the receptor or the afferent nerve but in the nerve centers. The nature of fatigue is still unknown, but it seems to be related to the intense metabolic activity of the centers.

METABOLIC ACTIVITY OF THE NERVE CENTERS

Nerve centers are particularly susceptible to lack of oxygen. A reflex center ceases to function after a few minutes of anoxia, while nerve fibers conduct impulses during a considerable time in an oxygen-free atmosphere. Heymans and Bouckaerts[2] have examined the relative sensitiveness to anoxia of the different nerve centers. The higher centers, particularly the cortex, were found to be very sensitive to lack of oxygen; ischemia of 5 min. duration produced irreversible damage, and in some cases death. Recovery was possible if the blood supply was interrupted for a shorter time, but even then blindness often occurred, owing to the great susceptibility of the striate cortex (occipital lobe). Recovery of subcortical centers governing postural reflexes was observed if ischemia did not last more than 10 to 15 min.; decerebrate rigidity (see Chap. 81) was caused by more prolonged ischemia. Respiratory, vasomotor, and pupillary reflexes were definitely abolished by cutting off the blood supply for 30 to 60 min., and all spinal reflexes were permanently suppressed if ischemia lasted over 1 hr.

Oxygen consumption of slices of cerebral cortex, determined *in vitro*, is in the order of 5,000 cu. mm. per gm. per min. during the first few minutes, and later falls to 2,000 cu. mm. These figures have no great value, because nervous tissue is a delicate structure that suffers considerable damage by this experimental procedure, but they show that the neuron soma has much higher oxygen consumption than the axon, which in similar conditions takes up only 40 cu. mm. per gm.

Susceptibility to drugs. The high metabolic rate of the nerve centers is associated with their susceptibility to certain drugs such as strychnine, anesthetics, and narcotics (barbiturates). Low concentrations of these drugs, which have little or no effect on the axons, depress or totally suppress reflex activity.

ELECTRICAL PHENOMENA OF SYNAPTIC TRANSMISSION

Transmission of an impulse from one neuron to another (synaptic transmission) is accompanied by electrical phenomena. These have been recorded in autonomic ganglia (stellate, superior cervical, ciliate, lumbar, inferior mesenteric), in the spinal cord following stimulation of receptors or afferent fibers, in motor nuclei such

glionic fibers in a curarized ganglion evokes a potential—*synaptic potential*[1]—similar to the end-plate potential (see Chap. 67). It reaches its summit in 10 to 15 msec. in the cat's stellate ganglion *in situ*, and decays exponentially with a time to half decay of 60 to 90 msec. This potential spreads with decrement along the postsynaptic neuron, *i.e.*, it has the characteristics of electrotonic potentials. The size of the synaptic potential is related to the concentration of curare; as the drug diffuses out and its effect diminishes, the synaptic potential increases and may reach the threshold of the propagated excitatory state, in which case a postsynaptic impulse with spike potential is fired off. This occurs when the amplitude of the synaptic potential rises to a critical level, which is 5 to 12 per cent of the spike amplitude in the cat stellate ganglion *in situ*, but may be more in other cases, *e.g.*, 22 to 29 per cent in the isolated superior cervical ganglion.[2] Synaptic potentials evoked by repetitive stimulation of adequate frequency summate, and a potential may be built up to the threshold level. The synaptic potential is not modified significantly by eserine when it is evoked by a single presynaptic volley, but this drug prolongs it considerably when it is produced by repetitive stimulation; release of acetylcholine, therefore, plays a part in its production (see pages 851–853).

In a noncurarized ganglion the synaptic potential is covered by the spike potential, but in certain conditions it can be seen as an inflection in the rising limb of the spike. Usually there are several postsynaptic spikes because of differences in the speed of conduction of preganglionic fibers[3] and asynchronic activation of the ganglionic neurons. The number of spikes increases with the strength of the stimulus; a sufficiently strong stimulus evokes not only one or two spikes with a relatively short latency, but also one or even two others with long latency due to stimulation of nonmyelinated preganglionic fibers.[4]

Ganglionic spikes are followed by a *negative afterpotential*, due in part to the synaptic potential which outlasts the spike, and in part to an electrical phenomenon similar to the negative afterpotential of the nerve. There is also a *positive afterpotential*, analogous to the corresponding positive waves in nerves. Repetitive stimulation is followed by larger and prolonged negative and positive afterpotentials.

[4] Rosenblueth, A., and F. A. Simeone, *Am. J. Physiol.*, **122**, 688, 1938.

Posttetanic potentiation is observed after repetitive presynaptic stimulation (1 to 30 sec.); single volleys evoke larger spikes, and the positive wave is at first depressed, then enhanced. Repetitive stimulation may be followed by afterdischarge, *i.e.*, persistent activity of the ganglionic neurons after stimulation has ceased.[1] Afterdischarge is easily observed in eserinized ganglia.

Motorneuron potentials. (Fig. 377.) Electric phenomena of motor neurons have been recorded by means of fine insulated-wire electrodes inserted into a motor nucleus, but a more precise analysis has been made by means of glass electrodes introduced into a single motor-neuron of the anterior horn of the spinal cord.[2] The average resting potential was found to be 70 mv., but probably the maximum figure (80 mv.) is nearer the true value because experimental conditions tend to diminish it. An antidromic impulse (stimulation of the ventral root) evokes a spike potential of 95 mv. (average) which reverses the resting potential by 25 mv.; the true value is probably nearer 110 to 120 mv., the maximum figures recorded. The spike lasts 1 msec., twice the duration of the spike of large motor fibers; it is followed by a negative afterpotential, which after several milliseconds is reversed to a prolonged positive afterpotential reaching a maximum of 3 to 6 per cent of the spike in 10 to 15 msec., and lasting for about 100 msec.

An orthodromic impulse evoked by stimulating a muscle nerve, in order to provoke a monosynaptic reflex, is followed by a synaptic potential after a latency of 0.6 msec. This potential reaches its summit in 0.6 to 1 msec. after the onset, then decays exponentially, falling to half its value in 2.5 to 3.5 msec., and is later reversed to a small positive afterpotential which is increased by repetitive stimulation. The antidromic spike rises at a rate of 300 to 500 volts/sec. (half the rate at which the motor fiber spike rises), but the synaptic potential rises slowly. If

[1] Larrabee, M. G., and D. M. Bronk, *Proc. Soc. Exper. Biol. & Med.*, **38**, 921, 1938; *J. Neurophysiol.*, **10**, 139, 1947.

[2] Brock, L. G., J. S. Coombs, and J. C. Eccles, *J. Physiol.*, **117**, 431, 1952.

the rate of rise is 50 volts/sec., it reaches the threshold and the spike potential of the propagated impulse appears, in which the synaptic potential is marked by an inflection in the ascending limb. The critical voltage for this is 6 to 14 mv., 8 to 15 per cent of the spike.

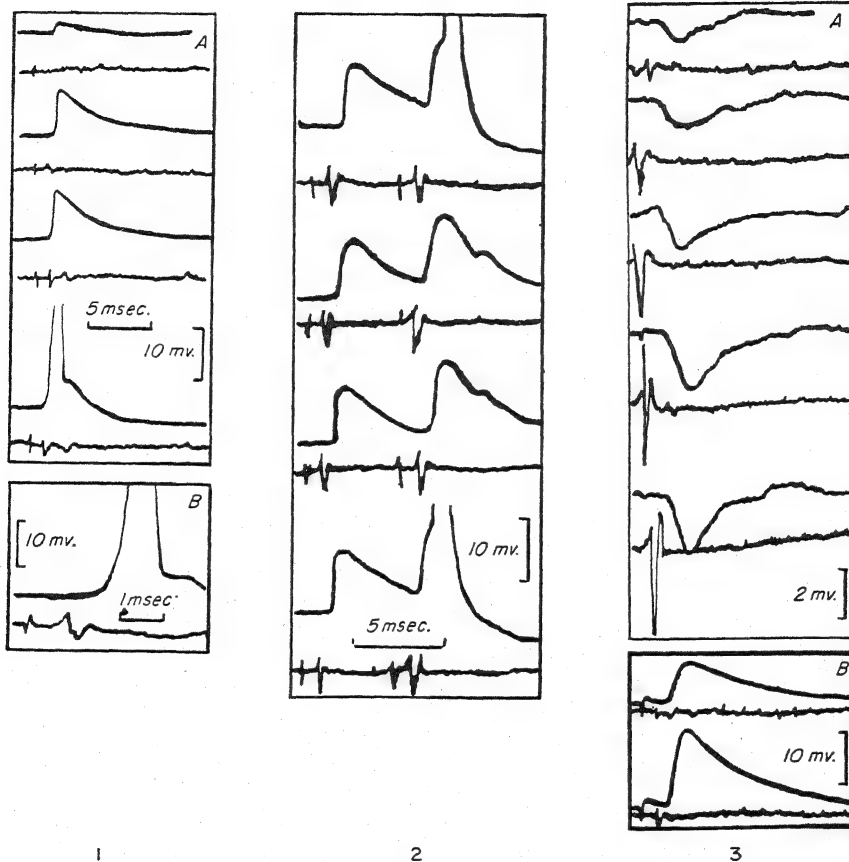
two or more stimuli are applied to the afferent fibers at adequate intervals, the synaptic potentials evoked by each impulse summate, and a potential can be built up which reaches the threshold and fires off a postsynaptic impulse with a spike potential (temporal summation).


Fig. 377. 1.*A*, intracellular potentials set up in spinal motor neuron by afferent volleys; synaptic potentials increase with size of volley; the largest sets up a spike. *B*, faster record shows spike arising from initial synaptic potential. Lower tracings in all the records correspond to dorsal root potential, negativity downward.

2. Intracellular potentials set up in spinal motor neuron by two afferent volleys from the same fibers. Summation of synaptic potentials that set up a spike occurred at the shortest interval (upper record). The intervals in the second and fourth record, which are equal, are just critical.

3. Intracellular potentials of spinal motor neuron responding with synaptic potentials to afferent volleys from semitendinosus biceps nerve (*B*). Volleys of increasing size (from above downward) from quadriceps (antagonist of semitendinosus and biceps) nerve evoke positive potentials in the same motor neuron as in (*B*). (*Brock, L. G., J. S. Coombs, and J. C. Eccles, J. Physiol., vol. 117, p. 431, 1952.*)

The synaptic potential increases with the strength of the stimulus until it reaches the threshold. This increase is due to activation of a larger number of end knobs so that depolarization spreads over a wider area of the motor-neuron membrane (spatial summation). When There is evidence suggesting that under each end knob maximum depolarization occurs but that a sufficient area of the motor-neuron membrane must be activated before a self-propagated process is initiated, *i.e.*, before an impulse with a spike potential will spread throughout the neuron.

If the electrode is moved out of the motor neuron so that its tip is placed in the intercellular space, the postsynaptic potentials are modified, but there is no change in the presynaptic potentials. Therefore the latter when recorded by an intracellular electrode are extracellular in respect of the presynaptic neuron. This is definite proof of discontinuity at the synapse and crucial demonstration of Cajal's neuron doctrine (Fig. 378).

FIG. 378. Potentials recorded in response to afferent volley; upper record, dorsal-root potentials (negativity upward); lower record, motor-neuron potential (negativity downward). *A*, extracellular record; *B*, intracellular record. Root potentials do not vary. Motor-neuron potentials recorded intracellularly are reversed and increased with respect to the extracellularly recorded potentials. (*Brock, L. G., J. S. Coombs, and J. C. Eccles, J. Physiol., vol. 117, p. 431, 1952.*)

When a motor neuron which responds with a synaptic potential to stimulation of a given muscle nerve, *e.g.*, the biceps-semitendinosus nerve, receives an impulse set up by stimulation of the nerve of a muscle which is an antagonist of the former, *e.g.*, the quadriceps, it responds not by a synaptic potential but by increased negativity with respect to earth, *i.e.*, by an increase in polarization. This potential reaches a maximum of 1 to 2 mv. in 1 msec., then decays to half its value in 2 msec. A stimulus which provokes direct inhibition, therefore, is followed by a state of anelectrotonus in the motor neuron. This state is not produced by potentials outside the cell, but is an active response of the motor neuron to the inhibitory volley. The significance of this fact will be discussed later.

Spinal-cord potentials. Spinal-cord potentials can be recorded by placing one electrode on the dorsal surface near the dorsal root stimulated and the other on the ventral surface of the same segment or of an upper segment. Stimulation of a dorsal root evokes a spike followed by a second negative potential of lower voltage and greater duration; finally there is a prolonged positive potential of low voltage (Fig. 379). The spike is due to intraspinal fibers of dorsal ganglion neurons, and when two roots are stimulated simultaneously there is summation of their respective spikes. The second negative potential has been considered as the sum of the spikes of internuncial neurons,[1] the lower voltage and greater duration being due to temporal dispersion in the excitation of these neurons. When two dorsal roots are stimulated, the second negative potential is not the sum of the respective individual root potentials, as occurs with the spikes; it is only slightly larger than that of a single root because afferent fibers of both roots converge to the same internuncial neurons, some of which are occluded. The positive potentials of the neurons first excited may also contribute to lower the voltage of the second negative potential.

When a volley of impulses, or even a single impulse, enters the spinal cord by a dorsal root, slow, prolonged negative potentials can be recorded from the same or neighboring dorsal roots (dorsal-root potentials, DRP) or from the ventral roots (ventral-root potentials, VRP).[2] These potentials spread electrotonically along the spinal cord and the dorsal and ventral roots. The DRP is a slow negative potential, preceded often by a positive deflection. There are no significant differences in these potentials evoked by stimulation of muscular or cutaneous nerves, in anesthetized animals or in nonanesthetized

decerebrated animals. The VRP is modified by anesthesia and differs according to whether it is evoked by stimulation of muscular or cutaneous nerves. It is made up of two groups of waves, both prominent in nonanesthetized animals. In an anesthetized animal a weak stimulus evokes a small slow rising negative potential, frequently preceded by a positive deflection. A stronger stimulus provokes the appearance of spikes superimposed on the slow potential. The spikes are synchronous when a muscular nerve has been stimulated; they are the electrical concomitant of a monosynaptic reflex.[1] When a cutaneous or a mixed nerve is stimulated, asynchronous spikes appear as a result of a plurisynaptic reflex. In most cases large positive potentials follow the propagated discharges. In nonanesthetized decerebrated animals there is no positive afterpotential, but a long-lasting negative potential related to the DRP. The early waves in the VRP are the electrical manifestation of reflex activity evoked by incoming impulses acting on the motor neurons. The slow potentials may be due to reverberating activity of interneuron circuits, or, as suggested by Barron and Matthews, to ionic changes external to the fibers produced at the axonic terminals following impulse activity. The process which gives rise to these slow potentials is undoubtedly of physiologic importance, because sustained and integrated reflex movements are observed only in conditions in which they appear. When they are absent, as in anesthetized animals, the excitability of the motor neuron is depressed after a short burst of activity (during the positive afterpotential) and only brief, rudimentary reflex movements can be performed.

CHEMICAL MEDIATORS OF SYNAPTIC TRANSMISSION

The existence of a chemical mediator (acetylcholine) in neuromuscular transmission of excitation and in the conduction of the nerve impulse has already been considered (Chaps. 67 and 68). Acetylcholine has also been found in the nerve centers, and it will be convenient to discuss at this point the part it plays in synaptic transmission of excitation, first in sympathetic ganglia and then in the central nervous system.

Chemical mediators in sympathetic ganglia Kibjakow[1] discovered the presence of acetylcholine in sympathetic ganglia and suggested that it played a part in synaptic transmission. Varying amounts have been reported; *e.g.*, 10 to 44 μg per gm. of fresh weight in the cat and 8 to 19 μg per gm. in the sheep. No ACh is found in a ganglion one or two weeks after its preganglionic fibers have been cut. Feldberg and Gaddum[2] perfused the superior cervical ganglion and showed that stimulation of preganglionic fibers liberated acetylcholine (Fig. 380). The preparation had to be eserinized in order to protect acetylcholine from the hydrolytic effects of

[1] Kibjakow, A. W., *Pflüger's Arch. f. d. ges. Physiol.* **232**, 432, 1933.

cholinesterase, which was also found in the ganglion. Antidromic stimulation of postganglionic fibers, or stimulation of fibers that did not end synaptically but passed through the ganglion, produced the release of only very small quantities of acetylcholine. Care must be taken, however, to maintain the preparation in good condition; otherwise, as it deteriorates, increasingly larger amounts are set free after preganglionic stimulation, and eventually this occurs even without stimulation.[1]

The output of ACh from a perfused eserinized ganglion submitted to repetitive preganglionic stimulation is at first about 100 μμg. per volley (superior cervical ganglion of cat) but then falls exponentially as stimulation is kept up. After 40 min. stimulation, the output of ACh is considerably reduced. If the ganglion is not eserinized, the output of ACh does not diminish with sustained stimulation; thus after a preliminary period of 40 min. preganglionic stimulation the output is the same as before stimulation. It seems that ACh is normally resynthesized from the products of its hydrolysis; eserine interferes with this process of synthesis, and the available stock of ACh is gradually depleted.[1]

Acetylcholine added to the perfusing fluid causes postganglionic, but not preganglionic, discharge.[2] Postganglionic discharge is also obtained by intravenous injection or by injecting small doses into the artery of the ganglion (*e.g.*, the carotid artery for the superior cervical ganglion). Larger doses provoke repetitive discharge, and very high doses have a depressing effect and may cause complete block.

Eserine and other anticholesterinases prolong the effect of ACh, potentiate subliminal doses of this drug and subliminal preganglionic stimulation, and cause repetitive discharge in response to a single preganglionic volley. Curare de-

presses, and in relatively large doses completely blocks, ganglionic synaptic transmission; it does not, however, prevent the release of ACh by preganglionic stimulation, but antagonizes the effect of ACh, *i.e.*, it has the same activity as in the myoneural junction. ACh and anticholinesterases exert a decurarizing effect on the ganglion similar to that observed in muscle.

ACh depolarizes the ganglionic neurons. Normally this effect is of very short duration, because ACh is destroyed by cholinesterase. If it is protected by anticholinesterase or a large dose is injected, persistent depolarization causes ganglion block. ACh has the same effects as nicotine and certain quaternary ammonias (tetramethylammonium): the ganglionic neurons are first stimulated, then blocked. Curare alkaloids and other drugs such as pentamethonium, hexamethonium, and decamethonium block the ganglion without producing depolarization, perhaps by substrate competition with ACh.[1]

Potassium is released by preganglionic stimulation and by ACh; when added to the perfusion fluid, it releases ACh and causes postganglionic discharges. Adenosinetriphosphate (ATP) and creatinephosphate (CP) are powerful stimulants of the perfused ganglion. Their effects persist after denervation and degeneration of the preganglionic fibers, therefore they are not dependent on ACh release. The effects of ATP and CP are related to the phosphate in the molecule and are not suppressed by curare. The action of ATP and CP is similar to that of potassium.[2]

The adrenal medulla is in certain respects analogous with sympathetic ganglia (see Chap. 85), and its cells are innervated by preganglionic fibers of the splanchnic nerves. Stimulation of these nerves causes the release of acetylcholine, which can be collected in the adrenal vein, if the preparation is eserinized, *i.e.*, if destruction of acetylcholine by cholinesterase is prevented. Acetylcholine, moreover, provokes secretion of the adrenal medulla.

There is, therefore, good evidence that acetylcholine is released in sympathetic ganglia by preganglionic stimulation, and that it stimulates the ganglion cells.

Chemical mediators in the central nervous system. Acetylcholine,[1] cholinesterase,[2] and choline acetylase[3] have been found in the tissue of the central nervous system. Acetylcholine concentration and enzymatic activity vary in different parts of the nervous system, but usually the three values are in agreement. Exceptions to this rule are the ventral roots which have high ACh and low cholinesterase, and the cerebellum, in which ACh is low and cholinesterase high. The dorsal roots and dorsal column of the spinal cord (f. gracilis and cuneatus) have low ACh and enzyme concentrations; the dorsal horns and the nuclei gracilis, cuneatus, and vestibularis have high values; in the internal capsule the values are low. Therefore the first neuron of the sensory pathway is noncholinergic, the second neuron is cholinergic, and the thalamic neurons are noncholinergic. The lower motor neuron is cholinergic, the pyramidal tract is noncholinergic, and the motor cortex has intermediate values. Acetylcholine and eserine stimulate the motor cortex; therefore some of its neurons, though probably not the Betz cells, are cholinergic. The ACh content of the brain increases during sleep or under the influence of anesthetics (ether) or narcotics (nembutal). Activity, such as is produced by emotional excitement, electrical stimulation, or drugs which provoke convulsions (metrazol, picrotoxin), lowers the ACh content of the brain. Normal values are recovered after a short period of rest; therefore, ACh is rapidly resynthesized.[4]

Acetylcholine applied locally increases the activity of the motor cortex,[5] and injected into the carotid in cats after section of the brain stem it evokes the awakening reaction in the electroencephalogram[6] (see Chap. 87). In the perfused spinal cord, eserine and prostigmine enhance the flexor reflex and depress the knee-jerk. Flexor responses to stimulation of the descending spinal

tracts are usually facilitated by ACh and depressed by adrenaline, and extensor responses are facilitated by adrenaline and depressed by ACh.[1] Acetylcholine injected into the basilar artery evokes a burst of impulses from the ventral roots of the first cervical segment, and increases the area, reducing the latency of ipsilateral reflexes. The ventral root potential is increased in amplitude and rapidly reaches its peak. Eserine and prostigmine increase and prolong these effects of ACh.[2]

There is, therefore, sufficient evidence that the acetylcholine cycle functions in the central nervous system, that some of the neurons are cholinergic, and that ACh modifies synaptic transmission in the central nervous system, facilitating it in some cases, depressing it in others.

Sympathomimetic activity has been found in extracts of brain tissue.[3] This "sympathin" is a mixture of noradrenaline and adrenaline, the former predominating (93 per cent in cats and 86 per cent in dogs).[4] It has been found in all parts of the central nervous system, but unevenly distributed. The highest concentrations are in the hypothalamus (1.4 μg/gm. in the cat), midbrain (gray matter around the aqueduct), and medulla (floor of fourth ventricle and reticular formation); i.e., regions which contain centers of the sympathetic. Asphyxia and certain drugs which stimulate central sympathetic activity (ether, morphine, insulin) diminish the concentration of noradrenaline in the hypothalamus and midbrain. These facts are suggestive but the evidence is not sufficient to assign a definite functional significance to noradrenaline and adrenaline as chemical mediators of synaptic transmission in sympathetic centers.

SYNAPTIC TRANSMISSION

The nature of the processes taking place at the synapse, resulting in the transmission of a propagated impulse from the axon terminals of one neuron to the soma (dendrites and perikaryon) of another, or in the suppression of activity (inhibition) of the postsynaptic neuron, is one of the fundamental problems of neurophysiology. The processes of transmission appear to be essentially the same at myoneural junctions, synapses in autonomic ganglia, and central synapses, although there are features characteristic for transmission at each one of these sites.

There is sufficient evidence that, at myoneural junctions and ganglionic synapses, the impulse on arriving at the axon terminals releases acetylcholine (at some of the visceral myoneural junctions, adrenaline and noradrenaline are released). Acetylcholine acts on the postsynaptic membrane and causes depolarization, the electrical sign of which is the end-plate or synaptic potential. When depolarization covers a certain minimum area the synaptic potential reaches a critical level and a self-propagated excitatory process, the electrical sign of which is a spike potential, is initiated and spreads over the whole fiber or postsynaptic neuron. The membrane subjacent to several neighboring synaptic knobs must be activated simultaneously or within a very short interval for a spike to be fired off; otherwise there is only subliminal depolarization and a subliminal synaptic potential is observed. Acetylcholine probably acts on a receptor substance initiating changes in membrane permeability and ionic fluxes (inflow of Na^+, outflow of K^+) leading to depolarization and reversal of the membrane potential.

Evidence of chemical mediation of transmission at central synapses is not as satisfactory as it is for peripheral synapses. Eccles and his associates have demonstrated that in direct inhibition there is an increase in polarization in the motor-neuron membrane subjacent to the inhibitory synaptic knob. No electrical explanation of this actively produced anelectrotonus can be given; therefore, "inhibitory synaptic action is mediated by a specific transmitter substance that is liberated from the inhibitory synaptic knobs. . . . If inhibitory synaptic action is caused by a chemical transmitter, it seems probable that excitatory synaptic action in the central nervous system would also conform to the pattern of chemical transmission that seems to obtain with all other junctions."[1]

The nature and mode of action of the mediators are not known. The acetylcholine cycle has been demonstrated in the tissue of the central nervous system, and ACh can modify synaptic transmission in the central nervous system, but the part it plays in central synaptic transmission

is not well understood. Several possibilities can be considered: (*a*) ACh released at different points of a neuron or at different neurons may exert different effects, *i.e.*, polarization at one place (inhibition) and depolarization at another (excitation); or (*b*) there may be two transmitters, one for excitation and one for inhibition, which may be released by the same cell, or more probably by different cells. There is no inherent impossibility for either of these hypotheses. Chemical mediators acting on myoneural junctions produce excitation at one place and inhibition at another, *e.g.*, acetylcholine stimulates the intestinal wall muscle and inhibits intestinal sphincters. The existence of more than one mediator in peripheral transmission is a well-known fact. Moreover, ACh and adrenaline influence central nervous activity in opposite ways,[1] and there is evidence that some of the central neurons are cholinergic and others are not. Adrenergic nerve endings release adrenaline and noradrenaline; it is possible, therefore, that the same neuron may release two chemically related mediators with different activity or that a mediator may be slightly modified after release, and its activity thus changed.

Bibliography will be found at the end of the next chapter.

CHAPTER 70

Reflex Coordination

A SIMPLE, ISOLATED REFLEX is a theoretical abstraction; it is convenient in the analysis of the functions of the nervous system, but it has no real existence. A particular reflex is conditioned by the activity of other nerve centers, and activity in a given reflex arc conditions that of others. This reciprocal action of reflexes on each other is possible because there are synaptic connections between all the paths, as is demonstrated by the effects of strychnine and tetanus toxin. These substances destroy the central inhibitory state, and stimulation of an afferent nerve no longer produces contraction of certain muscles and relaxation of their antagonists, but only contraction. In an advanced stage of intoxication it is possible to provoke convulsive contraction of all the muscles in the body by stimulation of any receptive field. In normal conditions only reflexes provoked by very weak stimuli or in widely separated areas exert no influence on each other. Irradiation of the effects obtained by stimulating an afferent path is considerably reduced by the action of certain drugs, such as chloroform and chloral, and during depression following section of the spinal cord (see "Spinal shock," Chap. 81).

The central nervous system normally functions as an integrated unit, and the combination of reflexes, taking place simultaneously or successively, into orderly responses is a fundamental aspect of nervous coordination. Integration of nervous activity is carried out at different levels of increasing complexity. The first and simplest integration is performed in the spinal cord. It can be examined by suppressing the influence of higher centers. For this purpose a spinal animal is used, *i.e.*, an animal that has been decapitated by section below the medulla oblongata. Artificial respiration must be performed, because the respiratory center is situated above the section. A "chronic" spinal animal can be kept alive with adequate care for several months if the section is made in the lower cervical region below the emergence of the roots forming the phrenic nerves.

The principle of reciprocal innervation. A fundamental process of reflex coordination is made evident on examination of the flexion reflex. This reflex consists in flexion of a limb in which a cutaneous nerve is stimulated centripetally; at the same time the limb on the other side is extended (crossed-extension reflex). If the activity of the different muscles that take part in the reflexes is recorded, the flexors of the ipsilateral limb will be seen to contract, and the extensors to relax (Fig. 381); the flexors on the contralateral limb relax and the extensors contract. Stimulation of the receptive field awakens activity in certain motor units (the protagonists of the movement) and inhibits others (the antagonists) (Fig. 382). There is close correlation in the intensity of the opposite processes. Thus, if the flexors are 100 per cent stimulated, the extensors are 100 per cent (*i.e.*, completely) relaxed; if the flexors are 25 per cent stimulated, activity in the extensors is reduced by 25 per cent. Smooth performance of a movement is the result of interaction between excitation and inhibition; one process is as important as the other. The part played by excitation is obvious; that of inhibition is demonstrated in the following experiment: All the nerves to the eye muscles, except the sixth nerve, which innervates the external rectus muscle, are cut on one side, *e.g.*, the left. The eye at rest is turned outward by tonic contraction of the external rectus. The animal's attention is drawn to an object (food or light) placed in the right eye field. The right eye is accurately fixed on the object, and the left eye is brought to the mid-line, *i.e.*, looks straight

a

b
FIG. 381. Reciprocal innervation of antagonists. Flexion reflex evoked by stimulation of the ipsilateral internal saphenous nerve by a series of induction shocks. *a*, contraction (excitation) of the flexor muscle of the knee. *b*, relaxation (inhibition) of the extensor muscle of the knee. (*Sherrington, C. S., "The Integrative Action of the Nervous System," Yale University Press, New Haven, 1926.*)

forward. If the object is then placed in the left eye field both eyes are fixed on it, and will follow it as it is slowly displaced toward the right. When the object passes the mid-line, the right eye continues to follow it, but the left eye remains motionless, looking straight forward. The movements of the left eye toward the right are due exclusively to inhibition of the postural tonus of the external rectus, because all the other muscles have been denervated. Moreover inhibition is accurately coordinated with excitation of the right external rectus and inhibition of the right internal rectus, until the external rectus is fully relaxed and the eyeball adopts the resting position with the pupil directed straight forward. Whenever an integrated phasic movement is performed, there is a similar coordination of excitation in the protagonists and inhibition of the antagonists. Sherrington has called this the "principle of reciprocal innervation of antagonistic muscles."

In coordination of movements that involve muscles on both sides of the body, in some cases the principle of reciprocal innervation extends to symmetrical muscles. Thus in the flexion and crossed-extension reflexes evoked by stimulation of a cutaneous nerve of a limb, the ipsilateral flexors contract and the contralateral flexors relax, although these muscles are not, strictly speaking, antagonists. In other cases, *e.g.*, in symmetrical movements such as the clasping reflex of the toad and galloping movements in mammals, coordination takes place by *identical innervation*, *i.e.*, symmetrical pairs of muscles are excited or inhibited together. Muscles that are antagonists in certain movements act as synergists in others. For example, the flexors and extensors of a limb, which are antagonists in flexion and crossed-extension reflexes, contract together in the postural reflex which fixes the limb into a supporting column (see "Postural reflexes," Chap. 81). In this case also they are coordinated by the process of identical innervation.

The role of the receptors. The receptors, placed on the afferent end of the reflex arc, act as the first "analyzers" of changes in the external or internal environment.

This is due to their "specific irritability" (see Chap. 71), *i.e.*, each receptor has a low threshold for one kind of stimulus and a high threshold for others. Moreover, each receptor is more closely connected, by reason of the physiologic archi-

tecture of the nervous system, with certain motor mechanisms than with others. For example, a painful stimulus applied on the plantar surface stimulates one type of receptor and provokes the defensive flexor reflex; pressure on the same surface stimulates another type of receptor and the response is an extensor thrust.

Another factor which may condition the response is the site on the receptive surface on which the stimulus is applied. Thus, in the spinal cat stimulation of the skin of a limb evokes flexor responses except when the area over the antagonistic extensors is stimulated. Moreover, stimulation of the skin over a flexor muscle inhibits it.[1]

The "receptive field" of a reflex is the aggregate of receptors that respond to the same type of stimulus, the application of which produces a series of reflexes very similar, but not quite identical, to each other. In each field there is a central focal area where the threshold is lowest; in the periphery of the field, stronger stimuli must be applied to obtain a response. For example, the receptive field of the flexion reflex in the dog extends over the surface of the whole limb, but its focal area lies in the toe pads.
FIG. 382. Diagram of reciprocal innervation of antagonists in the flexion and crossed-extension reflexes. Stimulation of the afferent fiber α evokes ipsilateral excitation (+) in the flexors (*F*) and inhibition (−) in the extensors (*E*) (flexion reflex), and contralateral excitation (+) in the extensors and inhibition (−) in the flexors (crossed-extension reflex). (*Sherrington, C. S., "The Integrative Action of the Nervous System," Yale University Press, New Haven, 1926.*)

The threshold of a reflex can change from one moment to another, according to the physiologic condition of the animal. The change takes place in the whole field, so that the relative excitability of its different areas remains unchanged, but this relative value may be upset by "local fatigue" at a point that has been submitted to prolonged stimulation.

The receptive field of a reflex does not coincide with that of a dorsal root. Usually the afferent fibers enter the spinal cord by several roots; field and reflex are, therefore, plurisegmental in

[1] HAGBARTH, K. E., Excitatory Skin Areas for Flexor and Extensor Motoneurons, *Acta physiol. Scandinav.*, **26**, Suppl. 94, 1952.

extension. Conversely, in the same dorsal root there are afferent fibers of many superficial and deep receptive fields.

The local sign of reflexes. Reflexes are responses, the purpose of which is to adapt the organism to changes in the environment. The "purpose" of complex reflex patterns is usually clearly evident; *e.g.*, the flexion and crossed-extension reflexes evoked by a painful stimulus are directed to the removal of the limb from the harmful agent. The "purpose" of simple reflexes, however, is not always easy to understand. Adequacy of adaptation is clearly seen in the so-called "local sign" of reflexes, which consists in the orientation of the reflex movement in relation to the position of the stimulus. For example, the scratch reflex is made up of two components: (*a*) rhythmic alternating flexion and extension of one of the hind limbs; (*b*) sustained posture, the trunk being sent toward the side on which the stimulus is applied, the head slightly extended and rotated, both forelimbs and the hind limb of the opposite side extended, and the hind limb on the stimulated side brought more or less forward, according to the situation of the place stimulated, this being the local sign. Here, adequacy of response (scratching to remove the stimulus) is evident.

"In the execution of spinal reflexes the most important afferent factor as regards local sign is the afferent channel from the place of initiation of the reflex."[1] The correct direction of the reflex demands a state of equilibrium in the central nervous system, which is lost in spinal shock; in this condition there are gross errors in localization. Deafferentation also disturbs adequate orientation of reflex movements, even though the response can be obtained with facility equal to or greater than in the normal animal. In this condition afferent impulses from the activated muscles that serve to guide the movement are missing.

SIMULTANEOUS COMBINATION OF REFLEXES

Many types of receptors are found close to each other in all parts of the body. In the skin there are tactile, temperature, and pain receptors, and in the deeper structures there are the different kinds of proprioceptive receptors. The stimulus may act on a single receptor or on several receptors of the same or different types. When several receptors are stimulated and the afferent impulses act in the same sense, the effect of each one is reinforced by that of the others. Thus, a substance that stimulates the taste buds in the tongue produces reflex secretion of saliva; if this substance dries the mouth, this fact provides a new stimulus, which also provokes secretion of saliva; the reflexes reinforce each other. When impulses from different receptors use the same final common path in the same direction, either for excitation or for inhibition, their reflex effects are summated and they are called "allied reflexes."

The reflex arcs of a type reflex form an aggregate of allied reflexes. Impulses arriving at the center from each one of the receptors excite a certain number of motor neurons, and around them other neurons are excited subliminally. The subliminal fringe may be of low intensity and widely spread (*e.g.*, in labyrinthine reflexes) or narrow and of relatively high intensity (*e.g.*, in the flexion reflex). Impulses that arrive from other receptors to this subliminal fringe are facilitated. Thus two subliminal stimuli applied simultaneously, or with a short interval, to two different receptors can summate and a response will be evoked. Sherrington has called this type of facilitation "immediate spinal induction." Induction is more marked when the central connections of the receptors are close to each other.

When impulses from two receptors converge to a motor center and produce opposite effects, *i.e.*, excitation and inhibition respectively, the reflexes are known as "antagonistic." The response in each case is the result of the algebraic sum of the opposite central states of excitation and inhibition. For example, if a limb that is in extension as the result of a crossed-extension reflex is stimulated with a harmful stimulus, the state of excitation in the motor centers of the extensors is suppressed and the flexor muscles are stimulated (flexion reflex). If the stimulus is weak, there will be no apparent flexion, but the strength of contraction in the extensors will be reduced; if the stimulus is strong, the flexion reflex will be preponderant and the limb will be flexed. In both cases there is an occult reflex covered by the apparent effect of the stronger reflex. Inversion of the response is provoked by

[1] SHERRINGTON, C. S., "The Integrative Action of the Nervous System," Yale University Press, New Haven, 1926, p. 251.

a change in the relative strength of the stimuli, which may be due to a change of posture, to a third reflex converging on the same center which reinforced either the c.e.s. or the c.i.s., or to other circumstances. Experimental stimulation of an afferent nerve artificially increases occult reflexes, because many afferent paths producing opposite effects are stimulated simultaneously. In normal conditions the stimulus falls on a receptive surface and, because of specific irritability, excites some receptors and not others.

Graduation of the strength of reflex contraction. Stimulation of an afferent nerve of a limb produces almost simultaneous activation of all the motor centers of the flexion reflex, which thus takes place suddenly (jet or *d'emblée* reflexes). This is due to simultaneous stimulation of a great number of afferent paths. When, as normally occurs, the reflex is initiated by stimulation of receptors, the reflex develops gradually; there is progressive "recruitment" of motor units.

The strength of the response is graded by two mechanisms:

1. A variable number of motor units takes part in the reflex. At the beginning only two or three may be activated; later the number increases progressively.
2. An increase in the frequency of the impulses discharged by the center increases the tension developed by each motor unit. For example, in the phrenic nerve 15 impulses per second have been registered in shallow breathing and 60 to 80 impulses per second in deep breathing.

Both mechanisms are closely associated and the response can thus vary in extension and intensity.

The motor center is a mechanism for summation of c.e.s. and c.i.s. produced by afferent impulses that converge to it. Some neurons may be stimulated maximally and discharge with a frequency sufficient to provoke the strongest tetanic contraction possible. Other neurons, close to the former, are also stimulated above the threshold, but less intensely, and these discharge at a lower frequency, producing in the corresponding muscle fibers a more or less incomplete tetanus (subtetanic contraction). Neurons that are farther away from the focus are stimulated subliminally, and even more distant neurons remain quiescent (Fig. 369).[1] The arrival of further impulses through either the same or other paths intensifies and extends the c.e.s. The effect on maximally stimulated neurons cannot be any greater, because they are "occluded," but submaximally stimulated neurons discharge at a higher frequency, and those of the subliminal fringe also discharge. This ascending scale of excitation takes place at the beginning of a reflex until the latter is fully developed; as it wanes, the process is reversed and motor units drop out progressively until the reflex ceases completely.

IRRADIATION OF REFLEXES

Certain reflexes take place within a small segment of the spinal cord; the afferent impulses enter through one or a few dorsal roots, and the motor centers are situated in one or a few spinal segments. These are called *short reflexes*, and they develop following a fairly constant pattern.

Other reflexes, *e.g.*, the scratch reflex, have arcs that occupy many segments of the spinal cord. They are *long reflexes*, and their development may show considerable differences in individual instances.

Sherrington's laws of reflex irradiation.[2] The spread of a reflex to an increasing number of motor units takes place according to a certain pattern, which is described by Sherrington's five laws of reflex irradiation.

1. The degree of reflex spinal intimacy between afferent and efferent spinal roots varies directly as their segmental proximity. Motor effects are obtained more easily through the efferent roots of the stimulated and neighboring segments than through the roots of more distal segments (law of spatial proximity).
2. For each afferent root there exists in its own segment a reflex motor path of as low a threshold and of as high a potency as any open to it anywhere else. It must be kept in mind that afferent fibers make central connections in several segments with many motor neurons, either directly or through internuncial neurons.

[1] Probably in all neurons of the central nervous system there is always some degree of excitation or inhibition produced by "bombardment" from internuncial neurons. It is perhaps not strictly accurate therefore to speak of neurons in a state of complete rest or quiescence in a normal nerve center.

[2] SHERRINGTON, *op. cit.*, p. 158.

3. The motor mechanisms of a segment are unequally accessible to the local afferent channels. As judged by excitatory effects, synaptic resistance is not the same in all the paths, but if inhibitory effects are taken into account, the reflex connection is found to be wider.
4. The motor neurons simultaneously discharged by a spinal reflex innervate synergic and not antergic muscles.
5. The spinal reflex movement elicited in and from any one spinal region will exhibit much uniformity despite considerable variety of the locus of incidence of the exciting stimulus. Even when the receptive field is spread over several spinal segments, the motor response is fundamentally the same.

Reflex figures. (Fig. 383.) Long reflexes spread following a path determined by laws of spatial proximity and synaptic resistance. Thus certain "reflex figures" are established, which can be observed in the "spinal animal" (*i.e.*, after section of the cord below the medulla) or the "decerebrate animal" (*i.e.*, after section of the brain stem between the colliculi).
FIG. 383. Reflex figures. *a*, position of spinal animal; *b*, position of animal in decerebrate rigidity; *c*, change of attitude in spinal animal produced by a stimulus on the left hind foot; ipsilateral flexion and crossed-extension reflexes; *d*, simultaneous stimulation of both hind feet; bilateral flexion reflexes inhibiting the crossed-extension reflexes; *e*, stimulation of left hind foot irradiated to forelimbs, extension of the ipsilateral and flexion of the contralateral limb; *f*, stimulation of the left forefoot irradiated to the neck and hind limb, ipsilateral extension and contralateral flexion; *g*, stimulation of the left pinna irradiated to the neck and limbs. (*Sherrington, C. S., "The Integrative Action of the Nervous System," Yale University Press, New Haven, 1926.*)

In the spinal animal, on increasing the strength of the stimulus of a flexion reflex started in a hind limb, the following sequence is observed: (*a*) extension of the contralateral hind limb; (*b*) extension at the elbow, and retraction at the shoulder, of the ipsilateral forelimb; (*c*) flexion at the elbow, extension at the wrist, and a certain degree of protraction at the shoulder, of the contralateral fore limb; (*d*) twisting of the neck toward the stimulated side, with snapping of the jaws and switching of the tail. The animal appears to try to avoid proximity to the stimulus, first by a flexion reflex, which reduced to its minimum consists in the contraction of a few motor units flexing the knee; then by movements of locomotion; and

finally by trying to remove the nocuous agent with its teeth. From the other limbs and the ears similar reflex figures may be evoked.

In the mammal it is easier to obtain irradiation along the spinal cord in a caudal than in a cephalic direction. Movements of the limbs and tail are frequently obtained by stimulating the pinna, but the reverse rarely occurs. Sometimes in the course of irradiation one or more segments are skipped over; from the head the movement spreads to the hind limb without involving the forelimb, or the tail switches while the limbs are still. Reflexes, however, can also spread in the opposite direction, *e.g.*, ear twitching on caudal stimulation.

Crossing over to the opposite side of the spinal cord takes place more easily at certain levels than at others; this varies with the species and with the condition of the animal. Thus, irradiation to the opposite side is more frequent at the level of the hind limb than at that of the forelimb in the dog and the cat. In the frog and toad, spreading from one forelimb to another is facilitated in spring and summer, when the sexual reflex is active. This reflex consists in bilateral flexion of the forelimbs on stimulation of the skin on their internal aspect or on the chest. This response is symmetrical; in other instances irradiation produces an asymmetrical response, *e.g.*, the crossed extension which accompanies the flexion reflex.

Irradiation does not usually take place gradually or smoothly, but by "jumps," because the different allied arcs have approximately the same threshold; therefore when the stimulus is sufficiently strong to activate one of them it soon reaches a level that activates the others. A considerably greater increase in the strength of the stimulus is necessary to excite centers of other reflexes with a higher threshold.

Lloyd[1] has determined the paths and internuncial neurons that take part in long reflexes. This was done by recording the action potentials of spinal nuclei and fiber paths, using extremely fine electrodes inserted in the spinal cord at different levels. Unilateral reflexes (*e.g.*, the scratch reflex) are mediated by the fasciculus proprius in the ventral columns of both sides and the ipsilateral lateral column. Bilateral reflexes (*e.g.*, hand-foot reactions) are mediated by propriospinal fibers on both sides of the cord. Internuncial neurons of these reflexes are grouped in the ventral horn, near the motor neuron (nucleus proprius cornu anterioris). Collaterals of fibers in the ventral column end on the nucleus of the anterior commissure; axons emerging from this nucleus pass through the anterior commissure and converge on the motor neurons of the opposite side. The fasciculus proprius extends into the brain, under the name of "medial longitudinal fasciculus." It is of great importance in reflexes mediated by the cranial nerves.

[1] Lloyd, D. P. C., *Physiol. Rev.*, **24**, 1, 1944.

SUCCESSIVE COMBINATION OF REFLEXES

Reflexes and reflex figures follow each other in orderly sequence. There is no fusion of responses; one reaction replaces another without confusion. This is evident in alternation of antagonistic reflexes. For instance, flexion takes the place of extension because the predominance of c.e.s. and c.i.s. is inverted in the centers. Coordination also occurs when one reflex replaces another with which it is in part allied. For example, when a scratch reflex provoked by stimulation of the anterior part of the receptive field is replaced by a scratch reflex provoked by a stronger stimulus in a posterior part of the field, the rhythmic alternating movements of flexion and extension are not altered, but the postural contraction is changed so that the leg is directed to the spot where the second stimulus is applied, and not to an intermediate spot between the two stimuli.

Factors that condition predominance of a reflex. A predominating reflex may give place to another in certain conditions. The following factors play a part in bringing about a change in the reflex pattern: (*a*) successive spinal induction; (*b*) fatigue; (*c*) relative intensity of different stimuli; (*d*) type of reflex; (*e*) plasticity.

Successive sbinal induction. After a final common path has been used in one sense, the response of a reflex that uses it in the opposite sense is augmented. For example, a crossed-extension reflex is repeatedly provoked at certain intervals. Between two stimuli, another stimulus is applied to provoke a flexion reflex, which has the opposite effect on the motor centers. Crossed extension following flexion is augmented, although the strength of the stimulus has not changed. This augmented capacity of response lasts for some time and disappears gradually. It is not an effect of rest, because it does not occur

Time in secs.

Signal

a

Time in secs.

b
Fig. 384. Successive spinal induction. *a*, "mark-time" reflex (upstrokes correspond to flexion and downstrokes to extension) inhibited by stimulation of the tail; when the inhibitory stimulus ceases the reflex reappears with increased amplitude and quickening of the movements (successive induction). *b*, the same reflex interrupted by removing the stimulus between the two marks; when the stimulus once more acts, the reflex response reappears with the same strength as before (there is no induction). (*Sherrington, C. S., "The Integrative Action of the Nervous System," Yale University Press, New Haven, 1926.*)

when the reflex is not inhibited but merely interrupted by ceasing to apply the stimulus (Fig. 384). The greater response is due to a stronger c.e.s. This mechanism, which has been called "successive spinal induction" or "indirect spinal induction" by Sherrington, facilitates the use of the common path by different reflexes and prevents one afferent path from appropriating a motor center permanently.

Rebound is similar to successive spinal induction. Withdrawal of a stimulus or a sudden reduction in its strength may be followed not by a mere lapse of the response but by an outbreak of fresh activity, which may be in the same direction as before but more considerable, or may be in the opposite direction; *e.g.*, strong contraction follows moderate contraction, or marked relaxation follows less marked relaxation, or contraction replaces inhibition. Rebound has a relatively long latent period, lasts a long time, begins and ends gradually, and is easily inhibited. It is peculiar to the motor centers and is independent of the higher centers, since it is observed in the spinal animal. It is not due to stimuli coming from the active muscles, because it can be observed after deafferentation, nor is a change of tension or length in the muscles a necessary factor. It is marked when the reflex is provoked by stimulating an afferent nerve instead of the corresponding receptor, because excitatory and inhibitory fibers are activated simultaneously and occult reflexes are provoked. On altering the strength of the stimulus, the preponderance of a reflex may vary and the final response is thus changed. Reflexes provoked by normal stimulation of the receptors also show rebound. Thus pressure on the palate and the upper dental arch opens the mouth, partly by contraction of the digastric muscle but principally by inhibition of the temporal and masseter muscles. On withdrawing or diminishing the pressure, the mouth is quickly closed by a sharp contraction of the muscles that raise the jaw. This mechanism plays a part in mastication (see Chap. 36).

Successive spinal induction is important in alternating and rhythmic reflexes and in reflexes that serve to compensate for the effects of a previous reflex.

Fatigue. When an afferent path has had the use of a final common path for some time, it gradually loses its control by "fatigue," in spite of the fact that the motor unit can fully respond to stimulation through another afferent path. The threshold of the reflex increases gradually, and the stimulus becomes subliminal. Local fatigue disappears after a few minutes' rest.

Relative intensity of different stimuli. When several stimuli act simultaneously, the stronger stimulus takes possession of the final common path, but its efficiency gradually diminishes because of local fatigue in the centers and because a receptor discharges impulses at a lower frequency as time passes, in spite of the continuous action of the stimulus (see "Adaptation," Chap. 71). Successive spinal induction also contributes to increase the relative efficiency of a stimulus with respect to another stimulus that has been evoking a response.

Type of reflex. Reflexes that are accompanied by an intense sensation of pain or pleasure ("affective tone") predominate over others of lower affective tone. Thus phasic reflexes produced by nocuous stimuli easily replace postural reflexes. Predominance of this nature is of short duration, because this type of reflex is soon fatigued, and the receptors show marked adaptation. Postural reflexes are easily inhibited, but they can hold a motor path for a long time because they are not easily fatigued, and the corresponding receptors have a moderate degree of adaptation.

Plasticity, *i.e.*, changes in the capacity to transmit impulses caused by previous "experience" (use or disuse) of a synaptic path. Eccles and McIntyre[1] have given a good demonstration of this in monosynaptic reflexes. Two dorsal roots (*e.g.*, the seventh lumbar and the first sacral, on the left side) were cut distal to the ganglion, taking care not to damage the ganglion or the ventral root. Forty days later, *i.e.*, after a long period of disuse of the synapses of the cut roots, these were stimulated and the reflex response was compared with that obtained by stimulation of the corresponding normal roots on the opposite side. Reflex discharges in the ventral roots or motor nerves of the operated side were much smaller than those obtained from the normal side. Posttetanic potentiation gave a smaller enhancement on the operated side, but it had a more prolonged effect. The response from the root immediately rostral to the cut one was larger than from the corresponding root on the intact side, as if some compensatory reaction to the operative disability had developed.

There are many mechanisms for replacing

[1] Eccles, J. C., and A. K. McIntyre, *Nature, London*, **167**, 466, 1951; *J. Physiol.*, **121**, 492, 1953.

one reflex figure by another. When several stimuli are applied at the same time, factors that change preponderance come into play. When they are applied successively, if they produce allied reflexes, immediate spinal induction facilitates the effect of successive stimuli; if they produce antagonistic reflexes, successive spinal induction comes into play.

In certain instances the effect of one reflex acts as a stimulus for another. In swallowing, for example, a reflex sends the bolus into the esophagus and distends it. This distention produces contraction of the circular muscle of the esophagus above the bolus and relaxation below. The bolus therefore progresses, distends a lower segment, and stimulates another reflex.

The possibility of changing the use of a final common path from one movement pattern to another, or from excitation to inhibition, is essential for adaptation to the environment by adequate response to changes that may occur in the environment.

CHAPTER 71

The Mechanism of Sensation

THE ORGANISM COMES into contact with its environment through receptors distributed on its surface; stimulation of these receptors is followed by reactions of adaptation to the outside world. In complex organisms there are also many receptors in the depth of the tissues, which are stimulated by changes within the body. Stimulation of this second type of receptor is followed by reactions that integrate the organism into a coordinated unit. Excitation of the receptors is the initial step in sensation, which is the raw material used by the mind to build up its knowledge of the universe around it and of its own inside world.

Knowledge of the material universe is conditioned—therefore limited—by the competence of the receptors. Man has used his intelligence to increase the scope of his receptors, in order to acquire knowledge of phenomena that do not stimulate them directly. This is done by converting energy set free by these phenomena into other forms of energy that act as stimuli. Thus rays of shorter or longer wavelength than light (less than 330 and more than 900 mμ) do not excite the human photoreceptor; nevertheless accurate knowledge of ultraviolet rays, and of those of even shorter wavelength such as x-rays and cosmic rays, has been obtained. In a similar way infrared rays and rays of longer wavelength, such as those used in broadcasting, have been studied. The natural capacity to differentiate quality and quantity in the stimuli has been considerably increased; thus in optimal conditions the human skin cannot appreciate differences in temperature of less than 0.2°C., while thermoelectric piles can register changes in temperature of 0.0000001°C.

Insufficiency of one sensory apparatus can be compensated by training another. Compensation takes place subconsciously and is remarkably efficient in some cases. Thus in locomotor ataxia, a disease in which deep sensations are lost, the patients can keep their balance as long as they see, because visual sensations compensate for the loss of those from the muscles and tendons, but on shutting their eyes they fall down. Persons who are born deaf (deaf-mutes) learn to speak when they are taught, through visual and tactile senses, how to use their muscles in the complicated movements necessary to articulate words. The blind learn to read the Braille system, in which tactile sensations replace visual ones. Helen Keller, when 19 months old, lost her sight and hearing owing to disease, yet she not only learned to read and write, but was able to acquire a vast amount of knowledge and cultivate her exceptional intellect, mainly on the basis of tactile sensations.

CLASSIFICATION OF THE RECEPTORS

Sherrington has distinguished three divisions in the distribution of the receptors. The deep-lying ones are in what he calls "the *proprioceptive field*, because its stimuli are, properly speaking, events in the microcosm itself, and because that circumstance has important bearing upon the service of its receptors to the organism."[1] The receptors distributed on the surface can be divided into those of the outer surface, the *exteroceptive field*, and those of the inner, or alimentary and respiratory, surface, the *interoceptive field*. This classification has been slightly modified. Proprioceptors, stimulated by pressure, tension, and stretching, together with the exteroceptors, form part of the somatic division of the nervous system. Interoceptors

[1] SHERRINGTON, C. S., "The Integrative Action of the Nervous System," Yale University Press, New Haven, 1926, p. 317.

of the inner surface are visceral receptors, similar to those found in the heart, blood vessels, bladder, and other viscera. These visceroceptors are stimulated by changes occurring in the organism and, with the proprioceptors, give information of internal changes. The different receptive fields can be summarized as follows:

Somatic afferent system { Exteroceptive / Proprioceptive } / Visceroceptive } Interoceptive

Exteroceptors. The exteroceptive field is the richest in receptors, some of which are highly differentiated. Exteroceptors give rise to clearly defined, well-localized sensations, and provoke reactions that usually are conscious. Two groups can be recognized in this field, the *distance receptors* or *telereceptors* and the *contact receptors.*

Distance receptors. Stimulation of this type of receptor gives rise to sensations that are localized, or psychically "projected," outside the organism and referred to the origin of the stimulus. Sight and hearing form part of this group.[1] These receptors have the following characteristics:

1. They are placed in the head, *i.e.*, the highest and most forward part of the body; therefore they come into contact with a great number of stimuli.
2. They are served by a much larger number of afferent fibers than other receptors. Thus the photoreceptor is innervated by approximately a million fibers in the optic nerve, and these form part of secondary neurons, each one of which is connected with several primary retinal neurons. On the other hand all the exteroceptive, interoceptive, and proprioceptive fields of the head, trunk, and limbs are served by little more than half a million afferent fibers, *i.e.*, those of the dorsal spinal roots and the cranial nerves not attached to the distance receptors.
3. They have an extensive representation in the cerebral cortex and appear to be particularly important in the development of the nervous system. According to Sherrington, "the brain is always the part of the nervous system which is constructed upon and evolved upon the distance receptors."[1]
4. They are widely connected with the different parts of the nervous system by many internuncial neurons.
5. Distance receptors evoke reactions that can be complex and widespread, sometimes involving the whole organism. These reactions are of anticipatory nature, preparatory to other final reactions that complete adaptation.
6. The "affective tone," *i.e.*, feeling of pleasure or pain, accompanying sensations evoked from these receptors is usually low, but it may be considerable when they are associated with previous experience of high affective tone.

[1] The receptors of smell and taste are placed on the internal surface, therefore in the interoceptive field; but they are stimulated by outside agents, therefore they are considered as forming part of the exteroceptive field, because they give information about the external environment. Smell has no proper localization; nevertheless by integration with other sensations it is "projected" outside the body. Taste has contact receptors.

Contact receptors. Tactile, temperature, and pain receptors give rise to sensations that are localized on the stimulated receptor; often they have a high affective tone. The response is usually of a terminal nature and completes adaptation.

Proprioceptors. Receptors placed in the depth of tissues, muscles, tendons, etc., evoke less well-defined sensations. The reactions are usually unconscious and are of limited scope, such as the myotatic reflex. Labyrinthine reflexes, which arise in proprioceptive receptors, involve, however, a large number of muscles widely distributed in the organism.

Visceroceptors. Receptors on the internal surface of the body give rise to poorly defined and badly localized sensations. The most important reactions initiated in these receptors take place in the viscera (viscerovisceral reactions) and are usually unconscious. Other responses are carried out by somatic effectors (viscerosomatic reactions), and sometimes the sensitiveness of the outer surface is modified (viscerosensitive reactions).

STIMULATION OF RECEPTORS

Müller's law of specificity of nervous energy. Excitation of a receptor always gives rise to the same sensation, whatever the nature of the stimulus. Thus stimulation of the retina by light gives a sensation of light; stimulation by a mechanical or electrical stimulus also evokes a sensation of light. This fact, known as "Müller's law of specificity of nervous energy,"

[1] SHERRINGTON, *op. cit.*, p. 325.

was clearly stated by the famous German physiologist a century ago. This is due to the termination of the afferent path in the cerebral cortex, as is demonstrated by stimulating any part of the afferent path or the cortical center. Thus stimulation of the optic nerve or pathway, or of the occipital cortex, gives rise to a luminous sensation. This also explains why, after amputation of a limb, the patient refers irritation of the severed nerve endings, and pain thus caused, to the nonexistent limb.

Specific irritability of the receptors. There is an adequate stimulus for each receptor, *i.e.*, a form of energy for which it has a low threshold, while the threshold is high for other stimuli; this is known as the specific irritability of the receptors. The appropriate stimulus for the photoreceptor is light, *i.e.*, electromagnetic waves of 330 to 900 mμ wavelength. Vision is limited on the red side of the spectrum because rhodopsin (visual purple) does not absorb rays of more than 800 to 900 mμ. Ultraviolet rays do not stimulate the retina; they produce fluorescence in the transparent media of the eye. Mechanical vibrations of frequencies between 16,000 and 20,000 per second stimulate the human phonoreceptors. Certain substances in solution are the specific stimuli of the so-called "chemical receptors," *i.e.*, smell and taste. Deformation of the skin stretches or deforms the tactile receptors and acts as their specific stimulus. There are two kinds of temperature receptors; some respond to cooling, and others to warming, of the skin. Any harmful agent that damages the cells stimulates the pain receptors, probably because the damaged cells set free substances (algogenous substances) that irritate the free nerve endings in the tissues. Proprioceptors respond to pressure, stretching, and changes in tension.

QUANTITATIVE RELATIONS BETWEEN STIMULUS AND RESPONSE

Strength of response, measured objectively, *e.g.*, by electrical registration, or subjectively by intensity of sensation, is related to several parameters of the stimulus. Thus there are thresholds for intensity, time, area on which the stimulus acts, and several difference thresholds.

Intensity threshold. The amount of energy required to stimulate a receptor depends on several factors: (*a*) the nature of the stimulus; (*b*) the condition of the receptor; (*c*) the locus of stimulation; (*d*) the species.

The nature of the stimulus. The threshold is low for the specific stimulus and high for other stimuli, *i.e.*, a small quantity of energy is efficient in the first case, while large quantities are needed in the second.

The visual threshold for light has been measured in optimal conditions of adaptation to darkness, with very brief stimuli, of selected wavelength, applied on a small surface of the peripheral retina. For a blue-green light it is 2.1 to 5.7×10^{-10} erg. The 500 rods within the stimulated area absorb 5 to 14 quanta of energy; therefore either a single rod absorbs the total amount, or 5 to 14 rods absorb 1 quantum each. The visual threshold is, therefore, close to the limit imposed by the nature of light, because the receptive cell apparently responds to the smallest particle of energy that exists.[1]

In complex receptors, such as the eye, there are differences in the thresholds for the various kinds of specific stimuli. Thus in the light-adapted eye the green-yellow part of the spectrum is the most luminous. The threshold sensation is produced by 0.0015 watt per lumen (see Chap. 76) of light of 550-mμ wavelength; with other wavelengths greater quantities, in some cases many thousand times this amount, are needed.

The condition of the receptor. The intensity threshold of a receptor does not remain at a constant level but varies in different circumstances. If stimuli very near the threshold strength are applied, the intensity of the sensation varies from one moment to another, as if spontaneous fluctuations in sensitiveness occurred.[2] There are many factors that cause variations in threshold; the following can be mentioned:

1. Simultaneous or previous application of a stimulus raises the threshold for certain stimuli and lowers it for others (see further

[1] Hecht, S., S. Shlaer, and M. H. Pirenne, *J. Gen. Physiol.*, **25**, 819, 1942.

[2] Apparently spontaneous fluctuations in the threshold of visual sensations may be due to the stimulus, because the threshold of this receptor is so low that it is statistically probable that the receptor does not always absorb the same quantity of energy. On the other hand, fluctuations are also observed in auditory sensations. In this case the amount of energy that must be used to obtain a response is such that the influence of the stimulus can be discarded; therefore fluctuations must be due to variations in the sensitiveness of the receptor.

on, "Simultaneous and successive contrast" and "Masking").
2. Adaptation takes place, *i.e.*, certain specific changes in the receptor can lower or raise the threshold considerably; *e.g.*, a dark-adapted eye is sensitive to approximately 0.0000007 millilambert, using achromatic light, while the eye adapted to a luminosity of 2,000 millilamberts is not sensitive to light intensities below 4 millilamberts.
3. Metabolic conditions are also of importance; *e.g.*, deficiency in vitamin A interferes with the formation of visual purple and diminishes sensitiveness to achromatic light. Anoxia and hypoglycemia also increase the threshold of a dark-adapted eye.[1]
4. In old age, sensory acuity diminishes.

The locus of stimulation. A tactile sensation can be obtained with a weight of 2 gm. per sq. mm. on the tip of the tongue; on the palm of the finger tip, 38 gm. per sq. mm. is necessary, and 48 gm. per sq. mm. on the skin of the loins. The different parts of the retina also have different thresholds. This is due to uneven distribution of receptor cells or to variations in the type of these cells in different parts of the receptive field.

Species differences. Sensory capacity varies in different species. Two methods have been used to measure objectively and accurately the sensitiveness of receptors in animals: (*a*) establishment of conditioned reflexes; (*b*) registration of electrical activity evoked by excitation of the receptor. Thus it has been proved that rats are less sensitive than man to sounds of frequencies below 8 kc. (kilocycles) but are more sensitive to sounds of a higher pitch. The lowest threshold is for 20 kc., a pitch almost inaudible to the human ear, and sounds of 40 kc. are well perceived. Bats have an even greater sensitiveness; they can hear ultrasounds of over 100 kc. Vision in man is more sensitive than in the dog, an animal that is almost color-blind. Visual acuity is similar in man, the chimpanzee, and the rhesus monkey; this monkey can distinguish colors almost as well as man, except in the red part of the spectrum, to which it is less sensitive. Many other data on the sensory capacity of animals have been obtained; some of them will be mentioned further on.

[1] Subjects breathing 13 per cent oxygen and injected with 4 units of insulin showed a fourfold increase in threshold (McFarland, R. A., and W. H. Forbes, *J. Gen. Physiol.*, **24**, 69, 1940).

Time threshold. Two time factors must be considered in connection with the stimulation of receptors: (*a*) the time in which the energy change takes place; (*b*) the duration of the constant phase of the stimulus. If the gradient of change is not sufficiently steep, the receptor adapts itself before the threshold can be reached. Utilization time is related to the intensity of the stimulus in the dark-adapted eye ($T \times I = K$) for times less than 0.1 sec. Chronaxie determinations confirm this. In complex receptors there is more than one chronaxie, as each type of cell has its own; thus the peripheral retina has a chronaxie of 1 to 1.9 msec., corresponding to the rods, and the fovea a chronaxie of 2.1 to 2.8 msec., corresponding to the cones.

Area (or size) threshold. A stimulus that acts on a circumscribed area of a receptive field stimulates only one sensory unit or a small number of them; on the other hand, a widespread stimulus excites a large number of units, and the impulses they evoke are summated in the center. Threshold intensity, therefore, decreases as the size of the stimulated surface increases. For example, a source of light must be of a certain size, which must increase as luminosity decreases, for the eye to perceive it. For achromatic light,

$$S \times I = K$$

where S is the area of stimulated surface and I is the luminosity. A tactile sensation can be produced on the skin by light touches if these act on a large surface, but the stimulus must be of greater intensity if it acts on a more limited area.

Difference thresholds. It is possible to discriminate the strength, duration, and other properties of different stimuli. The minimum difference that can be perceived is known as the difference threshold of intensity, time, etc.

Difference threshold of intensity. Weber examined the capacity of the tactile receptor and concluded that to obtain an increase or decrease in sensation it was necessary to increase or decrease the stimulus by a definite fraction of its total strength (Weber's law). The ratio of change varied between 1:10 and 1:40 in different parts of the skin. Thus if a stimulus of 0.9 gm. is distinguished from one of 1 gm. (a ratio of 10 per cent), a stimulus of 10 gm. must be increased or decreased by 1 gm. to produce a stronger or

weaker sensation. The eye distinguishes differences in luminosity of 1:167 (Helmholtz). The ear can differentiate from 1:9 to 1:20 in sound intensity. Fechner has stated Weber's law with greater precision (Fechner's law): above the threshold and up to a certain maximal intensity, sensation is a linear function of the logarithm of the stimulus (Fig. 385). The condition of the receptor modifies its discriminating capacity. Thus when the skin temperature is between 27 and 32°C., differences of 0.2°C. can be distinguished, but at lower or higher temperatures discrimination is not so efficient.
FIG. 385. Fechner's law. Solid line, size of stimulus; broken line, intensity of sensation.

Difference threshold of time. Successive stimuli can be perceived separately if the interval between them is not too short. When the interval is below a minimum, the sensation becomes continuous. The minimum frequency necessary to produce fusion varies from one receptor to another. It is influenced by the condition of the receptor and by the nature and strength of the stimulus. Adaptation (see further on) plays an important part in fusion. Successive mechanical stimuli can be individually perceived up to a frequency of 500 to 600 per second, but faradic stimulation becomes continuous at rates above 120 to 150. The eye has a slow adaptation rate, and threshold stimuli must be repeated at least every 0.25 sec. to avoid flicker; as the intensity of the stimulus increases, the interval must be reduced to obtain complete fusion.

Difference threshold of size. Differences in the size of the surface stimulated can also be perceived. Thus the eye distinguishes the size of objects when they differ by 1:100 if they are compared simultaneously in optimal conditions. Discrimination is less efficient if the objects are seen one after the other. Simultaneous stimulation of two points on the skin gives rise to two separate sensations if the distance between the points exceeds a minimum, which varies from one part of the body to the other (1 mm. on the tongue, 67 mm. on the back). Discrimination occurs only when stimuli act on separate sensory units. On the retina (central vision) the images must fall on separate cones (visual acuity); on the skin, receptors innervated by at least two afferent neurons must be stimulated.

In addition to the difference thresholds already mentioned, there are others, which also condition the analytical capacity of the senses. Thus the ear not only differentiates pitch and quality (timbre) in a sound, but it can also pick out the melody played by a certain instrument in an orchestra and distinguish it from the rest of the symphony. Vision distinguishes brightness, color (wavelength), and color saturation (the amount of white light that "dilutes" the color).

There are considerable individual differences in discriminating capacity. For example, the normal eye can differentiate about 165 chromatic tones; in the yellow region differences of 1 $m\mu$ are perceived, whereas in the red and purple, the variation must be of 6 to 8 $m\mu$ to be appreciated. Certain individuals, however, distinguish fewer tonalities and others are more or less color-blind (see "Color vision," Chap. 76). Experience and education considerably increase the capacity to discriminate; a painter or a musician will perceive fine differences that are not noticed by those who lack an artistic or a musical education.

THE RECEPTOR OR SENSORY UNIT

The motor unit consists of a motor neuron and all the muscle fibers innervated by the branches of its axon; likewise, a sensory unit is made up of an afferent neuron and all the receptors innervated by its peripheral branches.[1] The distribution of these units in a receptive field has been studied by anatomical methods and by registering the electrical potentials in single afferent fibers.[2] For example, in the central part of the fovea in the retina, each bipolar cell is connected peripherally with only one cone and centrally with one ganglion cell. In the peripheral parts of the retina each bipolar

[2] ADRIAN, E. D., and J. ZOTTERMAN, *J. Physiol.*, 61, 151, 1926; ADRIAN, E. D., McK. CATTELL, and H. HOAGLAND, *J. Physiol.*, 72, 377, 1931.

cell innervates several cones or rods; cone units are less extensive than rod units. In the rabbit's skin one afferent fiber innervates up to 300 hair follicles, but each follicle is innervated by at least two nerve fibers and sometimes by as many as seven.[1] The tactile units in the cat's tongue have a diameter of 5 mm., and those of the frog's skin cover 4 to 10 sq. mm. at least. The area of a pain unit has a diameter of 0.75 mm. on the back of the hand in man; it is much smaller on the palmar surface of the fingers, and twice as large on the skin of the forearm. Sensory units on the surface of the frog's viscera cover an area of 2 to 3 sq. cm. or more. On the cornea a unit covers a quadrant and spreads out into the neighboring sclera and conjunctiva, but it does not innervate the whole region in a uniform manner. These examples show that the size of the unit varies in the different receptive fields and sometimes in different parts of the same receptive field.

The receptive fields of neighboring sensory units overlap, so that a given point may be innervated by two or more units. This is demonstrated by cutting a cutaneous nerve. If the nerve is sufficiently large, there will be a region of complete anesthesia, surrounded by another of hypoesthesia, in which sensitiveness increases from the anesthetized to the normal parts. The intermediate region is due to suppression of units belonging to the cut nerve and persistence of units belonging to neighboring nerves that have remained intact.

FIG. 386. Impulses in a single afferent fiber from a proprioceptive receptor in the toe of a frog. *A*, stimulation by stretching the toe with a load of 5 gm.; *B*, 2 sec. after the beginning of stimulation; *C*, 5 sec. after the beginning of stimulation; *D*, at high speed, the outline of the electric variation is invariable. (*Courtesy of Professor E. D. Adrian.*)

Stimulation of single receptors. Adrian and his collaborators studied the action potentials of an afferent nerve after stimulating a single receptor in the field it covered. Responses from a single receptor were also obtained by cutting all but one or two fibers of a nerve and then stimulating the area innervated by this nerve. The first experiments were made on a single proprioceptor of the sternocutaneous muscle of the frog[1] and of a muscle of the middle toe of the same animal;[2] both were stimulated by stretching. Later, single receptors were stimulated in many other receptive fields

A series of impulses follows the application of a single stimulus to a receptor, not merely a single response such as occurs when the nerve is stimulated (Fig. 386). The speed with which the frequency of the discharges reaches a maximum increases with the strength of the stimulus. The maximum frequency also increases in relation to the strength of the stimulus,

[1] ADRIAN, E. D., and J. ZOTTERMAN, *J. Physiol.*, **61**, 161, 1926.

[2] MATTHEWS, B. H. C., *J. Physiol.*, **67**, 169, 1929.

following an exponential curve. For example, if a proprioceptor is stimulated by stretching a muscle, the maximum frequency of discharge increases as the logarithm of the weight used as stimulus. This is in agreement with Fechner's law. The maximum frequency is limited by the refractory period, which is slightly greater than that of the afferent nerve. Factors that modify the refractory period, such as fatigue which lengthens it and heat which shortens it (in the frog), also modify the maximum possible frequency.

Continuous stimulation evokes a discontinuous response. After the first impulse has been fired off a second impulse is discharged as soon as the receptor recovers its excitability sufficiently to respond to the stimulus that is still acting. The threshold is lower for a strong stimulus than for a weak one; therefore it is reached sooner, and frequency of impulses increases with the strength of the stimulus. When impulses are discharged at low rates, the intervals between them are usually irregular; in this case the refractory period has ended, and there is complete recovery between two impulses. The rate of discharge in physiologic conditions is far below the maximum possible.

ADAPTATION

The rate at which a receptor discharges diminishes even when it is stimulated continuously. This decrease is particularly marked in touch receptors, which rapidly cease to discharge; it is less marked in pacinian corpuscles. This is known as adaptation. It occurs at a faster rate with strong stimuli than with weak ones; also after a receptor has been repeatedly stimulated. Adaptation is almost lacking in stretch receptors, which continue to discharge at a low rate for a considerable time (Fig. 387).

Several factors modify adaptation; *e.g.*, the ion equilibrium. Thus, a decrease in Ca^{++} (by means of oxalate) delays adaptation in the touch receptors of frogs. If the calcium concentration falls even more, spontaneous bursts of activity are observed. An increase in K^{+} has the same, while an increase in Ca^{++} produces the opposite, effects.

Adaptation occurs in the receptor itself and not in its nerve fiber. Thus adaptation of a receptor in a sensory unit has no influence on that of other receptors innervated by branches of the same axon. Adaptation may be due in some cases to a progressive loss in the efficiency of the stimulus. For example, mechanical deformation stimulates the tactile receptors on the hair follicles and the pacinian corpuscles; in the hair follicles adjustment to the new mechanical conditions takes place rapidly and the receptor soon ceases to discharge, while it is more gradual in the pressure corpuscles, which therefore continue to discharge for a longer time.
FIG. 387. Adaptation in different receptors. Abscissa, time in seconds. The stimulus is applied continuously. Frequency of discharge from a muscle spindle (top curve) remains high throughout the period of observation; that of a pressure corpuscle (second curve) falls gradually. Tactile corpuscles (third curve) and touch receptors of hair roots (fourth curve) cease to discharge in more or less 1 sec. The nerve fiber (last curve) responds with a single impulse. (*After Adrian.*)

After-discharge. Certain receptors continue to discharge impulses after stimulation has ceased. This is known as after-discharge. It is more marked in proprioceptors, less in pain receptors, and almost nonexistent in touch receptors.

Fatigue. Adaptation must not be mistaken for fatigue. When the receptor is fatigued by repeated and prolonged stimulation, the initial frequency of discharge diminishes and adaptation is more rapidly established. Fatigue occurs sooner with strong and prolonged stimulation, and disappears after a period of rest. Anoxia accelerates the onset of fatigue and retards recovery, but it has no influence on adaptation.

Intensity of sensation. When the strength of the stimulus is increased, the receptors discharge at a higher frequency and more sensory units

are activated. Thus intensity of sensation is conditioned by two mechanisms: (*a*) the rate with which the impulses arrive to the center along a given afferent path; (*b*) the number of afferent paths in activity.

Latent period and reaction time.[1] The latent period of sensation, *i.e.*, the interval between the application of a stimulus and its perception (perception time) can be measured only indirectly. Stimulation of receptors disturbs the α-rhythm in the electroencephalogram of a resting subject (see Chap. 87). This fact has been used to measure the time taken by a stimulus, *e.g.*, a painful stimulus, to produce an effect on the cortex.[2] Since perception is dependent on cortical activity, this method gives a near approach to perception time.

Usually the reaction time is measured, *i.e.*, the interval between the application of a stimulus to a receptor and the response of the subject on perceiving the stimulus. The reaction time to a given stimulus varies considerably from subject to subject, and in the same subject from day to day. The site of the receptive surface on which the stimulus is applied also has an influence on the reaction time. Reaction time to stimulation of a cutaneous tactile receptor diminishes with increasing strength of stimulus and with increasing area of surface stimulated. The relationship in both cases is a logarithmic one,[3] *i.e.*, it follows Fechner's law. Fatigue increases reaction time; repetition of the stimulus, *i.e.*, training, diminishes it.

An important fact made evident by these studies is that *whatever recebtor is stimulated, and whatever stimulus is used, the effect on the afferent nerve is fundamentally the same:* impulses are discharged which can vary in number, rate, voltage of the action potential, speed of conduction, and other details, but they are essentially alike.

SIMULTANEOUS AND SUCCESSIVE CONTRAST

Stimulation of a receptor diminishes the sensitiveness of neighboring parts of the receptive field for the same kind of stimulus and augments it for the opposite kind of stimulus. This explains simultaneous contrasts, which are easily demonstrated in color vision. If a red disk is placed on a white surface, a green halo is seen around it, because the threshold for green is lowered and that for red increased in the proximity of the parts of the retina stimulated by red light, and the green component of white light can be perceived.

After a stimulus has ceased to act on a receptor, the threshold is increased for this kind of stimulus and lowered for the opposite kind. Thus a stimulus when it follows one of an opposite kind evokes a more intense sensation than when it is applied alone (successive contrast). In the example already given, on removing the red disk from the visual field a green patch of the size and shape of the disk is seen on the white surface.

Contrast phenomena are also observed in other sensations. For example, if one hand is submerged in water at 10°C. and the other in water at 38°C., and then after a few minutes both hands are placed in a basin with water at 25°C., the water will seem warm to the hand that has been at 10°C. and cold to the one that has been at 38°C. The receptors for warmth have become hypersensitive in one hand and those for cold in the other.

LOCALIZATION

Sensations have a local sign; they are referred either to some point on the receptive surface, which is not always the place stimulated, or to some place outside the organism, related to the source of the stimulus. In the skin there are spots that are specifically sensitive to different kinds of stimuli (Blix, von Frey), and in the cerebral cortex the different parts of a receptive field have a localized representation. These two facts led to the belief that the local sign of a sensation is due to transmission of the impulses from a receptor, through a definite chain of neurons, to a circumscribed and fixed area in the cerebral cortex. This correlation of points in the periphery with points in the cerebral cortex, through a chain of neurons, exists in the central part of the fovea of the retina, for which there is point-to-point projection in the lateral geniculate body and the occipital cortex. There is, however, a certain degree of overlapping (*i.e.*, the terminals of a given axon end on the somas of more than one neuron, and each soma receives terminals from more than one axon) even in the pathway of foveal vision,[1] which has a very high degree of spatial discrimination.

[1] O'LEARY, J. L., *J. Comp. Neurol.*, **73**, 405, 1940.

Cutaneous and visceral sensory unit fields have been found to overlap and the same probably occurs in other receptive fields. There is convergence and divergence in the centers at all levels. Afferent nerve impulses are, therefore, not transmitted from the receptor to the cortex along a simple chain, each link of which is a neuron, but through complex ramified multineuron chains, in which are interposed closed reverberating circuits of excitation (Fig. 388).
Fig. 388. Diagram of sensory nerve path (highly schematic). There is overlapping of sensory units in the periphery, and convergence, divergence, and internuncial neuron circuits in the spinal cord. A similar architectural plan is found in cortical and subcortical centers.

Functional architecture undoubtedly conditions the local sign of reflexes and sensation, but not in such a simple way as was at one time supposed. Impulses arrive at the centers and eventually at the cortex, not from a single receptor but from several receptors stimulated simultaneously or successively more or less intensely. An excitation pattern is formed which is analyzed at the center, recognized, and localized as a "sensory point."[1] A weak stimulus may activate only one or a few receptors of a single sensory unit; a strong stimulus excites receptors of several units with different intensity. In the first case the sensation is referred to the whole field covered by the unit; in the second, localization is more precise because the overlapping area diminishes in size as the number of units that serve it increases (Fig. 389). Accuracy of localization depends therefore on (*a*) the size of the sensory unit field; (*b*) the number of overlapping units covering a given field; (*c*) the number of units activated, *i.e.*, the strength of the stimulus. Experience, *i.e.*, repeated application of a stimulus, is of considerable importance for accuracy of localization.
Fig. 389. Localization. Diagrammatic representation of sensory fields of three overlapping units. When the receptors of only one unit are stimulated, the sensation is referred to the whole area covered by the unit. When two or three units are stimulated, the sensation is referred to the overlapping areas.

CHAPTER 72

Cutaneous Sensation. Touch, Temperature Senses, and Pain

THE SKIN IS a receptive surface in which there are many nerve endings. In man, these nerve endings are of two types (Fig. 390): (*a*) fine, profusely ramified, nonmyelinated free terminals arising in myelinated or in large nonmyelinated fibers; and (*b*) complex, closely knit, localized endings, surrounded or not by a visible capsule of variable thickness. Among the latter, several different types have been described: the Meissner corpuscles, Krause's end-bulbs, Ruffini's endings, and Merkel's disks, to which can be added the nerve baskets of the hair follicles. Many years ago Ruffini[1] remarked on the great variability of peripheral nerve endings and the difficulty in classifying them. More recent work has confirmed this opinion, showing that there are many intermediate forms "from the simplest to the most complicated, from superficial loosely encapsulated whorls, to the thickly capsulated
FIG. 390. Cutaneous receptors. *a*, Merkel's disks; *b*, Meissner's corpuscle; *c*, nerve basket of hair follicle; *d*, Krause's end-bulb; *e*, free nerve endings in the cornea (*Cajal*); *f*, pacinian corpuscle.

[1] RUFFINI, A., *Rev. gén. d'histol.*, **1**, 421, 1905.

highly complex dermal corpuscles."[1] These "organized nerve endings" are found in the mucous membranes of the mouth, genitals, anus, and the conjunctiva, and in hairless parts of the skin, such as the plantar surface of the foot and the palmar surface of the hand and fingers. They are distributed in two groups, one immediately beneath the epithelium and the other in the dermis 0.5 to 1.5 mm. below the surface. The more deeply placed corpuscles usually have a thicker, apparently noncellular, capsule. In hairy parts of the skin these organized nerve endings have not been found; there are only nerve baskets around the hair follicles and free nerve endings.

The end organs are usually distributed in groups. Each one receives one or two myelinated nerve fibers, which lose the myelin sheath on penetrating into the corpuscle; one nonmyelinated fiber also innervates a group.[2] The nerve baskets of the hair follicles are formed by two to seven nerve fibers, and the same axon sends branches to several follicles. This type of receptor is highly developed in the vibrissae of nocturnal animals, such as cats and rodents.

There are four main modalities of sensation, *i.e.*, touch, cold, warmth, and pain. Several other distinct types of sensation are recognizable, but these are usually considered as produced by special patterns of activation of the nerve endings corresponding to the main modalities, or the combined stimulation of receptors of two or more modalities at various frequencies and intensities. Thus itch is a special type of response to weak stimulation of pain receptors, and vibratory sensation is produced by intermittent stimulation of touch and pressure receptors. Other sensations such as tickling, roughness, smoothness, wetness, tridimensional form (stereognosis), etc., are also complex sensations. "The selection of four fundamental modalities for the classification of cutaneous sensation is a compromise between simplicity and confusion, and between specificity of stimulation and flexibility of central interpretation."[3]

The work of von Frey, Goldscheider, and Blix demonstrated that the skin is a mosaic of sensitive "spots" (punctate sensibility), *i.e.*, that certain parts are highly sensitive to one kind of stimulus, while the areas surrounding them are relatively insensitive. Each modality of sensation has been attributed to a special type of receptor. There is good evidence that this is so in the case of deep sensibility; the muscle spindles and Golgi tendon organs respond to differences in tension, and the pacinian corpuscles mediate pressure sensations. In the skin, movement of a hair stimulates the nerve basket surrounding its follicle, and shaving considerably diminishes sensitiveness to touch. Meissner's corpuscles and Merkel's disks have been considered touch receptors, Krause's end-bulbs cold receptors, and Ruffini's corpuscles warmth receptors. The evidence, however, is far from satisfactory. As has already been mentioned, identification of the different types of end organs is not easy, and some of them may be only artefacts, *e.g.*, Merkel's disks, because these structures are very sensitive to manipulation. Histological examination of the skin where "spots" for touch, cold, or warm sensation had been localized by previous stimulation has not given consistent results. Moreover, cold and warm sensations can be evoked from parts of the skin (lips, ear, abdomen) where only free nerve endings and nerve baskets of hair follicles have been found. Therefore, no exclusive association between a specific form of nerve ending and a specific modality of cutaneous sensation can so far be considered as certain.

The sensibility of the skin varies considerably from one part to another, depending on the number of receptors. A high degree of sensitiveness to one modality of sensation does not necessarily coincide with an equivalent degree of sensitiveness to another. Stimulation of a single spot, however, may arouse different sensations according to the type of stimulus applied, either because the spot contains receptors corresponding to two or more modalities, or because different patterns of stimulation are applied to the same receptor; *e.g.*, weak stimulation of pain endings provokes "nonpainful" sensations, such as itch.

TOUCH

Touch is the modality of sensation aroused by mechanical deformation of the skin. Meissner showed that, when a finger is submerged in mercury, a sensation is felt only at the level of

[1] Sinclair, D. C., G. Weddell, and E. Zander, *J. Anat.*, **86**, 402, 1952; Hagen, E., H. Knoche, D. C. Sinclair, and G. Weddell, *Proc. Roy. Soc., London, s.B.*, **141**, 279, 1953.

[2] Weddell, G., *J. Anat.*, **75**, 441, 1941.

[3] Bishop, G. H., *Physiol. Rev.*, **26**, 77, 1946.

the surface between air and mercury, where there is deformation of the tissues, and not over the rest of the finger, where there is uniform pressure. Touch cannot always be clearly distinguished from light pressure, *i.e.*, the persisting sensation aroused by the application of mechanical force to the skin over a wider area than that necessary to provoke touch sensations. There is therefore considerable ambiguity in the interpretation of touch and light pressure sensations. Some authors consider that they are different stimulation patterns of the same modality of sensation (touch-pressure); others, that they are two separate modalities. Pressure in this case is not considered a cutaneous sensation in the strict sense of the term, because it is mediated by the pacinian corpuscles situated in the inner layers of the dermis, the subcutaneous tissues, and other deep structures, such as the subperitoneal tissue, tendons, periosteum, etc.

FIG. 391. Cutaneous unit areas. Above, *A* and *C*, unit touch areas with strong stimulus; *A′* and *C′*, with weak stimulus; *C″*, with threshold stimulus. *B*, unit touch areas with 0.0001 mf. stimulus; hair shafts; high spot for touch. Three of the areas overlap; above the fourth area there is a space insensitive to touch with three hair shafts sensitive to touch. E_1, single touch area containing no hair shafts; E_2, three touch areas with · high spot in two of them to which the sensation is referred; E_3, area around isolated hair shaft (*hs*); *pp*, pain points; *tp*, touch point; $\odot$, hair endings. Stimulation of the touch point with the threshold for touch also stimulated the adjacent pain point. Over the pain point itself the pain threshold was much lower. (*Bishop, G. H., J. Neurophysiol., vol. 6, p. 361, 1943.*)

Sensory thresholds. There are several methods for stimulating touch receptors. One of the oldest is von Frey's, which consists in touching the skin with a hair mounted on a wooden handle. The length and thickness of the hairs vary so that different weights are needed to bend them, and the force exerted on the skin can thus be measured. Hensen used glass-wool thread instead of hair; nylon threads of standard thickness have also been used. When touch is explored by lightly stroking the skin with the loose strands of a wad of cotton wool (Head's method) or a camel-hair brush, only qualitative results are obtained. Bishop[1] has used high-voltage low-current sparks to stimulate single sensory units without deforming the skin. By means of this method he has mapped out the areas covered by touch and pain units in regions with many receptors of different types. This method was combined with anesthesia of small cutaneous nerve branches. Small units were thus isolated in which a single sensitive point was found surrounded by an insensitive area[2] (Fig. 391). The size of the area covered by one unit varies in different species and in different parts of the skin, *e.g.*, 5 sq. mm. in the cat's tongue and 100 sq. mm. in the skin of the frog. There is considerable overlap among the areas of different units.

[1] BISHOP, G. H., *F. Neurophysiol.*, **6**, 361, 1943.
[2] BISHOP, G. H., *F. Neurophysiol.*, **7**, 71, 1944.

Certain regions have a very low touch threshold, *e.g.*, the tip of the tongue, lips, nose, and the balls of the fingers. The dorsal aspect of the hand and forearm have a considerably higher threshold than the palm and the anterior aspect of the forearm. The skin of the back, loins, and lateral aspect of the thighs has a very high touch threshold. The number of receptors is much larger and the size of the sensory unit much smaller in the more sensitive parts than in the less sensitive ones.

Difference thresholds. Regions that have a low intensity threshold also have low difference thresholds. A difference in intensity of sensation can be perceived on the lips and forehead if the strength of the stimulus varies by one-fortieth or one-thirtieth, while the change must be of one-tenth to be recognized on the thigh, shin, or foot.

Spatial discrimination (two-point discrimination) is explored by means of Weber's compass. When its two blunt points are applied to the skin, they are separated by a distance sufficiently large for them to be perceived as separate points of contacts. The distance is then reduced until a single sensation of contact is aroused. Spatial discrimination varies considerably from one region to another. Areas with a low intensity threshold also have a low two-point threshold, but variations in the two thresholds are not strictly parallel (Table 93). Spatial discrimination can be increased (*i.e.*, the distance between two points at which a double sensation is perceived can be reduced) by

Table 93. Distance between Two Stimuli Needed to Obtain Separate Touch Sensations

Area	*Distance, mm.*
Tip of tongue	1.1
Palmar surface of the finger	2.3
Back of the third phalanx	6.8
Palm	11.3
Back of the hand	31.6
Neck	54.0
Arm, thigh, back	67.1

searching out touch spots. Thus on the ball of the fingers it is only 0.1 mm. in some places. The two-point sensibility of the skin is, however, far below that of the eye.

Fusion, i.e., a continuous sensation, is not aroused by intermittent mechanical stimulation at rates below 500 per second; each stimulus is perceived separately. On the other hand fusion occurs at rates between 130 and 150 per second when induction shocks are applied to the skin.

Fatigue and old age diminish sensitiveness to touch, especially the capacity to discriminate.

Adaptation. Touch receptors show a high degree of adaptation and have no after-discharge. Thus, nerve baskets around the hair follicles cease to discharge after a few seconds of continuous stimulation. This fact explains in part why the clothes are not felt unless they are displaced by movement and thus excite receptors that have been quiescent. Nerve baskets of the vibrissae of nocturnal animals do not adapt so rapidly, and they continue to discharge impulses during several minutes.

Localization. Touch sensations are fairly accurately referred to the point stimulated (within 1 cm. on the forearm). Localization is conditioned by experience. Aristotle's observation is a remarkable demonstration of this fact; if two fingers are crossed so that the sides normally separated face each other, an object that touches both of them at the same time is felt as if it were double. Accuracy of localization and discrimination can be increased by training, as occurs in blind people. There is also, to a certain extent, the capacity to "project" the sensation outside the organization, as when a surgeon explores a cavity with a probe. The affective tone of touch is very high and usually of a pleasurable nature. Rapid adaptation prevents intense stimulation from becoming disagreeable.

TEMPERATURE SENSES

There are two temperature senses; certain spots in the skin are sensitive to cold, others to warmth. Thermal receptors are sensitive to the temperature of the skin and its changes, provoked by variations in the temperature of the environment or changes in the circulation of the skin; thus, blushing arouses a sensation of warmth and cutaneous vasoconstriction one of cold.

Bazett and his associates[1] have measured with thermocouples the rate of penetration of heat through the skin and correlated it with latency of sensation. They conclude that receptors for

[1] Bazett, H. C., Temperature Sense in Man, in "Temperature, Its Measurement and Control in Science and Industry," Reinhold, New York, 1941.

cold are placed superficially and those for warmth more deeply, approximately at the levels at which Krause's and Ruffini's corpuscles, respectively, are found. In the cat's tongue cold receptors are placed close beneath the epithelium, as has been shown by measuring the latency of spike potentials evoked in cold fibers in the lingual nerve and simultaneously recording the temperature changes in the tongue.[1]

There are spots for cold and warmth in the skin. The former are more numerous than the latter; it has been estimated that there are 250,000 cold spots and 30,000 warm spots. Cold spots are distributed in clusters, covering areas with irregular contours, which are separated by zones where there is little or no sensitiveness to cold. In man there are more cold spots per unit of skin surface in the thorax and upper limbs than on the lower limbs.[2]

Many factors, such as changes in the circulation and in the temperature of the skin, alter the apparent number of receptors. Thus, on raising the temperature of the skin from 25 to 33°C. the cold spots were found to increase from four to five times.[3] This has been attributed to an increase in the number of receptors that respond at the higher temperature, or to a higher rate of discharge from the receptors, which would thus reach the central threshold of sensation. Local injections of acetyl-β-methylcholine or prostigmine increase, and of adrenaline or atropine decrease, the number of cold spots significantly.[4] Acetylcholine injected into the cat's tongue increases the rate of constant discharge of cold receptors and their response to a fall in temperature.

Stimulation of receptors. Thermal receptors can be stimulated by means of tubes of small bore through which water at different temperatures is kept circulating. More precise methods of stimulating with constant temperatures or changes in temperatures, and recording the temperature of the stimulated area with thermodes, have been devised.[5] Receptors for

[5] Hensel, H., and Y. Zotterman, *J. Neurophysiol.*, **14**, 425, 1951.

warmth can be stimulated by irradiation with heat rays, measuring the radiant energy necessary to evoke a sensation.[1]

Cold receptors discharge continuously when they are maintained at a constant temperature below a certain level, as is shown by records of spike potentials in the afferent fibers of the cat's tongue. This stationary threshold temperature varies for individual receptors; some may discharge at a low rate at 41°C., but for the majority the threshold lies between 35 and 40°C. The maximum frequency, about 10 impulses per second, is observed between 25 and 35°C.[2] At lower temperatures frequency of discharges diminishes gradually until between 10 and 15°C. a secondary peak two-thirds of the maximum frequency appears. The discharges cease (cold paralysis) when the temperature of the thermode on the tongue falls to 10 to 12°C. If the temperature is raised above 45°C., the cold receptors also discharge, frequency of discharge increasing to seven to eight per second at 50°C. (paradoxical cold).[3]

Warm receptors also discharge when maintained at a constant temperature. Above 47°C. (occasionally 50°C.) and below 20°C. no discharges were observed; maximum frequency (three to four impulses per sec.) occurred at 37 to 40°C.

A sudden fall in temperature causes a rapid increase in the rate of discharge of cold receptors up to a maximum (140 impulses per second) over ten times the frequency of the continuous discharge. The rate of discharge then falls and remains at a constant level dependent on the constant temperature level. If the receptors are rapidly warmed, they cease to discharge; and after a time, if the final temperature is lower than the upper threshold for constant discharge, the impulses reappear. This postexcitatory depression is dependent on the rate of warming and the temperature level; if warming takes place very slowly, the discharge does not cease but continues at a lower level.

A sudden rise in temperature stimulates receptors for warmth; there is an initial rise in the rate of discharge and a fall to a lower constant

[1] Herget, C. M., L. P. Granath, and J. D. Hardy, *Am. J. Physiol.*, **134**, 645; **135**, 20 and 426, 1941.
[2] Hensel, H., and Y. Zotterman, *Acta physiol. Scandinav.*, **23**, 291, 1951.
[3] Dodt, E., and Y. Zotterman, *Acta physiol. Scandinav.*, **26**, 358, 1952.

frequency if the constant temperature level lies between the temperatures at which this is observed. A sudden fall of 8 to 15°C. may cause discharge of a "paradoxical" burst of impulses. Rapid cooling of nerve fibers can stimulate them and evoke spike potentials; this discharge has the same short latency and time course as that of paradoxical warmth,[1] so it is possible that this sensation is caused by stimulation of superficially placed fibers innervating receptors for warmth.

In man changes of outside temperature evoke a sensation if they occur at a certain rate.

The threshold for cold is a fall of 0.004°C. per sec.; for warmth it is a rise of 0.001°C. per sec. In both cases the change must last at least 3 sec. if a very small area is stimulated. Stimulation of a larger area lowers the threshold,[2] probably because a greater number of receptors are stimulated simultaneously and there is summation of their effects. Sensations evoked from receptors situated far from each other can also be summated. When the entire body surface is stimulated, a rise in skin temperature of 0.0008°C. per sec. produces a sensation of warmth.[3] Certain workers make a distinction between warm and hot sensations and determine the threshold for each. Perhaps there are two types of receptor stimulated by an increase in skin temperature, one with a low threshold, which gives the sensation of warmth, the other with a high threshold, which gives the sensation of heat. Temperatures above 45°C. stimulate simultaneously receptors for warmth, cold (paradoxical cold), and pain; the sensation "hot" could therefore be due to a complex pattern of stimulation involving several types of receptors, while stimulation of the receptors for warmth alone by a small increase in skin temperature might give the sensation of warmth. Receptors for warmth soon cease to discharge at temperatures above 45°C.; therefore it has been suggested that the sensation "hot" is initiated by stimulation of warmth receptors and paradoxical stimulation of cold receptors but is maintained by impulses from cold and pain receptors.[4] Observed facts can thus be explained without having to suppose the existence of two types of receptor for warmth and heat, for which there is no morphologic foundation.

[3] OPPEL, T. W., and J. D. HARDY, *J. Clin. Investigation*, **16**, 525, 1937.

[4] DODT, E., and Y. ZOTTERMAN, *Acta physiol. Scandinav.*, **26**, 345, 1952.

There are considerable regional differences in sensitiveness to changes in temperature. Parts of the skin that are usually covered by clothing, such as the chest and abdomen, are more sensitive; the nose is more sensitive than the cheeks, and the anterior aspect of the forearm is more sensitive than the dorsal one. The mucosa of the mouth has a high threshold; it can be submitted to temperatures (*e.g.*, hot drinks) that are painful to the skin. The conjunctiva, the margin of the cornea, and the genital mucosa are sensitive to cold but not to warmth. Heat applied to these mucosae evokes an unpleasant sensation, which becomes definitely painful if the intensity of the stimulus is increased. The esophagus, stomach, and rectum are sensitive to extreme temperatures (cold or hot), but other viscera and tissues are not sensitive to changes in temperature.

Sensitiveness to temperature changes is modified by several factors. The most important seems to be the condition of the circulation in the skin. If the circulation is stopped, an increase in temperature well below the maximum tolerated by the normal skin becomes intolerable. When the blood is circulating, it carries away heat, and the rise in temperature is thus less than when the circulation is stopped. CO_2 increases sensitiveness to heat. Menthol lowers the threshold of cold receptors and increases that of warm receptors, so that the slightest movement of air, which produces a loss of heat by the skin, gives rise to an intense sensation of cold. Acetylsalicylic acid lowers the threshold for warmth.[1]

Difference thresholds. An increase in the intensity of cold or warm stimulation of the skin produces an increase in the intensity of sensation according to Fechner's law,[2] up to a certain strength of stimulus. Stronger stimuli evoke painful sensations; this occurs when cooling or heating act as noxious stimuli and set free algogenous substances which stimulate pain receptors. With radiant heat the threshold for pain is reached when irradiation is increased to approximately

[1] WICKLER, A., H. GOODELL, and H. G. WOLFF, *J. Pharmacol. & Exper. Therap.*, **83**, 294, 1945.

[2] HARDY and OPPEL, *loc. cit.*

2,000 times the energy required to evoke the threshold sensation of warmth. There are about ninety steps of intensity of sensation distinguishable between the thresholds for warmth and pain.

The difference threshold of intensity is at a minimum when the temperature of the skin is between 27 and 32°C. When the skin is either very cold or very warm, a change of several degrees is needed for temperature differences to be appreciated.

The difference threshold of surface for radiated heat is approximately 3 sq. cm. on the skin of the forehead.

Adaptation. Cold and warmth receptors undergo rapid adaptation, and if the temperatures are not extreme the sensation of cold or warmth soon diminishes.

Contrast phenomena are intense, as is commonly experienced on passing from a warm to a cold environment or vice versa.

The sensory image usually persists for a short time; a cold or hot coin placed on the skin is still felt for a few moments after it has been removed, even though skin temperature begins to rise or fall as soon as the stimulus has ceased to act.

Localization. Cold and warm sensations are referred to the receptor, and there is fairly good localization of the area stimulated. There is very little "projection" into the environment.

The affective tone is usually high; moderate stimuli produce pleasurable sensations. Strong stimuli damage the cells and stimulate pain receptors.

Reactions to cold and heat. (See Chap. 48 and "Hypothalamus," Chap. 84.) Stimulation of the receptors for cold provokes a series of reactions which diminish loss of heat from the body, such as constriction of the arterioles and reduction of blood flow through the skin, erection of cutaneous hair, etc. If cooling is sufficiently marked and prolonged, heat production increases owing to increased muscle tonus and shivering.

Stimulation of the receptors for warmth produces another series of reactions which increase loss of heat, such as cutaneous vasodilatation with an increase in blood flowing through the skin, sweating, etc.

These reactions have a higher threshold than the threshold for the corresponding sensation of cold or warmth.

PAIN

Pain is a conscious state in which there is a more or less high affective tone of unpleasantness, which increases to distress when it becomes more severe, accompanied by reactions that tend to remove or evade the cause that provokes it. Physical pain is produced by alterations in the structural or functional normality of the organism. Sensitiveness to pain is greatly developed in the skin and also exists in other tissues, but in some tissues there are no receptors for pain, and they can be damaged or even destroyed without giving rise to it.

Pain is a specific modality of sensation. At one time it was considered that strong stimulation of any receptor evoked pain. This is not so; the tactile receptors of the skin can be stimulated so as to produce discharges of maximum frequency in the afferent nerve, without any of the reactions typical of pain.[1] A strong stimulus applied to a differentiated receptor can provoke pain if it produces damage and thus acts on specific pain receptors. Certain sensory organs, *e.g.*, Meissner's corpuscles, are innervated not only by a myelinated fiber, which conducts tactile impulses, but also by a fine unmyelinated fiber, which might be the receptor and conductor of pain impulses in response to a strong stimulus.

The specific nature of the sensation of pain has been fully demonstrated by the following observations: (*a*) pain alone, and no other sensation, is evoked on stimulating certain areas of the skin in which there are free nerve endings and no other type of receptor,[2] whereas areas where there are no free nerve endings are insensitive to pain, and a needle can be stuck into the skin without causing pain; (*b*) stimulation of certain structures elicits pain sensations only, *e.g.*, the pulp of the teeth, the arteries of the brain, the middle meningeal and the temporal arteries, etc;[3] (*c*) accidental or surgical transection of certain tracts of the spinal cord suppresses pain without loss of other modalities of sensation (see Chap. 74); (*d*) analgesic drugs may raise the threshold of pain, without modifying other sensory thresholds.[4]

Receptors. Pain is provoked by the stimulation of free nerve endings, which have been carefully studied in the cornea (Fig. 390*e*) and in the skin.[1] A cutaneous area is innervated by myelinated nerve fibers approaching it from all directions to form the cutaneous nerve plexus. Fibers in the plexus ramify but do not fuse with one another. Branches from one fiber may innervate many receptors, but these are all of the same type. The fibers for pain emerge from the plexus and give rise to fine ramifications or nerve nets, which emit free nerve endings, often beaded in appearance. These nerve nets are found mainly at two levels; in the deeper layers of the epidermis and in subepidermal tissues near the blood vessels. Some of the nerve nets are connected to myelinated, and others to nonmyelinated, fibers. Differentiated cutaneous receptors, such as Meissner's corpuscles, Krause's end-bulbs, etc., are supplied not only with their "specific" fiber, but also with a fine fiber similar to those of nerve nets.

The area covered by a sensory unit of pain varies in different parts of the body. Thus a single nerve net in the human forearm has been found to be 7.5 mm. in diameter, and one in the thumb pad of the monkey only 1.5 mm. (Weddell). In the cornea one fiber may supply a whole quadrant, *i.e.*, an area approximately 1 cm. in diameter. There is a considerable amount of overlapping of the territories of the different units and of the areas innervated by different cutaneous nerves and dorsal roots.
Fig. 392. Areas innervated by sensory spinal roots. *A*, cutaneous areas (dermatomes), according to Foerster; *B* and *C*, deep areas, according to Kellgren. (*Lewis, T., "Pain," Macmillan, New York, 1942.*)

The dorsal spinal roots supply innervation to the skin in overlapping bands, called "dermatomes," which do not coincide with the areas innervated by peripheral nerves, these being made up of fibers from several dorsal roots. Sherrington first delineated the territories of the dermatomes in the cat by severing three roots above and three below the intact root to be studied; a sensitive segment was thus isolated

[1] Weddell, G., *loc. cit.; J. Anat.*, **75**, 346, 1941; **77**, 49, 1942.

between two areas of complete anesthesia. The dermatomes were found to overlap considerably, so that any point in the skin was innervated by two or even three dorsal roots. A similar dorsal-root distribution has been found in the monkey and in other species.

Table 94. Distribution of Sensitiveness to Pain

Sensitive Structures	*Insensitive Structures*
Skin	
Superficial mucosae: conjunctiva, nasal, buccal, anal, genital	
Muscles, tendons, fasciae	
Periosteum, synovial membranes	Bone
Perivascular tissues	Blood vessels
Intracranial structures:	Intracranial structures:
Tissues around arteries and sinuses	Dura
	Pia and arachnoid
Dura near the large meningeal vessels and sinuses	Cerebral parenchyma
	Ependymal canal
Origin of fifth, ninth, and tenth nerves	
Pleura (parietal and diaphragmatic)	Pleura (visceral)
	Lung
Base of fibrous pericardium	Pericardium, visceral and parietal serous membranes
Myocardium (ischemia)	
Subperitoneal tissue (parietal and diaphragmatic)	Esophagus (except to distention)
Mesentery (perivascular tissues)	Peritoneum, omentum
	Liver, spleen, kidneys
Pancreas, duodenum, hepatic pediculum	Stomach, intestine, colon, rectum*
Ureter, renal pelvis	Bladder
Periovarial tissues	Ovary, uterus, vagina
Peritesticular tissues	Testes

* Distention and contractures provoke pain.

Observations made in cases of herpes zoster (a virus infection of the posterior-root ganglia, commonly known as "shingles") and in patients in whom dorsal-root section was necessary for therapeutic reasons[1] have shown that in man also there is a dermatomal distribution. The root segments can be fairly well distinguished in the trunk (Fig. 392*A*). They slope downward and spread out from the dorsal to the ventral surface. In the limbs, especially in the lower limb, the dermatomes are not so clearly discernible, because several spinal segments concur in each limb, but there is also a dermatomal distribution of the nerve fibers.

[1] Foerster, O., *Brain*, 1, 56, 1933.

The dermatomal area of pain is smaller than that of temperature, the largest being that of touch. Dermatomal charts are by no means accurate; nevertheless, they give a general idea of dorsal-root distribution.

Cutaneous dermatomes do not coincide with the distribution of the dorsal root in the deeper structures (Fig. 392*A*, *B*, and *C*). Kellgren[1] has studied this distribution by injecting 0.3 cc. of a 5 per cent NaCl solution in the interspinous ligament, a procedure that elicits short-lasting pain referred to the territory innervated by the corresponding root.

Distribution of sensibility to pain. Pain sensitiveness is most developed in the skin but is not limited to it; other structures, listed in Table 94, are also sensitive to pain. Trauma evokes little or no pain in somatic muscles, but when they contract in conditions of ischemia a sustained pain is felt, the intensity of which is related to the amount of work performed by the muscle. The heart can be handled and cut without pain, but ischemia due to occlusion of a coronary artery produces the intense pain of angina pectoris. The digestive tract is also insensitive to trauma and can be cut and burned without provoking any sensation, but distention of the esophagus or any part of the gastrointestinal tract and strong contracture of the stomach or the intestine (colic) can be very painful.

Sensory threshold. Pain can be provoked by many different agents; mechanical, thermal, electrical, chemical, etc. The receptors are apparently anelective. "But it is to be remarked that these agents, regarded as excitants of skin-pain, have all a certain character in common, namely this, that they become adequate as excitants of pain when they are of such intensity as threatens damage . . . and they are all able to excite when applied to naked nerve directly."[2] Free nerve endings are an adequate mechanism for this type of excitation, in which there must be a response to a great variety of stimuli. A differentiated receptor, with specific irritability, would be less well adapted to such an end.

Pain can be investigated by recording either the sensation of pain or reactions to painful stimuli, such as a defense reflex, a muscle twitch, etc. In the first case the subject gives a verbal

[1] Kellgren, J. H., *Clin. Sc.*, 4, 35, 1939.

[2] Sherrington, C. S., "The Integrative Action of the Nervous System," Yale University Press, New Haven, 1926, p. 227.

report of his sensations, and unless special precautions are taken, subjective differences in appreciation may have great influence on the results. The subject should be instructed in the procedure to be used for the determination of the threshold. He should be in a condition of objective attention and free from fear of harm or great suffering. Apprehension may alter the results to a considerable degree, and voluntary or involuntary inattention, such as is produced by an intercurrent stimulus, raises the threshold.

"The pain threshold sensation may be defined as the lowest perceptible intensity of pain. The pain threshold stimulus is the amount of stimulus required to induce threshold pain,"[1] and it is most conveniently stated in terms of physical energy, *e.g.*, the force of a prick, voltage of an electric current, concentration of a caustic substance, radiant energy of heat, etc. A method commonly in use is to prick the skin with varying strengths; there are special appliances (algometers) that permit fine graduation of the force used. This method deforms the skin and therefore may stimulate touch receptors at the same time.

Bishop[2] has used high-voltage and low-current sparks to stimulate the receptors without deforming the skin. He has thus been able to excite separately touch and light-pressure corpuscles, the receptors attached to hair follicles, and cold receptors, but not the more deeply placed warmth receptors. Pain, with this method of stimulation, has a lower threshold than touch, except on the finger tips. With weak stimuli a painless prick, surrounded by an aura of itching, is felt after a relatively long latent period; this becomes a prickling pain when the strength of the stimulus is increased.

Radiant heat has been used to stimulate pain receptors.[3] The results are expressed in gram-calories per square centimeter per second. With weak stimuli a sensation of warmth is felt, which increases with the strength of the stimulus and sharply changes to one of pricking pain when the pain threshold is reached. This threshold is about 1,000 times the radiant energy needed to produce the minimum sensation of warmth.

Bishop[4] points out that three thresholds may be recognized when pain endings are stimulated: (*a*) a nondescript threshold contact sensation; (*b*) a sharp prick, perceived as painful, but without emotional protest; (*c*) reaction to pain manifested by defense reflexes and emotional protest.

The pain threshold is fairly constant in the same individual if there are no disturbing factors. The pricking-pain threshold provoked by radiant heat applied to the forehead remains constant within ± 3 per cent on successive determinations in the same individual. Daily variations were found to be within ± 8 per cent, and sometimes the same threshold was maintained for several weeks. Individual differences were not great (± 15 per cent). Young people seem to be more sensitive to pain than the aged. There is a significant correlation between the threshold of skin pain provoked by radiant heat and that of visceral pain provoked by distention of the esophagus; persons highly sensitive to one kind of pain are also highly sensitive to the other.

Factors that cause variations in pain threshold. Psychic factors are of great importance in pain and may exert considerable influence on the pain threshold.

Autosuggestion and external suggestion, such as is produced by giving a substance with supposed analgesic properties (placebo) and by hypnosis, may increase the threshold sufficiently to make painless the action of agents that destroy the tissues. Suggestion and autosuggestion can also lower the threshold; thus the lowest thresholds observed have been found in cases of hysteria. One of Hippocrates' aphorisms states that, if two pains occur together in different parts of the body, the stronger weakens the lesser. In persons suffering spontaneous or previously provoked continuous pain, the threshold for cutaneous pain is raised.

Damage to the skin that diminishes the thickness of the epidermis, sunburns, inflammatory processes, etc., lower the pain threshold. On the other hand, thickening of the epidermis (callosities, etc.) raises it.

Analgesic drugs raise the pain threshold. If sufficiently intense pain is experienced early in the course of the action of an analgesic agent, the pain threshold is not raised much above the normal, but the reaction to pain is considerably diminished, *i.e.*, the subjects perceive pain but remain indifferent to it.

[1] Wolff, H. G., and J. D. Hardy, *Physiol. Rev.*, **27**, 167, 1947.

[2] Bishop, G. H., *J. Neurophysiol.*, **6**, 361, 1943.

[3] Hardy, J. D., H. G. Wolff, and H. Goodell, *J. Clin. Investigation*, **19**, 649, 1940.

[4] Bishop, G. H., *Physiol. Rev.*, *loc. cit.*

There is no peripheral spatial summation of pain. The threshold does not vary with the surface of skin irradiated; after the minimum area has been exposed, the threshold is not reduced, nor does the sensation increase on irradiation of a larger surface, but the discomfort is greater as the irradiated surface increases.

Approximately twice the threshold energy for pain is needed to cause tissue destruction; the organism is thus warned of the imminence of damage. Wolff and Hardy point out that "there is no need in the body economy for a wide range of experience between the onset of pain and tissue damage since with the first pain impulses the organism receives warning that the limit of safety has already been passed."[1]

Hyperalgesia. Two different phenomena are included under this term: (*a*) lowering of the threshold; (*b*) an increase in the intensity of pain sensation. They can occur simultaneously or separately.

Mechanical trauma, burning, freezing, irritating substances, ultraviolet rays, etc., produce, after a period ranging from a few seconds to several hours, a triple response: (*a*) capillary dilatation; (*b*) arteriolar dilatation; (*c*) local edema, accompanied by spontaneous pain and by hypersensitiveness (low threshold and increase in response) to pain-producing agents (friction, cold, warmth, etc.). The area of redness and hyperalgesia extends farther than the damaged tissue, especially when the injury is severe. When no visible lesion has been produced, the condition is known as "erythralgia," because of the redness caused by vasodilatation of the hypersensitive area.[2] If there is no spontaneous pain, it is easily awakened by increasing the tension of the skin, *e.g.*, by stretching it with the fingers, or warming it up to 32 to 34°C., or hindering the circulation. Rubbing immediately produces intense pain of short duration, followed after an interval of 15 sec. by another pain which increases gradually and lasts longer. If the circulation is stopped, the second pain is more severe and prolonged. Apparently it is produced by algogenous substances set free by friction (see "Mechanism of excitation," further on).

These facts are of importance in the treatment of cutaneous pain. The patient should be placed so as to avoid tension of the damaged skin. Excessive warmth must also be avoided, so as to keep the skin below the critical temperature. All contacts and friction should be carefully prevented. Immobilization in a plaster cast, leaving the injured area uncovered, has been used successfully in the treatment of pain caused by burns.[1]

[1] Wolff and Hardy, *loc. cit.*
[2] Lewis, T., *Clin. Sc.*, **1**, 175, 1933–1934.

Discrimination in intensity of pain. Subjective intensity of pain varies considerably from one person to another. There are no data to support the idea that this variation is due to anatomic or physiologic individual differences such as a greater or lesser number of receptors, differences in the resistance to agents that set free algogenous substances, variations in these substances, etc. Injury of the same type and severity produces many and loud complaints from some individuals and is well tolerated by others; the psychic factors are of predominant importance.

By means of the radiant-heat method of provoking pain it is possible to demonstrate the capacity to discriminate the intensity of pain in relation to strength of stimulus.[2] Applying stimuli ranging in intensity from the threshold (218 μcal per sec. per sq. cm.) to 45 per cent above (480 μcal per sec. per sq. cm.), 21 just-noticeable differences of pain intensity can be distinguished. Differentiation of intensity is not possible if stronger stimuli are applied.

Adaptation. There is a certain degree of adaptation in pain receptors, but much less than in touch and thermal receptors. The *duration* of pain varies considerably; it is often of great use in the clinical diagnosis of the cause of pain. Figure 393 shows diagrammatically the time-intensity curve of several types of pain.

Quality of pain. The quality of pain can be expressed only vaguely and in terms of the cause that most frequently produces it. Two types of cutaneous pain have been distinguished since Gad and Goldscheider first pointed them out in 1892. One type of pain has a pricking quality; it begins and ends abruptly, it is fairly well localized, and there is good discrimination in the degrees of intensity. The second type has a burning quality; it is slow in onset, recedes more slowly, and is more diffuse and less well localized than pricking pain. By means of the thermal-radiation method the threshold of "burning" pain was found to be 13 per cent lower than the threshold for "pricking" pain.[3] Pricking pain

[1] Zeno, L., *Rev. Asoc. méd. argent.*, **57**, 854, 1943.
[2] Wolff and Hardy, *loc. cit.* (quotation from Hardy, Goodell, and Wolff).

is felt more rapidly ("first" or "quick" pain) than burning pain ("second" or "slow" pain). The impulses of the former are conducted by fibers at the rate 10 to 90 m. per sec., and those of the latter by slow-conducting C fibers (see Chap. 74). The second type of pain is similar to deep pain arising in the viscera and deep-lying structures, such as the joints and muscles (see Chap. 73).

CONTINUOUS PAIN, FLUCTUATING
FIG. 393. Diagrams illustrating time-intensity curves of pain. (*Lewis, T., "Pain," The Macmillan Company, New York, 1942.*)

The conjunctiva, cornea, and nasal and genital mucosae have a pain sensibility of the second (burning) type. These structures are hypersensitive to pain. They also have cold receptors, but they are insensitive to warmth.

Section of the descending root of the trigeminal nerve produces analgesia in the territory it innervates, but has little effect on sensitiveness to touch. In the cornea mechanical stimuli are no longer painful, but arouse a tactile sensation. Therefore it is possible that, in normal subjects, hypersensitiveness to pain masks the sensation of touch. If this is so, free nerve endings would act as touch receptors, since in the central part of the cornea there are no other nerve structures, and in the periphery there are only free nerve endings and Krause's end-bulbs.

Localization. Pricking pain in the skin and the mucosae of the mouth and anus is well localized. The error is less than 1 cm. on the hand. Accuracy in localization is not due to the simultaneous touch sensation, as it persists after touch has been suppressed by ischemia. Localization is less precise in mucosae with pain sensibility.

Pain reaction. Perception of pain is often, but not always, accompanied by reaction to pain, which has psychic, somatic, and visceral components. The emotional state evoked by pain consists in aversion to, and a protest against, pain; an intense desire to avoid or suppress the cause of pain; and fear. Somatic reactions to pain are of two types: (*a*) increase of muscular activity, manifested by defense reflexes and the "fight or flight" pattern of behavior, often accompanied by vocal protest; (*b*) depression of muscular activity (quiescence) together with localized contractures, immobilizing the painful parts of the body. The first type of somatic reaction is associated with increased activity of the sympathicoadrenal system, *i.e.*, tachycardia, cutaneous and abdominal vasoconstriction, hypertension, mydriasis, hyperglycemia, etc. Visceral reactions characteristic of the second type are bradycardia, hypotension, nausea, and vomiting ("sickening" pain). Sweating is common to both. The first type of reaction is usually observed in response to pain evoked from the skin; the second is associated with deep somatic or visceral pain. Painful stimulation may cause a decrease in urinary output by two different mechanisms: (*a*) renal vasoconstriction, evoked reflexly or by a humoral mechanism (sympathin, adrenaline), since it persists after denervation of the kidney;[1] (*b*) increased secretion of posterior hypophyseal antidiuretic hormone.[2]

Perception of, and reaction to, pain are often dissociated. Pain may be perceived without causing a reaction, *e.g.*, during combat, games, sexual excitement, or mystic experience, or in patients suffering from traumatic shock, certain lesions in the brain (*e.g.*, after frontal lobotomy), or psychic disturbances. Many of the components in the reaction to pain can be voluntarily suppressed, *e.g.*, vocal protest, and some of the somatic defense reflexes. In this case visceral reactions persist and may produce syncope. Certain drugs, such as ethyl alcohol and morphine, depress the reaction to pain. Wolff and his associates[3] have analyzed bodily reactions to pain by measuring changes in the electrical

resistance of the skin on the palm of the hand, and by observing wincing, as revealed by narrowing of the eyelids. These "alarm" reactions are much more variable than the pain-perception threshold. Drugs, psychic conditions, etc., may increase or lower the threshold of reaction, without significantly altering the pain-perception threshold.

Mechanism of excitation. Free nerve endings, *i.e.*, pain receptors, are stimulated directly by the many noxious agents (mechanical, chemical, etc.) that cause pain.

Tension is a frequent cause of pain; *e.g.*, when a hair is pulled the pain is due to tension exerted on the nerve endings, pulsating pain is produced by distention of the tissues at each systolic wave, and the immediate relief felt on opening an abscess is due to release of tension.

The free nerve endings sensitive to pain are also stimulated by a chemical factor released when the cells are injured. The following facts support this statement:

1. When a muscle contracts after its circulation has been stopped, pain develops and increases in intensity until movement is no longer possible. The intensity of pain depends on the amount of work done, and if contraction ceases it does not increase, but persists at the same level as long as ischemia is maintained. It disappears in 3 to 4 sec. after the circulation has been reestablished. Contraction produces an "algogenous" substance, which diffuses into the interfibrillar spaces and excites the free nerve endings.[1] In normal conditions this substance is removed as soon as it is produced and does not reach the concentration needed for stimulation of nerve endings. Intense and prolonged exercise leads to accumulation of the substance and thus to lowering of the pain threshold, and the muscles feel sore. Anoxia alone is not the cause of pain; there must also be contraction of the muscle. Anoxia plays a necessary part, however, as is shown by the fact that contraction becomes painful if the muscles are supplied with anemic blood (lack of oxygen carriers) or with blood that is poor in oxygen as a result of breathing air with a low oxygen partial pressure. In this case there is no vascular spasm; on the contrary, asphyxia causes vasodilatation. Nevertheless, vascular spasm can produce pain on contraction of the muscles, because it reduces the blood supply. Obstruction of a blood vessel has the same effect. Angina pectoris is caused by thrombosis or spasm of a coronary artery; the heart continues to beat (contract) in spite of the deficient circulation, and an intense pain is felt which persists until the circulation improves.
2. Mechanical stimulation (rubbing, hitting) of an area of hyperalgesia immediately provokes pain of short duration, followed 15 sec. later by a second pain of longer duration.[1] If the circulation is stopped the second pain persists. Ischemia alone can provoke it, and it disappears when the circulation is restored.

[1] Lewis, T., G. W. Pickering, and O. Rotschild, *Heart*, **15**, 359, 1929; **16**, 1, 1931.

The *chemical nature* of this algogenous substance (Lewis's P factor), which can be extracted from a piece of traumatized skin, is yet unknown. Perhaps there is more than one such substance. It is not a protein, nor is it acetylcholine, histamine (which causes itching), or lactic acid.

Effects of denervating the skin. Section of a cutaneous nerve, if the severed trunk is sufficiently large, produces complete anesthesia over a certain limited area, surrounded by an area of hypoesthesia involving all types of sensation, in which sensitiveness decreases progressively from the normal skin to the central area of complete anesthesia. In the intermediate zone the sensory units of the cut nerve have been destroyed, but those of other nerves still remain and are responsible for the remnant of sensibility. When the nerve regenerates, sensitiveness increases gradually. Touch and pain are recovered first, together with cold; warmth is recovered only later. The threshold is higher, but the response (intensity of sensation) is greater and is referred to the periphery, *i.e.*, to the site where the receptor is normally situated. These abnormal qualities in sensation are possibly due to stimulation of naked fibers growing out into the denervated area.[2]

Head and Rivers,[3] analyzing experiments of cutaneous denervation performed principally on Head himself, distinguished two types of sensibility.

[1] This second pain, due to liberation of a chemical factor, should not be mistaken for the second pain due to slow-conducting fibers.

[2] Trotter, W., and H. M. Davies, *J. Physiol.*, **38**, 134, 1909.

[3] Head, H., and W. H. R. Rivers, *Brain*, **31**, 323, 1908; Head, H., "Studies in Neurology," vol. 1, London, 1920.

One was considered phylogenetically old, and included pain and the extremes of temperature (below 20 and above 37°C.); they called it "protopathic" sensation. The other, more recently developed, permits fine discrimination in tactile and thermic sensations; they called it "epicritic" sensation. According to Head, protopathic sensation is integrated in the thalamus, and epicritic sensation in the cerebral cortex. Normally the former is overshadowed by the latter, but denervation suppresses epicritic sensibility in the intermediate zone, where only protopathic sensibility persists; during the period of regeneration this latter type is recovered first. Head's observations, based on a rather small number of cases, have been confirmed only in part. Confirmation is lacking for some fundamental aspects needed to support his theory of the two sensibilities, which is not generally accepted.

Congenital analgesia. Pain, in spite of its importance as a defense mechanism and in the building up of the mental world, is not indispensable for survival or for an apparently normal physical and mental life. Several cases of congenital absence of sensitiveness to pain have been described.[1] These subjects did not feel pain when stimuli such as pricking and burning were applied to the skin, when the esophagus was distended, when muscles were made to contract in conditions of ischemia, or when the testes were compressed (although this provoked nausea), nor did the injection of histamine provoke headache (see Headache, Chap. 73). Noxious stimuli did not provoke the usual psychic and physical reactions that accompany pain; the subjects did not complain, the majority of defense reflexes were absent, and the psychogalvanic reflex (increase of sweat secretion) brought about by emotional stress was also missing. Some of the simpler defense mechanisms persisted, such as the corneal reflex, tear secretion on irritation of the nasal mucosae, and the pressor reflexes to cold. Tactile, temperature, and proprioceptive sensations were normal, but there was no sensation of itching. These subjects behaved in respect to pain as if they were under light ether or chloroform anesthesia. The pain mechanism seemed to be disconnected from the cortex, because the reactions that required cortical integration were missing. There are no anatomic data that permit localization of the disturbance in these cases.

Itch.[1] This is a disagreeable sensation that induces scratching of the part where it is felt. It is originated exclusively in the epidermis and cannot be provoked where the epidermal layers have been removed. Less well localized than touch and pain, it has a tendency to irradiate and to persist after the originating stimulus has ceased to act, and its degrees of intensity are not well differentiated.

Itching is associated with the sensation of pain:

1. It has the same features as deep pain (diffuseness, poor localization, and poor discrimination in the degrees of intensity).
2. Agents that provoke a triple response also produce itching. If they are weaker, a tickling sensation is felt; if they are stronger they are painful.
3. When there is dissociation of the different modalities (due to disease, local anesthesia, asphyxia of the nerve, or any other cause), pain and itching disappear or are reestablished at the same time.
4. When there is complete analgesia, itching is not felt. Loss of touch without analgesia does not entail the loss of itch.
5. Itch varies independently of the temperature senses.
6. Bishop[2] has provoked itching by stimulating pain fibers without deformation of the skin, by means of high-frequency low-intensity stimuli. Stronger stimuli provoked a prick sensation; if they were repeated at adequate intervals, they were followed by a sensation of itch.
7. Stimuli that provoke tickling, itching, and the second pain produce nerve impulses in slow-conducting fibers (Erlanger and Gasser's C fibers).[3]
8. Nerve impulses provoked by itching are conducted in the spinothalamic tract together with the pain impulses. Itch and pain in cases of anal or vaginal pruritis are suppressed by section of these tracts.

Itching is apparently due to the liberation of a substance similar to histamine (H substance). Intracutaneous injection of histamine produces itching only, if care is taken not to damage the

tissues. Lewis[1] maintains that the chemical agent responsible for itch (H factor) differs from that of pain (P factor). He does not agree with von Frey and Rothman that tickling, itching, and pain are simply increasing degrees of intensity of the same sensation. Pain and itch can be separated from each other when they exist simultaneously by immersion of the skin in water at 40 to 41°C.; itching promptly ceases, but pain is intensified.

Incompletely denervated skin areas are the site of intense itching, which produces violent scratching, leading to injury of the skin. If one or more dorsal roots in the cervical region in cats are severed, ulceration and loss of hair due to scratching are provoked in the borderline areas, which are incompletely denervated so that there are intact fibers from the trigeminal nerve or the following uncut dorsal root. When the head and neck are protected by a leather helmet there are no skin lesions, but as soon as the helmet is removed, the animal scratches violently and the observer can see the skin lesions being produced.[2]

Cortical localization of itch is probably the same as that of pain (parietal lobe). Psychic factors have great influence on itching, both in provoking it (phobias) and in suppressing it.

Adrenaline and ephedrine quickly suppress the itching of urticaria, probably by their effect on the local process that sets free the H factor. Bromides and barbiturates diminish itching by acting on the cortex and the subcortical nuclei, respectively. Bile salts and morphine can provoke intense itching. Morphine acts on the nerve centers, probably on the medulla, below the acoustic nucleus.

Tickling. There are two kinds of tickling. One is produced by deep pressure repeated at adequate intervals in certain regions (armpits, thighs, etc.). The other, known as "skin tickle" is provoked by applying an intermittent light stimulus to the skin, or successive stimulation of adjacent spots at a low intensity. Skin tickle has been attributed to simultaneous excitation of touch and pain receptors,[1] because tickling cannot be provoked (*a*) after pain has been suppressed by section of the spinothalamic tract or of the descending root of the fifth (trigeminal) nerve, operations that suppress pain but do not disturb touch sensations; (*b*) after touch sensations have been suppressed although sensitiveness to pain persists; *e.g.*, when the circulation to a limb is arrested, touch is lost first and pain only later, but tickling is lost together with touch.

The prickling sensation felt when the circulation is stopped apparently arises in receptors situated deeply under the skin.

CHAPTER 73

Visceral and Deep Somatic Sensations

SENSATIONS IN THE deep tissues may be classified as visceral or somatic, according to the structures in which they arise. Visceral sensibility is not so well developed as somatic sensibility; its impulses seldom enter the field of consciousness, and when they do, the sensations are not well localized. There is, however, no essential difference between the two types of sensibility; the same laws are valid and the structural basis is the same for both. The myelinated and unmyelinated sensory fibers of the viscera arise in neurons situated in the spinal and cranial sensory ganglia.

The visceral and somatic systems are closely associated functionally. Stimulation of visceral afferent fibers provokes reactions in (*a*) viscera (viscerovisceral reactions); (*b*) muscles (visceromotor reactions); (*c*) superficial and deep parts of the body's frame (viscerosensitive reactions). On the other hand, stimulation of somatic afferent fibers may provoke responses from the viscera (somatovisceral reactions). Visceral functions are regulated by these reactions. The heart rate, the blood pressure, the secretions and motility of the digestive tract, etc., are controlled partly by reflexes (considered in detail in the respective chapters). Sensory impulses initiating these reflexes travel in fibers that, with few exceptions, form part of the visceral nerves. Usually these impulses do not awaken conscious sensations, except in particular cases, such as hunger and thirst, evacuation of the rectum and bladder, genital reflexes, etc., in which the complete response is integrated by reflex and voluntary somatic movements.

Lesions in the viscera and disturbances in visceral functions in certain cases provoke pain (visceral pain). Impulses thus originated travel to the centers, in afferent fibers often included in sympathetic, and in a few cases in parasympathetic, nerves. Painful impulses arising in the internal aspect of the body wall, in muscle and other somatic structures, will be considered here together with visceral pain.

There are also deeply placed somatic receptors—in connection with the skeletal muscles, tendons, and joints—sensitive to changes in tension and pressure. They form part of the proprioceptive system which regulates the activity of somatic muscles.

VISCERAL AND DEEP SOMATIC PAIN

It is a well-known fact that the parenchyma of the viscera, even of the brain, is not sensitive to handling. In the course of surgical operations made under local anesthesia, the viscera of conscious subjects have been not only handled but also cut and cauterized without arousing any sensation. The viscera, however, are not completely insensitive; the membranes that cover them, the supporting tissue, neurovascular pedicles, and visceral muscles may give rise to localized or irradiated pain, which is often referred to parts of the body distant from the site of the disturbance. This pain is accompanied by reflex visceral and somatic reactions, and by cutaneous hyperalgesia and deep tenderness in definite areas, which vary according to the organ from which the pain arises. Visceral pain is provoked by (*a*) sudden distention, due to congestion or to the accumulation of fluid or gas in hollow viscera; (*b*) traction on the pedicles; (*c*) muscular contraction in conditions of ischemia; (*d*) irritation by chemical agents (algogenous substances) produced by inflammatory processes.

Characteristics of visceral and deep somatic pain. There is no essential difference between pain arising from the viscera and that arising from the deep somatic structures. Both

have an aching quality, both are more or less diffuse and poorly localized, and in both the phenomenon of referred pain can be observed. Pain having all the characteristics, including the reactions, of visceral pain can be aroused by stimulating somatic tissues. Thus, Lewis and Kellgren[1] reproduced the pain of angina pectoris by injecting 0.5 cc. of hypertonic (5 per cent) NaCl solution into the first thoracic interspinous ligament on the left side. Subjects who had suffered from anginal pain could not tell the difference, except for the local pain provoked at the site of the injection. The pain of renal colic was reproduced by injecting hypertonic saline into the first lumbar interspinous ligament, or into the abdominal oblique muscle at the level of the first lumbar dermatome. Pain identical to that of intestinal colic was provoked by injecting hypertonic saline into the rectus muscle of the abdomen.

Localization. In some cases pain is felt in the organ in which it arises (splanchnic pain); *e.g.*, the hepatic pain of a congested liver, deep retrosternal pain of angina pectoris, toothache, earache, etc. The pain, however, is more or less diffuse and localization is always poor.

Deep somatic pain is fairly well localized when it arises from tissues near the body surface, *e.g.*, superficial fascia or tendons, periosteum of bones under the skin such as the tibia, walls of the body cavities (thorax and abdomen), etc. When it arises in deeply placed structures, such as the belly of a muscle, it is diffuse and is often referred to a distant area.

Two factors are of importance for localization of sensory phenomena: (*a*) the extent of cortical representation; (*b*) previous experience of the sensation. The cortical representation of viscera and deep somatic structures is very poor compared with that of the cutaneous surface or of the great cephalic receptors. Moreover, impulses arising in the viscera seldom attain the level of consciousness; there is therefore very little experience of visceral sensation, while exteroceptive impulses are continually awakening sensations. These facts give a reasonable explanation for the poor localization of visceral and deep somatic pain.

Referred pain. Pain localized in a region distant from the site of its origin is known as "referred pain." It is commonly observed in all forms of deep pain, both visceral and somatic. The pain is not well localized but is diffuse and referred to different parts of the dermatome in which it arises; in some cases, when it is particularly severe or prolonged, it may spread to the whole dermatome or even to neighboring dermatomes.

The areas of the deep dermatomes do not coincide with those of the skin dermatomes (see Chap. 72, Fig. 392). Kellgren has determined their distribution by injecting hypertonic saline into the interspinous ligament. Deep-pain areas are concentrated near the mid-line on the ventral and dorsal aspects of the body, and those of the lower cervical, upper thoracic, lumbar, and sacral roots extend far into the corresponding limb. Irradiation and sites of reference of the principal forms of visceral and parietal pain will be considered later.

The mechanism responsible for referred pain and the reactions of deep pain has been the subject of much discussion. Sturge, in 1883, attributed cutaneous hyperalgesia of angina pectoris to increased irritability of the spinal centers caused by the abnormal impulses arising in the heart. Later Head and MacKenzie[1] developed this conception of the "irritable focus" in order to explain referred pain and the reactions of pain. According to MacKenzie, impulses from the viscera normally do not arrive at the cortex but remain at the spinal level. Abnormal impulses create an "irritable focus" so that normal impulses coming from the skin and other structures are "facilitated," *i.e.*, there is summation of abnormal visceral with normal somatic impulses which thus reach the cortex. The sensation aroused is referred to the corresponding cutaneous area, from which impulses habitually come, and not to the viscera, from which impulses are seldom sent. Increased focal irritability would also account for the reactions of pain, such as muscular rigidity, vasomotor and secretory responses, etc. Normal impulses from the muscles and viscera would summate with the abnormal visceral impulses and the corresponding reflexes would be facilitated (Fig. 394).

Hyperalgesia and muscular contracture often persist after the pain has ceased. This fact and certain observations on cutaneous hyperalgesia led Lewis to doubt the existence of the "irritable focus." According to Lewis, hyperalgesia

[1] KELLGREN, J. H., *Clin. Sc.*, **3**, 182, 1937–1938; LEWIS, T., and J. H. KELLGREN, *Clin. Sc.*, **4**, 47, 1939.

[1] MACKENZIE, "Symptoms and Their Interpretation," 2d ed., Shaw and Sons, London, 1912.

is due to liberation of a chemical agent in the sensitive area, which lowers the threshold of pain receptors. The origin of the impulses that release this substance is unknown. Lewis has postulated the existence of special "nocifensor" fibers in the posterior roots, but there is no anatomic evidence to support this hypothesis. Another possibility is the discharge of "antidromic" impulses in the afferent fibers of the dorsal roots (see Chap. 69), but they have as yet not been demonstrated.

Reflex reactions to pain may, in certain cases, be an extra cause of pain; thus, prolonged muscular contraction causes soreness and deep tenderness in the affected muscles. Peripheral changes in areas situated far from the original site of pain can, however, only prolong or increase pain; they cannot account for the initial sensations and reactions. Summation of abnormal visceral impulses with the normal stimulation of the skin is probably the main cause of hyperalgesia.
FIG. 394. Diagrams illustrating interpretations of visceral reflexes: *a*, Sturge's and MacKenzie's theory of the "irritable focus"; *b*, the "convergence-projection theory."

An adequate explanation of referred pain is given by the "convergence-projection theory" (Ruch). There is a certain degree of overlapping of the spinal endings of cutaneous and visceral fibers; therefore, some spinothalamic neurons receive impulses from the skin and the viscera. These impulses are transmitted to cortical centers and the sensation aroused is interpreted in the light of the most frequent experience, as coming from the corresponding cutaneous area. Splanchnic pain, *i.e.*, pain localized in the organ in which it arises, is caused by impulses traveling along "visceral" spinothalamic fibers (Fig. 394).

Reaction to visceral and deep pain. Cutaneous pain provokes reactions which form part of the "fight or flight" pattern of response. Deep pain, especially visceral pain, is accompanied by (*a*) cutaneous hyperalgesia; (*b*) tenderness in deep tissues; (*c*) sustained contraction, which immobilizes the painful parts (defense reflexes); (*d*) cutaneous vasoconstriction (paleness) and other vasomotor reactions, which may produce hypertension if the pain is not severe but which cause hypotension and collapse (syncope) if the pain is intense or prolonged; (*e*) nausea and vomiting (sickening pain); (*f*) sweat and other secretions.

Surgical treatment of visceral pain. Visceral pain, when it is severe and prolonged, can be treated by surgical methods, because its nerve paths can be cut without provoking serious disturbance in visceral function. The following methods are used: (*a*) denervation of the organ or region by cutting the nerves in the vascular pedicle, in which case the arteries must be stripped of periarterial tissue; (*b*) extirpation of the sympathetic chain in the region where the pain fibers of the diseased area enter into this chain (*e.g.*, the stellate and upper thoracic ganglia for the heart), or extirpation of the parasympathetic, where the pain fibers are included in this system (*e.g.*, the pelvic nerve, for relief of pain in pelvic structures); (*c*) section of the corresponding dorsal roots (rhizotomy); (*d*) section of the spinothalamic tract (cordotomy).

Abdominal Sensibility

The free nerve endings of somatic nerves branching in the subperitoneal tissue are pain receptors. Pressure on the parietal peritoneum, therefore, awakens pain which is fairly well localized and accompanied by cutaneous hyperalgesia and contraction of the abdominal wall muscles over the stimulated area. The peritoneum lining the diaphragm has the same sensibility as the diaphragmatic pleura, *i.e.*, the peripheral part is innervated by the intercostal nerves and the center by the phrenic nerve. Pain arising in the periphery is referred to the base of the thorax and the upper part of the abdominal wall on the affected side, over an area covered by the dermatomes of the seventh to twelfth thoracic roots. Pain arising in the central area is referred to the shoulder and lower part of the neck (dermatomes corresponding to the third, fourth, and fifth cervical roots).

The omentum is apparently completely insensitive; the peritoneum covering the duodenum and pancreas, on the contrary, has exquisite sensibility. Traction on the mesentery and stimulation of the mesenteric blood vessels or perivascular tissue cause intense pain referred to the epigastrium and the umbilical region.

The digestive tract from the esophagus at the level of the cricoid cartilage down to the anus is relatively insensitive. In conscious patients in the course of surgical operations it has been handled and cut or cauterized, without awakening pain, if care was taken not to pull on the gut. Pain can be aroused from the upper part of the esophagus and the anal canal by application of mechanical stimuli, and cutting the esophagus near the cardia may give rise to a sensation of heartburn. Certain lesions, such as ulceration of the stomach or duodenum and inflammation of the appendix, give rise to intense pain. Sudden distention or intense contraction of the gut at all levels causes pain (colic) which is referred to the epigastrium or the supraumbilical region when it arises in the stomach or small intestine and to the infraumbilical region when it comes from the large intestine. The pain is felt toward the midventral line, even when the affected gut is situated laterally, because the digestive tract develops in the embryo from median and not from lateral structures. Appendicular pain is at first referred to the epigastrium and the umbilical region. Later, when the inflammatory process has invaded the parietal peritoneum, it is localized in the right iliac fossa.

Pain fibers from the stomach form part of the major splanchnic nerves and enter the spinal cord in the dorsal roots from the sixth to the ninth thoracic segments, mainly in the seventh and eighth. Those of the small intestine also form part of the splanchnic nerves but enter the cord

at a lower level (ninth to eleventh thoracic segments). The preaortic plexus and lumbar sympathetic chain include pain fibers from the colon, which enter the cord at the level of the twelfth thoracic and first lumbar segments. Afferent fibers to the rectum are included in the pelvic nerves, and they enter the spinal cord at the level of the second to fourth sacral segments.

Stimulation of the digestive tract by adequate stimuli provokes digestive secretory and motor reflexes, which normally do not enter the sphere of consciousness (see Sec. IV, Digestion).

The parenchyma of the liver, kidney, and spleen can be handled, cut, cauterized, or crushed without evoking any sensation. Parenchymatous lesions of these organs are painless. Sudden distention by vascular congestion, such as occurs in liver stasis of cardiac insufficiency, is painful; the impulses probably arise from the fibrous capsule of the liver, owing to sudden stretching. Gradual distention of the capsule by hepatic hypertrophy, tumors, or hydatid cysts is not painful.

The pedicles of these organs are sensitive to pain. Thus distention or inflammation of the gall bladder and bile ducts is very painful and provokes severe reactions (nausea, vomiting, contraction of the upper right quadrant of the abdominal wall, etc.). The gall bladder, however, can be cut or cauterized without evoking pain.

Pain fibers from the bile ducts and gall bladder are found in the major splanchnic nerves. They enter the spinal cord with the dorsal roots of the sixth to the ninth thoracic nerves.

The renal pelvis and ureter and the neck of the bladder are sensitive to pain, which is provoked when these structures are distended. Renal "colic," such as is caused by renal stone, consists of intense pain in the lumbar region irradiated down the flank to the scrotum. The cremaster is contracted and the testicle is raised. The testicle is hypersensitive to pressure, and there is an area of hyperalgesia extending slightly below the area of referred pain. The pain fibers of the kidney and urethra form part of the major and minor splanchnic nerves; they enter the cord at the level of the twelfth thoracic and the first and second lumbar segments.

Pain fibers for the fundus of the bladder form part of the superior hypogastric plexus and enter the cord in the lumbar segments. Those for the neck of the bladder are innervated by fibers in the pelvic nerve (parasympathetic), which enter the cord at the second to fourth sacral segments. Pain from the bladder is referred to the suprapubic region, the perineum, and the penis.

Sensibility of the Heart and Blood Vessels

In the adventitia and media of the arch of the aorta, the innominate artery, and the carotid sinus, there are differentiated receptors, similar to the Golgi-Mazzoni organs of the tendons, which respond to changes in tension. These receptors are innervated by the aortic nerve (de Cyon and Ludwig's depressor nerve), the fibers of which form part of the vagus in man, dog, and other species, and Hering's sinus caroticus nerve, which is a branch of the glossopharyngeal. The cells of these fibers are in the sensory ganglia of the vagus (g. nodosum) and glossopharyngeal (g. petrosum) respectively, and they end in the sensory nuclei of the vagus and glossopharyngeal (nucleus of the tractus solitarius) in the medulla. When the walls of the aorta and carotid sinus are stretched, as occurs when the arterial blood pressure rises, the tension receptors discharge impulses along the afferent fibers at a rate proportional to the degree of tension, and reflexes are provoked that cause a fall in blood pressure and transitory apnea (see "Vascular reflexes," pages 195 and 296).

Fibers of the aortic and sinus caroticus nerves also end in the aortic and carotid body respectively. These bodies are chemoreceptors sensitive to changes in the chemical composition of the blood, such as variations in the partial pressures of oxygen and CO_2, pH, ionic equilibrium, certain drugs, etc. When these nerve endings are stimulated, cardiovascular and respiratory reflexes are provoked (see pages 195 and 296).

Certain fibers of the vagus nerve end around the roots of the large veins in the right auricle. These fibers are sensitive to changes in venous and auricular pressure. Thus an increase in venous pressure causes an increase in heart rate (Bainbridge's reflex), and a fall in pressure, such as occurs when there is severe hemorrhage, stimulates the vasomotor center, and prevents a fall in arterial blood pressure.

The intima of the arteries is insensitive to most stimuli. Pain evoked by intra-arterial injection of caustic substances does not arise in the arteries but in the periphery. Manipulation of the arteries is painful because of trauma to

the nerves surrounding the artery. In the neighborhood of the mesenteric arteries there are pacinian corpuscles which are stimulated by distention of the arteries, and impulses are thus discharged along afferent fibers included in the splanchnic nerves.[1] The rate of discharge is related to the degree of distention. The response may be an increase or a fall in blood pressure.

Most of the afferent nerves contain fibers that on stimulation evoke pressor reflexes. There are also fibers in the nerves of the blood vessels, skin, and viscera that on stimulation provoke a reflex fall in blood pressure through vasodilatation in the splanchnic area. To observe their effects the pressor fibers must first be depressed by cooling the nerves, or weak stimuli must be applied.

The normal activity of the heart evokes no sensations. Vigorous cardiac activity, such as occurs during physical exercise or emotional stress, or an abnormally fast rate (paroxysmal tachycardia), or a strong contraction, such as the one following an extrasystole, may be perceived and is usually referred to the thoracic wall, the epigastrium, or the lower part of the neck. These sensations do not arise in the heart but in the thoracic wall. The heart itself is insensitive to manipulation and to trauma, and even severe lesions of the endocardium are painless, but ischemia due to spasm or thrombosis of a coronary artery causes the painful syndrome known as angina pectoris (see page 161). It consists of intense pain, accompanied by a sensation of anguish and imminent death. There is deep retrosternal pain, which radiates to the upper part of the left side of the thorax and down the inner aspect of the left arm to the left hand, also up the neck to the angle of the jaw. A sensation of thoracic constriction and marked precordial oppression occurs as a result of contraction of the intercostal and retrosternal muscles (visceromotor reaction). Skin over the painful area is hypersensitive (viscerosensitive reaction), and there are several visceral reactions such as constriction of the blood vessels of the face and neck, sweating, salivary secretion, etc. (viscerovisceral reactions). The painful impulses of angina pectoris are conducted by fibers of the middle and lower cardiac nerves, which pass through the middle cervical, stellate, and upper thoracic sympathetic ganglia to the dorsal roots of the first five or eight thoracic nerves (Fig. 81, page 161). The pain of angina pectoris is temporarily relieved by anesthetizing with novocaine the stellate ganglion and the upper thoracic sympathetic chain down to the fourth or fifth thoracic segment. It is permanently abolished by extirpation of these nerves. The pain is not felt even when there is severe or fatal coronary thrombosis, but the nonpainful reactions, such as dyspnea, vasoconstriction in the skin of the face, palpitations, etc., persist because these reactions are mediated by fibers other than those conducting pain impulses.

On the other hand, stimulation of the stellate ganglion reproduces the pain of angina pectoris.

The mechanism of anginal pain is similar to that of pain provoked by the contraction of skeletal muscle after the circulation has been stopped. Here also there is probably accumulation of metabolites which stimulate the free nerve endings in the myocardium (see "Pain—Mechanism of Excitation," page 887).

The visceral and parietal pericardium are completely insensitive, except for the lower part of the fibrous pericardium, where stimulation provokes pain and cardiovascular reflexes. The pain of pericarditis is due to tension in those cases in which the effusion greatly distends the pericardium (dull precordial pain and oppression) or may be due to disturbances of the coronary circulation (anginal pain) or to extension of inflammatory lesions to the parietal pleura.

Pulmonary and Pleural Sensibility

The parenchyma of the lung and the visceral pleura are insensitive to manipulation and to trauma, but there are stretch receptors that respond to variations in tension and provoke respiratory reflexes (see "The Hering-Breuer reflex," page 292), innervated by the vagus nerve.

The respiratory mucosa (larynx, trachea, and bronchi) is innervated by the vagus. It is sensitive to mechanical stimulation (foreign bodies) and to irritating agents (gases), which may evoke pain and respiratory reflexes such as coughing, apnea or hyperpnea, and laryngeal spasm.

The serous surface of the parietal pleura can be stroked lightly without provoking pain or any other sensation, but the subpleural tissue is innervated by branches of those intercostal

[1] Gammon, G. D., and D. W. Bronk, *Am. J. Physiol.*, **114**, 77, 1935.

nerves which conduct pain impulses. Pressure exerted on the parietal pleura by means of a blunt instrument provokes localized pain, accompanied by hyperalgesia of the skin and deeper structures lying over the stimulated area. There is also contracture of the ipsilateral thoracic muscles, which reduces the excursion of the respiratory movements.

The diaphragmatic pleura is sensitive to mechanical stimulation and inflammatory irritation. Pain evoked from the peripheral part of the diaphragmatic pleura is referred to the base of the thorax on the stimulated side; *i.e.*, to the dermatomes of the sixth to the twelfth thoracic roots. Cutaneous and deep hyperalgesia and muscular contracture are also observed. The central portion of the diaphragmatic pleura is innervated by the phrenic nerve. Pain evoked by stimulation of this area is referred to the base of the neck and shoulder on the affected side, *i.e.*, to the territory of the third, fourth, and fifth cervical dermatomes. Cutaneous and deep hyperalgesia in this region and contracture of the neck muscles are also observed.

HEADACHE[1]

The different types of headache vary in intensity, duration, and the part of the head to which they are referred. Some have a throbbing or pulsating quality, but in all there is the persistent diffuse pain implied in its name and common to all forms of deep pain.

Headache always arises in structures situated in the head or the neck. Pain from other parts of the body is not referred to the head, except in severe and prolonged attacks of angina pectoris, in which case the pain irradiates up the neck to the jaw.

The soft structures covering the face and cranium are sensitive to pain, but the bones of the cranium, including the diploe, the emissary veins, the greater part of the dura, pia, arachnoid, and ependymal membranes, and the cerebral parenchyma are not. The following intracranial structures are sensitive to pain: (*a*) the tissues surrounding the venous sinuses and their tributary veins; (*b*) the arteries in the dura and the cerebral arteries, especially those at the base of the brain; (*c*) the dura of the base; (*d*) the roots of the fifth, ninth, and tenth cranial nerves and the first cervical nerve. Stimulation of endocranial structures evokes only pain sensation, except when an afferent path or center is stimulated, in which case the corresponding specific sensation is evoked.

[1] WOLFF, H. G., *Proc. Assoc. Res. Nerv. Ment. Dis.*, **23**, 173, 1943.

The fifth nerve conducts pain impulses from the face, scalp, and orbit and from the intracranial structures above the cerebellar fossa. Pain arising from endocranial structures in this area is referred to the frontal and parietal regions. The ninth and tenth cranial nerves and the first three cervical nerves conduct pain impulses from the cerebellar fossa and the base of the brain. Pain arising in this area is referred to the occipital region. All these facts have been ascertained in the course of endocranial operations performed under local anesthesia on conscious patients.

Headache of intracranial origin is due to dilatation of the arteries or veins, traction, compression or displacement of sensitive structures, inflammatory processes, and lesions of the sensory nerves (fifth, ninth, tenth, and upper cervical nerves).

Arterial dilatation. Injection of histamine provokes throbbing pain in the head due to dilatation of intracranial arteries, especially those of the base of the brain and the branches of the internal carotid. The intensity of the headache increases with the amplitude of pulsation. If the intracranial pressure is raised by injecting saline into the subarachnoid space, pulsation and headache diminish.

Arterial constriction does not provoke headache. Thus, adrenaline applied to the middle meningeal artery may provoke maximal contraction without causing pain, while dilatation of this artery is painful.

Changes in intracranial pressure. If a needle is introduced into the subarachnoid space and connected to a water manometer, fluctuations in intracranial pressure can be followed and correlated with sensations experienced by the subject.[1] A fall in pressure caused by extraction of a small amount of cerebrospinal fluid (about 20 cc.) provokes headache owing to dilatation of the venous sinuses. The intensity of the headache is increased by exerting pressure on the jugular veins (thus increasing intracranial venous pressure) or by tilting the subject to an upright position (thus increasing the difference between intracranial and venous pressures).

[1] KUNKLE, E. C., B. S. RAY, and H. G. WOLFF, *Bull. New York Acad. Med.*, **18**, 400, 1942.

On the other hand, headache is relieved by subarachnoidal injection of saline. Intracranial pressure changes provoke headache by causing tension to be exerted on perivascular tissues that are sensitive to pain.

Cerebral tumors. Pain in cases of cerebral tumor is due to compression or traction exerted on sensitive structures, either directly by the tumor or by the displacements it causes.

Migraine. This is a periodic form of severe headache limited to part of the head or face. It is usually preceded by scotomata (blind spots) and other visual phenomena in the opposite eye field to the side on which pain will be felt. In certain cases auditory, gustatory, or cutaneous sensations instead of visual ones precede the onset of headache. Photophobia, nausea, and sometimes vomiting form part of the syndrome. Migraine is due to dilatation of the branches of the external carotid artery and occasionally of the internal carotid (anterior meningeal, supraorbital, or superficial frontal arteries). Severity of headache is related to the amplitude of pulsation of these arteries. Vasodilating substances increase the intensity of migraine, and it is relieved by vasoconstricting drugs such as ergotamine. Digital compression of the temporal or other superficial arteries relieves the pain in the territory supplied by the compressed artery, while ligation suppresses it. Scotomata and other sensory signs experienced before the headache begins are due to intense transitory vasoconstriction and anemia of the nerve centers; they disappear on administration of amyl nitrite (a vasodilating drug) if the systemic pressure is not lowered at the same time, in which case they are accentuated. Migraine appears to be an allergic reaction; the attack may be brought on by the release locally of a vasodilating substance.

Headache of ocular origin.[1] Disturbances in the functions of the eye are a frequent cause of headache. The conjunctiva is sensitive to touch, cold, and pain; the cornea is sensitive to pain, and its peripheral parts are also sensitive to cold. Stimulation evokes pain well localized on the site where the stimulus is applied; intense and prolonged pain irradiates to the periorbital area and the territory innervated by the ophthalmic branch of the fifth nerve. Photophobia also occurs. The eye muscles are sensitive to stretching, which causes intense pain referred to the depth of the orbit.

Intraocular hypertension causes localized pain in the affected eyeball, the intensity being in direct relation to the degree of hypertension. It can be intolerably severe, and it irradiates to the whole territory innervated by the ophthalmic branch of the fifth nerve. A decrease in intraocular pressure relieves the pain, which disappears when the pressure falls to a normal level (20 to 30 mm. Hg).

Abnormalities in refraction cause headache owing to sustained contraction of the muscles of accommodation. At first pain is referred to the periorbital area, but later to the back of the head, owing to prolonged reflex contraction of the neck muscles. Hypermetropia and astigmatism are frequently the cause of headache, but myopia does not cause headache. Disturbances in the balanced action of the external musculature of the eye cause headache referred to the occipital region, due to sustained contraction of the neck muscles.

Irritation of the iris by mechanical agents or inflammation causes pain in the eyeball, irradiating to the whole territory of the ophthalmic nerve. In these cases a particular form of photophobia is experienced; there is no hypersensitiveness to light, but changes in illumination cause movements in the iris (see "Pupillary reflexes," Chap. 76) which are extremely painful and induce the patient to avoid light. Drugs such as atropine, which cause cycloplegia (paralysis in the mechanism of accommodation), relieve this form of photophobia, because the iris is immobilized.

True photophobia is the response to an excess of light; the eyes are shut or the palpebral fissure is reduced by contraction of the orbicularis, and the frequency of blinking increases. In normal subjects, a sudden increase in illumination provokes this response, but there is no pain, only a sensation of discomfort. In certain cases the threshold for light is lowered, and photophobia occurs when there is a degree of illumination well tolerated by normal subjects. This condition is due to irritation in the structures innervated by the ophthalmic nerve and, in some cases, to irritation in the territory of the maxillary nerve (nasal disturbances). Irritation of the conjunctiva or cornea is the most frequent cause of photophobia; it disappears if the conjunctiva is rendered insensitive by a local

[1] Eckart, L. B., J. M. McLean, and H. Goodell, *Proc. Assoc. Res. Nerv. Ment. Dis.*, **23**, 209, 1943.

anesthetic. Irritation of periorbital structures or the meninges innervated by the ophthalmic nerve also causes photophobia. In cases of disturbances in the pathway of the pupillary reflex to light (*i.e.*, when there is an Argyll-Robertson pupil) photophobia does not occur. Nerve impulses caused by irritation travel along the trigeminal nerve to its main nucleus, which is closely connected with the colliculi, and also to the nucleus of the spinal tract of this nerve, connected with the visual pathway by the spinotectal tract. These impulses are summated with those from the retina; thus the sensations aroused by light are increased. In summary, photophobia is due to summation of impulses from the retina provoked by light and impulses provoked by irritation in the territory of the fifth nerve. Photophobia ceases when the irritating agent is removed.

Nasal and paranasal headache.[1] Stimuli applied to the nasal mucosa and the structures connected with the nasal cavities (sinuses, etc.) arouse almost exclusively painful sensations. Pressure exerted on the floor of the nasal cavities or on the septum, however, is felt and recognized as such, but accompanied by a sensation of discomfort. The most sensitive areas are the conchae and the openings of the sinuses; the cavities of the latter are much less sensitive. The maxillary nerve innervates the nasal and paranasal cavities; therefore section of this nerve or of the fifth nerve, of which it is a branch, causes anesthesia of the whole area. When there is intense and prolonged pain, it irradiates and is referred to other areas innervated by the maxillary nerve and then to the territory of the ophthalmic nerve. This is usually accompanied by cutaneous hyperesthesia and vasodilatation, lacrimal and salivary secretion, and in some cases, photophobia and mydriasis.

Pain is referred as follows:

1. Pain arising from the inferior concha is referred to the upper dental arch. It irradiates to the zygoma, or to the orbit if its origin is the posterior part of the concha.
2. Pain arising from the middle concha is referred to the zygoma and irradiates to the temporal area.
3. Pain arising from the upper concha is referred to the medial wall of the orbit and irradiates to the neighboring parts of the frontal area and the nose.
4. Pain arising from the opening of the maxillary sinus is referred to the upper dental arch and the infraorbital region, irradiating to the forehead.
5. Pain arising from the nasofrontal duct is referred to the internal margin of the orbit and irradiates to the forehead, to the nose, and along the lower margin of the orbit to the zygoma.
6. Pain arising from the ethmoidal cavity is referred to the inner margin of the orbit and the posterior part of the upper dental arch.
7. Pain arising from the sphenoidal sinus is referred to the vertex of the head.

[1] McAuliffe, G. W., H. Goodell, and H. G. Wolff, *Proc. Assoc. Res. Nerv. Ment. Dis.*, **23**, 185, 1943.

Nasal pain is increased by circumstances that cause passive or active congestion of the nasal mucosa, such as pressure on the jugular veins, a draught of cold air, emotional stress, sexual excitation, menstruation, etc.

Headache arising from disturbances in the ear. The external auditory canal has only slight sensitiveness to pain; the tympanic membrane and the mucosa of the middle ear are highly sensitive; the eustachian tube with its opening in the pharynx is less sensitive. These structures are innervated by the glossopharyngeal, and pain arising in them is felt in the depth of the tissues, with little or no irradiation. If it is intense and prolonged, there is pain in the back of the head and shoulders owing to sustained contraction of the neck muscles, as occurs in all forms of prolonged headache.

Headache of other origin. Headache accompanying fever is due to dilatation of the cerebral arteries. Headache of persistent constipation has been attributed to the absorption of toxic substances from the bowel, but there is no evidence that this is the cause. The fact that this type of headache ceases as soon as the bowels are evacuated suggests it is due to a reflex vasodilatation of the cranial vessels.

PROPRIOCEPTIVE SENSIBILITY

Variations in pressure and tension in the depth of the tissues are of great importance for the regulation of posture and movement and for acquiring knowledge of the position in space, size, shape, weight, and resistance of objects in the environment. The receptors awakening these sensations are placed in Sherrington's proprioceptive field. They are found among the fibers of skeletal muscles; on tendons, fasciae, and periosteum; in subcutaneous, subpleural, and subperitoneal tissue; in the mesentery; and on synovial membranes. There are several types of proprioceptors: (*a*) muscle spindles; (*b*) Golgi

tendon organs; (*c*) pacinian corpuscles; (*d*) the labyrinth or vestibular organ placed within the temporal bone, which is formed by the semicircular canals, and the otolith organs (saccule and utricle). The labyrinth is stimulated by the position and movements of the head. It will be considered in detail in Chap. 81.

FIG. 395. Proprioceptive receptors of striated muscles: *A*, Golgi tendon organs, stimulated by stretching the tendon, actively by muscular contraction or passively by an outside agent; *B*, muscle spindle, stimulated by stretching the muscle; when the muscle contracts it ceases to discharge. *a* and *b*, muscle fibers; *m*, spinal cord; *s*, receptors. (*Fulton, J. F., and J. Pi-Suñer, Am. J. Physiol., vol. 83, p. 556, 1928.*)

Tension receptors. The muscle spindles and Golgi tendon organs are stimulated by tension.

Muscle spindles. (Fig. 395*B*) are made up of several coarsely striated fine muscle fibers (intrafusal muscle fibers) enclosed within a spindle-shaped connective-tissue sheath. They are innervated by several nerve fibers:

1. Several small myelinated fibers which degenerate after the corresponding ventral roots have been cut. They belong to the small-nerve motor system (see "Innervation of muscle fibers," page 790). Several spindles receive branches from the same fiber, so that activity in one fiber influences more than one spindle.
2. A large afferent fiber of the α type which loses its myelin sheath and ends around the middle of the intrafusal fibers, forming ribbonlike "annulospiral" endings.
3. A medium-size myelinated afferent fiber which ends by many fine branches on the intrafusal muscle fibers forming "flower-spray" endings.
4. An unmyelinated fiber of the C type similar to the unmyelinated fibers of the capsulated cutaneous receptors.

Golgi tendon organs (Fig. 395*A*) are situated on the tendons near the insertion of the muscle fibers. They are formed by several fine tendon fibers surrounded by a connective-tissue capsule and are innervated by a large afferent fiber which loses its myelin sheath and branches into many fine terminals among the encapsulated tendon fibrils.

When changes in tension occur in the muscle during contractions or passive stretching, discharges are registered in the afferent nerves. Matthews[1] has shown that in the cat individual stretch receptors fall into two classes:

[1] MATTHEWS, B. H. C., *J. Physiol.*, **78**, 1, 1933.

1. *A* receptors (muscle spindles), which discharge 5 to 10 impulses per second when the muscle is relaxed and discharge at a lower rate or cease to discharge when the muscle contracts (Fig. 396*A*). They have a low threshold to stretch, and when the muscle is passively stretched they discharge at a higher rate; a sudden pull may cause discharges of up to 500 impulses per second. Stimulation of the fine efferent fibers increases the rate of afferent discharge from the muscle spindles. At low muscle tensions this effect of the fine efferent fibers is less than at higher tensions, but it can nevertheless compensate for the effect of decrease in tension which occurs during ordinary muscular contraction. Facilitation of afferent discharges is apparently due to mechanical changes caused by contraction of the intrafusal muscle fibers. After stimulation of the small-nerve fibers or on release from stretch, there is a period of depression lasting several seconds during which afferent discharge may cease or takes place at a lower rate, returning later to the rate corresponding to the degree of tension.[1] Some of the *A* receptors (Matthews's A_2 type) discharge during contraction evoked by excitation of large efferent fibers; these fibers do not innervate the spindles and therefore are not the cause of the discharge, which is due to mechanical (tension) changes in the muscles. Stimulation by stretching causes depolarization of the sensory nerve endings in the muscle spindle and a local potential which spreads electrotonically along the axon. This local potential varies directly with the rate and amplitude of stretching and gives rise to repetitive discharge in the sensory nerve. At low tensions there is a low frequency of discharge, and propagated impulses alternate with monophasic action potentials which do not spread. In the ascending limb of the propagated potentials two or three steps may be seen due to these "prepotentials" of abortive impulses. Release from stretch is associated with a positive potential, which accounts for the poststimulation depression mentioned above.[1]
2. *B* receptors (Golgi tendon organs), which discharge when the muscle is stretched passively, and discharge at a higher rate when the muscle contracts, especially when it

Fig. 396. Left: A-type discharge. Recording from single spindle afferent in dorsal root; initial muscle tension of 10 gm. causes base-line discharge (*BL*). Lower record: maximal stimulus to muscle nerve causes cessation of discharge during contraction. Time base, 50 c.p.s. Right: B-type discharge. Recording from single afferent of another muscle; muscle tension of 20 gm. causes no discharge (*BL*). Maximal stimulus to nerve causes burst of discharges during contraction. (*Kuffler, S. W., and C. C. Hunt, Research Publ., A. Nerv. & Ment. Dis., Vol. 30, 24, 1950*).

[1] Hunt, C. C., and S. W. Kuffler, *J. Physiol.*, **113**, 283 and 298, 1951.

[1] Katz, B., *J. Physiol.*, **111**, 248 and 261, 1950.

shortens (Fig. 396*B*). Their stretch threshold is higher than that of the muscle spindles.

Muscle spindles are placed in parallel with the muscle fibers, and Golgi tendon organs in series. Passive stretch increases the rate of discharge from both types of receptors; contraction increases the discharge of Golgi tendon organs and diminishes that of muscle spindles. Afferent discharges from muscle spindles can evoke discharges from the motor neurons corresponding to the same muscle and can facilitate monosynaptic reflex responses (see "The stretch reflex," Chap. 81) in the same and in synergistic muscles. Activity of the large motor-nerve fibers is usually accompanied by activation of the small-nerve fibers. Afferent discharges from Golgi tendon organs inhibit the motor neurons to the same and synergistic muscles, and facilitate responses in the antagonistic muscles. The over-all effect tends to produce smooth muscle contractions.[1]

In the frog the muscle fibers and muscle spindles are innervated by branches of the same fibers; both systems are "coupled" (see "Innervation of muscle fibers," Chap. 67). In mammals muscle fibers and spindles are innervated by two separate systems of motor fibers, large and small. The pattern of spindle innervation is such that it allows finely graded excitation. This is associated with the importance in mammals of the myotatic reflex which arises in the muscle spindles.

Pressure receptors. The pacinian corpuscles (Fig. 390*f*) discharge when submitted to pressure. Stimulation of a single pacinian corpuscle of the cat's mesentery by mechanical deformation evokes impulses in the nerve with a threshold movement of 0.5 μ in 100 μsec. The duration of the maintenance of the displacement has no influence on the response; change, not duration, of the mechanical deformation is the important factor. Latency of response can be reduced from 1.5 msec. for the threshold stimulus, to 0.5 msec. by increasing the strength of the stimulus. The pacinian corpuscle acts simply as a means of applying mechanical stimulus to the axon.[2] These end organs are found in the deep layers of the skin; there are large numbers in the subcutaneous tissue of the palm and sole. They are also distributed on the fasciae and periosteum, on the tendons near their insertion at the joints, in the subpleural and subperitoneal tissue, in the mesentery close to the arteries, and on the surface of the joints. They are innervated by large fibers.

Pressure receptors are tested by placing weights on the body surface and asking the subject to differentiate the heavier from the lighter. Appreciation of tension can be examined by exerting a pull of known strength on a limb, or by lifting weights. The sense of active movement and position is explored by asking a blindfolded subject to place a limb in a certain position (*e.g.*, the first finger on the tip of the nose) or to describe the position of a limb. The sense of passive movement is examined by moving a joint, *e.g.*, by grasping a finger and flexing or extending it. Goldscheider noted many years ago that the minimum angle and rate of displacement perceived is smaller at the proximal than at the distal joint of a limb.[1]

Proprioceptors are explored in animals by means of the conditioned-reflex technique (see Chap. 86), or by making them learn to distinguish weights or strains in order to obtain a "prize" (food), or by the "placing" and "hopping" reactions. The "placing" reaction is evoked by bringing the paw of a blindfolded animal into contact with the edge of the table on which it is standing; when the leg is released, the animal places it on the table. The "hopping" reaction is evoked by holding the blindfolded animal so that the weight of the body is borne by only one leg; if the animal's body is brought forward, it will "hop," *i.e.*, displace the leg forward so as to keep it below the body in order to bear its weight.

Adaptation. Muscle spindles adapt very slowly and incompletely; they discharge continuously impulses of low frequency. The pacinian corpuscles have a slightly higher degree of adaptation (Fig. 387). Proprioceptors are not easily fatigued.

Proprioceptive reactions. Impulses discharged by proprioceptors initiate and maintain muscle tonus and postural reflexes. They are of

[1] Kuffler, S. W., *Research Publ., A. Nerv. & Ment. Dis.*, **30**, 24, 1952; Hunt, C. C., *J. Physiol.*, **117**, 359, 1952

[2] Gray, J. A. B., and J. L. Malcolm, *Proc. Roy. Soc., London, s.B.*, **137**, 96, 1949.

[1] The functional significance of this resides in the fact that an error in the execution of a movement is multiplied by the length of the lever. Precise movements, therefore, require greater accuracy of appreciation at the shoulder than at the fingers.

fundamental importance for the correct execution of movements, especially of automatic movements such as those of locomotion.

Proprioceptive impulses may reach the level of consciousness, but they are usually unconscious. They have little or no affective tone, unless they are associated by experience with actions of emotional significance.

Vibratory sensibility. Rhythmic deformation of the skin and deep tissues produced by a vibrating body arouses a peculiar sensation related to the amplitude and frequency of the vibrations of the stimulus. This sensation is tested by placing a vibrating tuning fork on the skin, usually over a bone near the body surface (*e.g.*, the distal end of the radius or the tibia), because the proximity of a resistant plane improves the mechanical conditions of vibration and increases the intensity of the sensation. Vibratory sensibility is not, however, peculiar to bone, and it is a misnomer to call it "osseous sensation"; it can be perceived in fleshy parts far from bony structures. Vibratory sensibility can be examined more accurately with special vacuum-tube oscillators (pallesthesiometers).

Vibration and pressure senses are closely associated. Impulses for both sensations are conducted by large α fibers along the proprioceptive pathway. Disturbances in deep somatic sensibility due to spinal lesions are always accompanied by disturbances in vibratory sensations, but chordotomy (section of the spinothalamic tract) does not affect it. Superficial anesthesia of the skin by cocaine infiltration does not alter the threshold of vibratory sensation, but if the deep tissues are also anesthetized over a fairly large area the sensation is lost. After extirpation of the gasserian ganglion (an operation performed in cases of persistent neuralgia of the trigeminal nerve) the skin of the face is no longer sensitive to touch, temperature, or pain, but vibratory sensations are still perceived because the afferent fibers of the facial muscles remain.

The vibration sense, as tested with a special vibrator giving 180 c.p.s., is highest on the finger tips and lowest on the eyelids. Cooling the skin, strenuous exercise, or general fatigue diminish sensitiveness to vibrations.

No special receptors for vibratory sensation have been identified. It is not a separate modality of sensation but a special pattern of pressure sensation caused by repetitive stimulation without the occurrence of fusion. It is therefore similar to flicker in visual sensations.

Stereognosis. The ability to recognize the shape and size of objects (*i.e.*, the geometric tridimensional form of objects) is called stereognosis. This also is not a particular modality of sensation, but a complex pattern integrated by cutaneous (touch) and proprioceptive sensation. It is usually explored by asking a blindfolded subject to describe or discriminate standardized geometric forms or various-sized objects placed in the hand,[1] by means of which an approximately quantitative statement of the stereognostic ability can be made.

Stereognosis is disturbed by lesions in the pathways of cutaneous or proprioceptive sensibility, but to a certain extent the one type of sensation compensates for losses in the other. Lesions in the parietal lobe cause a considerable defect in stereognosis, even though the particular sensations that contribute to it may be only slightly deficient. In these cases the cortical mechanism of association that synthesizes the different sensations into the stereognostic pattern is lost. The condition is known as astereognosis.

CHAPTER 74

Conduction and Integration of Afferent Impulses

IMPULSES DISCHARGED BY receptors are conveyed to the centers by nerve fibers of different types, according to the modality of the sensation. A first degree of integration takes place at the level of the spinal cord or the medullary and mesencephalic nuclei of the cranial nerve; the results are relatively simple reflex responses. The lower afferent centers relay impulses to higher centers, each modality of sensation having a special path. Some of the proprioceptive impulses pass into the cerebellum, and for these there is a cerebellar level of integration. All impulses traveling to the cortex, including those from the cerebellum, are relayed in the thalamus, where a more complex process of integration occurs. Olfactory impulses are the only exception to this rule; they arrive at the cortex without passing through the thalamus. Impulses from the thalamic nuclei are projected to the cortex, where integration is completed, the most complex patterns of behavior are coordinated, and the level of consciousness is attained.

Experimental and pathologic lesions provoke different disturbances in sensation according to the type of fiber affected or the level at which the lesion occurs. Thus section of peripheral nerves or dorsal roots suppresses sensation in certain areas, disturbs it in neighboring parts, and leaves it unaffected in others (topographic peripheral, or dermatomal, anesthesia). Fibers of one type are more easily damaged than others by asphyxia, narcotics, pressure, etc.; therefore the different kinds of sensation are unequally disturbed by these agents (peripheral modality dissociation). In certain cases of lesions or disease of the spinal cord in which some of the afferent paths are destroyed while others remain intact, modality dissociation is also observed. Lesions in the centers disturb integration at the corresponding level, but may leave the simpler integration carried out at lower levels almost, although not quite, normal.

CONDUCTION OF SENSORY IMPULSES IN AFFERENT FIBERS

The diameter of the fiber conditions not only its velocity of conduction and its contribution to the compound action potential of the nerve, but also its threshold and susceptibility to asphyxia, drugs (cocaine), cold, pressure, etc. If one of these agents is applied to a nerve, not all the fibers cease to conduct at the same time; some are blocked before others. The action potential is modified, and certain modalities of sensation are suppressed while others are not disturbed. By correlating data thus obtained, it has been possible to determine the type of fiber that conducts impulses corresponding to each kind of sensation.

Records of the action potentials of nerves thus blocked have given the following results: (*a*) *asphyxia*, provoked by compressing a limb with a pneumatic cuff, suppresses conduction first in δ fibers, then in other A fibers in order of diameter (the α fibers being the most resistant), and finally in C fibers; (*b*) *cocaine* blocks C and α fibers first, then other A fibers in the same order as asphyxia (*i.e.*, δ to α); (*c*) *pressure* blocks α fibers first, then A fibers in decreasing order of thickness, and finally C fibers. The different modalities of sensation are lost progressively in an order that varies with the method of blocking the nerve (Table 95).

Touch fibers. Tactile sensations are suppressed early in asphyxia but late when cocaine is applied to a nerve; moreover, action potentials

Table 95. Order in Which Modalities of Sensation Are Abolished in Different Types of Nerve Block

Order	*Asphyxia*	*Cocaine*	*Cold*	*Pressure*
1	Touch	Second (slow) pain	Cold	Pressure—vibration
2	First (rapid) pain	Cold	Touch	Touch
3	Cold	Warmth	Pain	First (rapid) pain
4	Pressure—vibration	First (rapid) pain	Warmth	Cold—warmth
5	Warmth	Touch		Second (slow) pain
6	Intense cold	Pressure		
7	Second (slow) pain			

typical of δ fibers are recorded in cutaneous nerves following tactile stimulation of the corresponding area of the skin. Touch impulses are apparently conducted by the largest myelinated fibers in cutaneous nerves, *i.e.*, β fibers, as well as by δ fibers. Probably the different types of receptors are innervated by fibers of different diameter.

Fibers for temperature senses. Krause's corpuscles (cold receptors) are innervated by relatively large myelinated fibers, and when a limb is asphyxiated sensitiveness to cold is lost soon after tactile sensibility and the first or "fast" pain. Intense cold and heat still provoke sensations, which disappear only after more prolonged asphyxia. During the whole process the latent period of thermic sensations increases progressively. These observations suggest that thermic sensations are mediated by a wide range of fibers, varying from δ to C.

Fibers for pain. A painful stimulus applied to a limb evokes a double pain sensation; the first is a well-localized prick, the second a more diffuse and prolonged burning ache. The interval between the two sensations increases as the stimulus is applied to more distal parts. Thus it was found to be 0.9 sec. when the stimulus was applied on the thigh, 1.3 sec. on the knee, and 1.9 sec. on the toe. If the limb is subjected to asphyxia, there is a sudden increase in the latent period of the pain sensation from 0.3 to 1.5 sec. at approximately the same time as the δ fibers cease to conduct. These facts suggest that pain impulses are conducted by two types of fibers, δ fibers and C fibers; moreover, when the skin is burned, action potentials typical of C fibers are recorded in the corresponding cutaneous nerve. It would seem that the first ("pricking") pain is conducted by δ fibers, and the second, or slow, pain by C fibers. No definite statement can be made, however, because the reaction time to a stimulus is subject to so many variations dependent on the condition of the subject, the strength of the stimulus, etc. (see "Reaction time," page 873), that it cannot be considered an accurate method for measuring conduction velocity of nerve fibers. Moreover, Bishop[1] has evoked pricking pain by electrical stimulation of the skin with a single shock, while repetition of the shocks on the same spot evoked pain with the aching quality of the second pain. It is therefore possible that the two kinds of pain are dependent on the pattern of stimulation, and not on the type of receptor and fiber that mediate the sensation.

Fibers for proprioceptive sensibility. Nerves passing into muscles have a large number of afferent fibers which innervate the muscle spindles (α and medium-sized myelinated fibers), the Golgi tendon organs (medium-sized myelinated fibers), and pacinian corpuscles (α fibers). There are also fine unmyelinated afferent fibers, which probably mediate pain sensations. The large α fibers convey proprioceptive impulses; they are very susceptible to asphyxia and to pressure, and when they cease to conduct, proprioceptive sensations are lost. The nature of sensations aroused by impulses conducted by medium-sized afferent myelinated fibers that innervate receptors in muscles and tendons has not yet been determined.

Summary. Fibers of a given type may conduct impulses corresponding to several modalities of sensation, although α fibers apparently convey impulses from proprioceptive receptors only. Each modality of sensation sends impulses by several types of fibers, but no modality occupies fibers in all the "fiber spectrum."

The dorsal roots. (Fig. 397.) The dorsal roots are made up of myelinated fibers of all sizes (from 1 to 20 μ in diameter) and unmyelinated fibers. The latter are at least 40 per cent of the total number, and there are more in the thoracic

[1] Bishop, G. H., *J. Neurophysiol.*, **6**, 361, 1943.

and sacral segments, where the visceral afferents enter the cord. The root divides into several filaments, which open out in a fanlike manner before entering the spinal cord at the dorsolateral sulcus. Each filament divides into a medial division, formed by large and medium-sized myelinated fibers, and a lateral division, formed by unmyelinated and fine myelinated fibers. After entering the cord, the fibers divide into an ascending and a descending branch, which give out several collaterals into the gray matter, where they end synaptically on spinal neurons.

All the fibers in the dorsal roots are afferent fibers. The ratio of the total number of fibers (myelinated and unmyelinated) in a root to the total number of cells (large and small) in the spinal ganglion is 1:1. The presence of efferent fibers in the dorsal root has not been demonstrated (see "Antidromic conduction," Chap. 69).

SPINAL ASCENDING PATHS

The fibers in the dorsal roots conduct impulses from all types of receptors; the roots are anatomic units, not functional ones. In the spinal cord there is a functional distribution of the fibers, *i.e.*, each spinal tract conducts impulses corresponding to certain modalities of sensation.

Proprioceptive paths. (Fig. 398.) Proprioceptors are innervated by large α fibers which form part of the medial division of the dorsal-root filaments. Some of these fibers conduct impulses which follow the thalamic route to the cortex; others pass into the cerebellum.
FIG. 397. Origin in receptors and termination in the spinal cord of dorsal-root fibers. 1 and 2, large fibers arising in pacinian corpuscles (1) and muscle spindles (2), and passing to the dorsal column; 3 and 4, fibers arising in tension receptors and ending on dorsal-horn cells, some of the axons of which cross the mid-line and form the ventral spinocerebellar and spinothalamic tracts, while others form the ipsilateral dorsal spinocerebellar tract; 5, fibers arising in tactile receptors and ending on dorsal-horn cells, the axons of which cross and form the ventral spinothalamic tract; 6, fine fibers (pain) ending on cells in the substantia gelatinosa Rolandi; the axons of these cells cross and form part of the spinothalamic tract. (*Fulton, J. F., "Physiology of the Nervous System," 3d ed., Oxford, New York, 1949.*)

Spinothalamocortical propriocebtive path. The fibers in the dorsal root nearest the mid-line form the posterior columns of the spinal cord known as the fasciculus gracilis and the f. cuneatus. These columns are laminated, *i.e.*, the fibers corresponding to each root are distributed in a thin layer or wedge, disposed in a dorsoventral direction. Fibers from the sacral roots are closest to the mid-line, and as the more cephalic roots enter the cord they are placed laterally to those corresponding to more caudal dermatomes (Fig. 400). The fibers send collaterals into the gray substance of the cord, which end on spinal neurons. Some of them end directly on motor neurons of the ventral horn, forming two-neuron monosynaptic arches, and others end on internuncial neurons. The dorsal tracts ascend to the medulla; the fibers near the mid-line end

in the nucleus gracilis, and the more lateral ones in the n. cuneatus. Dorsal-column fibers are relatively large; 16.7 per cent and 10.5 per cent of those in the f. gracilis and cuneatus, respectively, have diameters larger than 6 μ, and the largest are 15 μ in diameter. The speed of conduction is correspondingly great; in the fastest fibers it is 70 m. per sec. There is, however, an abrupt fall in the speed of conduction of impulses from the dorsal roots conveyed in the dorsal funiculi.[1] Thus, afferent impulses from the knee joint are transmitted at 90 to 100 m. per sec. in peripheral nerves, at 40 to 60 m. per sec. in the dorsal tract of the thoracic spinal cord, and at 20 to 30 m. per sec. at the level of the first cervical segment.[1] This may be due in part to the fact that the largest fibers enter almost immediately into the Clarke-Stilling column, and perhaps to a decrease in the size of the fibers as they ascend and give off collaterals.
Fig. 398. Proprioceptive pathways.

Second-order fibers, emerging from the gracile and cuneate nuclei, cross to the opposite side and form the medial lemniscus, an ascending tract placed close to the mid-line in the pons and more laterally in the cerebral peduncles. Lamination is continued in the medial lemniscus; fibers from the cuneate nucleus, *i.e.*, those corresponding to the cervical roots, are placed dorsally and those from the sacral roots ventrally. In the cerebral peduncle, the sacral fibers are the most lateral and the cervical fibers are closest to the mid-line.

The medial lemniscus ends in the thalamus, in the lateral part of the posteroventral nucleus. Fibers conveying impulses from the caudal segments end on cells situated laterally to the cells on which the more cephalic segments are projected. The main sensory (mesencephalic) nucleus of the trigeminal nerve sends fibers through the dorsal secondary tract to the medial posteroventral nucleus of the thalamus. Third-order fibers pass from these thalamic nuclei to the parietal cortex. Impulses from the more caudal segments are projected on the upper part, and those from the more cephalic on the lower part of the postcentral gyrus. Cortical representation is, therefore, contralateral and inverted; a similar topographic representation is found for cutaneous receptors.

Impulses conducted along this path give rise to well-localized, discriminative, and conscious sensations. Knowledge is thus acquired of the position of the limbs, active and passive movement, tension, and deep pressure (proprioceptive or kinesthetic sensations). Touch and pressure impulses and those serving to construct complex sensation patterns, such as vibration and stereognosis, are also conveyed along this path.

Spinocerebellar paths. The largest of the α fibers in the dorsal root enter almost immediately into

[1] Gasser, H. S., and T. H. Graham, *Am. J. Physiol.*, **103**, 303, 1933; Grundfest, H., and B. Campbell, *J. Neurophysiol.*, **6**, 275, 1942; Rexed, B., and G. Ström, *Acta Physiol. Scandinav.*, **25**, 219, 1952; Tasaki, I., *Japan. J. Physiol.*, **3**, 73, 1952; Holmgren, B., *J. Physiol.*, **123**, 324, 1954.

[1] Gardner, E., F. Latimer, and D. Stillwell, *Am. J. Physiol.*, **159**, 195, 1949.

the Clarke-Stilling column.[1] The axons of the cells in this column form the ipsilateral dorsal cerebellar tract (Flechsig's tract), which ascends along the dorsolateral margin of the lateral column, enters the cerebellum by the inferior cerebellar peduncle (restiform body), and ends in the cortex of the anterior lobe of the cerebellum (lingula, centralis, and culmen). The fibers in this tract are even larger than those of the dorsal column; almost half have diameters larger than 6 μ. The impulses are also conducted at a higher speed than in the dorsal columns.

Other fibers in the dorsal roots end on cells in the dorsal horn. The majority of the axons of these cells decussate and form the contralateral ventral cerebellar tract (Gower's tract) situated in the ventrolateral margin of the anterolateral column; a smaller number pass into the ipsilateral ventral cerebellar tract. All these fibers ascend into the brain stem and pass into the superior cerebellar peduncles, where they cross over to the opposite side and end in the cortex of the anterior lobe. The projection in the cerebellum is therefore ipsilateral, not contralateral as in the cerebral cortex.

Paths of cutaneous and visceral sensibility. *Spinothalamic tract.* (Fig. 399.) The fine myelinated and unmyelinated fibers in the lateral division of the dorsal-root filaments conduct impulses from touch and temperature receptors and from pain endings in the skin and viscera. These fibers form the tract of Lissauer at the tip of the posterior horn; they ascend for one to three segments and then penetrate into the substantia gelatinosa Rolandi, formed by small cells in the most dorsal part of the posterior horn. The axons of the neurons that conduct pain impulses cross the mid-line in the segment of entry or that immediately above; those conducting impulses from temperature receptors decussate in the three to five segments above the segment of entry; and those conveying tactile impulses cross in many, perhaps all, of the segments up to the medulla. A few fibers apparently do not decussate but pass into the ipsilateral spinothalamic tract; most of these appear to be visceral afferents. Temperature fibers are placed in the anterolateral column in a dorsal position with respect to the pain fibers; touch fibers are placed more ventrally. As in the dorsal column, there is dermatomal distribution in laminae in the spinothalamic tract; fibers corresponding to the cervical dermatomes are placed near the mid-line, next to these the thoracic, and more laterally and dorsally the lumbar and sacral fibers (Fig. 400).
Fig. 399. Spinothalamic tract.

Pain and temperature fibers ascend in the lateral part of the reticular substance, dorsal to the inferior olivary nucleus in the medulla. They are placed laterally and superficially with respect to the median lemniscus in the pons and even more so in the cerebral peduncle. In this part of the tract lamination is also observed; the fibers from caudal segments are placed dorsally with respect to those from more cephalic segments.[1]

[1] Walker, A. E., *Assoc. Res. Nerv. Ment. Dis.*, **23**, 63, 1943.

Some of the fibers in this tract end in the inferior colliculus (spinotectal tract), but most of the fibers pass through these nuclei and end in the posterior ventral nuclei of the thalamus. Fibers from the more caudal dermatomes end in the lateral part of the n. ventralis posterolateralis, and those from more cephalic dermatomes on cells nearer the mid-line. Fibers from the spinal nucleus of the trigeminal nerve (ventral secondary tract) end in the n. ventralis posteromedialis (arcuate nucleus).
FIG. 400. Diagrammatic section of spinal cord showing systematization of ascending fibers. *S*, fibers from sacral dorsal roots; *L*, fibers from lumbar roots; *T*, fibers from thoracic roots; *C*, fibers from cervical roots; *PT*, pyramidal tract. Large dots represent fibers conducting impulses from temperature receptors, medium-sized dots represent pain fibers, and fine dots tactile fibers. (*Walker.*)

Afferent impulses from the head. Afferent fibers in cranial nerves conveying cutaneous, visceral, and proprioceptive sensations are found mostly in the trigeminal, facial, glossopharyngeal, and vagus nerves. Impulses from proprioceptors in the eye muscles are conducted by fibers of unknown origin.

The trigeminal nerve has large and fine fibers. Most of the former ascend into the main sensory or mesencephalic nucleus and most of the latter descend into the spinal nucleus. This nucleus is a continuation of the substantia gelatinosa Rolandi of the spinal cord, and the trigeminal fibers ending in it convey mainly pain and temperature impulses, and secondarily those of touch. Touch, pressure, and proprioceptive sensibility are served by the fibers passing into the main nucleus. Destruction of the spinal nucleus completely suppresses temperature and pain sensibility in the territory innervated by the trigeminal nerve. The lower part of the nucleus receives fibers from the ophthalmic branch, and the upper part from the mandibular branch. Second-order fibers from the trigeminal nuclei end in the arcuate nucleus (n. ventralis posteromedialis) of the thalamus.

The thalamic nuclei are projected on the postcentral gyrus in the same way as the proprioceptive fibers, *i.e.*, the head and face in the lower part of the gyrus and the more caudal segments in the higher. The perineum and genital organs are represented in the medial aspect of the hemisphere above the falx, *i.e.*, in the paracentral lobule.

Cordotomy. Section of the anterolateral spinal column, *i.e.*, the spinothalamic tract (cordotomy), has been performed in many cases in order to relieve intractable pain. The operation must be bilateral to abolish visceral pain; therefore visceral pain fibers decussate only in part. Cordotomy also suppresses temperature sensations, but it has little or no effect on tactile sensibility. According to Foerster, bilateral cordotomy reduces the number of touch spots and raises their threshold, but the deficiency is detected only by the use of precise methods of exploration. Sensations from the bladder also persist, but those of sexual orgasm are lost. The persistence of bladder sensibility may be due to the dorsal position of the fibers that conduct these impulses, thus causing them to escape section; it is also possible that bladder sensibility is conducted by fibers in the dorsal columns.

Spinal sensory syndromes. Modality dissociation of sensation occurs in cases of spinal disease in which certain tracts are damaged while others remain intact.

Degenerative lesions of the posterior columns (fasciculus gracilis and f. cuneatus) cause a syndrome called locomotor ataxia (tabes dorsalis). Muscle tonus is lost or considerably diminished, owing to the loss of the myotatic reflex (see Chap. 81). Tendon reflexes, such as the knee jerk, are also abolished. The sensation of limb posture is lost, and the patient cannot coordinate voluntary or automatic movements. Visual sensations compensate in part for the deficiency; therefore if the patient closes his eyes he can no longer stand upright, but loses his balance (Romberg's sign). Tactile sensations are considerably

disturbed, especially perception of complex sensation patterns, such as stereognosis.

Destructive lesions in the gray substance of the spinal cord produce the syndrome known as syringomyelia (Greek σύριγξ, pipe, and μυελός, marrow). Cells and fibers of the spinothalamic tract are destroyed and pain and temperature sensations are lost, but tactile and proprioceptive sensibilities remain.

THE THALAMUS

The thalamus is a nuclear mass where all afferent fibers to the cortex, with the sole exception of the olfactory fibers, are relayed. Functional and anatomic connections of the thalamus with the cortex and other centers have been studied mainly by the following methods: (*a*) localized destruction of the thalamic nuclei or the fibers emerging from these nuclei, and examination of serial sections stained by the Marchi method, in order to visualize and follow the path of degenerating fibers; (*b*) localized destruction of cortical areas and examination of retrograde degenerative processes, such as chromatolysis (Nissl's method), which are particularly severe and end in complete atrophy of the thalamic nuclei; (*c*) local application of strychnine (2 per cent solution, mixed with a stain in order to localize the area into which the drug has diffused) and registration of electrical activity in the thalamus on stimulating its afferent paths, or in centers where the thalamic fibers end.[1]

The thalamic nuclei. The thalamus is divided into three parts by the internal medullary lamina, a vertical sheath of white matter which bifurcates at its anterior end.

The anterior nuclei are enclosed between the branches of this bifurcation. The mammillothalamic tract ends in these nuclei, which project to the gyrus cinguli.

The median nuclei are situated between the lamina and the mid-line. The main nuclei are (*a*) the dorsomedian (n. medialis dorsalis), which projects to the prefrontal lobe and the hypothalamus; (*b*) the centrum medianum, (*c*) clusters of cells in the lamina (intralaminar nuclei); (*d*) clusters of cells in the wall of the third ventricle (paleothalamus) connected with the hypothalamus, but with no cortical connections (nuclei of the mid-line).

[1] Dusser de Barenne, J. G., and O. Sager, *Ztschr. f. d. ges. Neurol. & Psychiat.*, **133**, 231, 1911; *Arch. Neurol. & Psychiat.*, **38**, 913, 1937.

The lateral nuclei are placed externally or laterally to the lamina. The main nuclei are (*a*) n. ventralis anterior; (*b*) n. ventralis lateralis, which receives fibers from the cerebellum through the superior cerebellar peduncle and projects to the precentral gyrus (areas 4 and 6); (*c*) n. ventralis posterior, divided into lateral and median (n. arcuatus) nuclei; the former receives the fibers of the median lemniscus and the spinothalamic tract conveying impulses from all the body; the n. arcuatus is a relay station for impulses coming from the head and neck through the trigeminal nerve and the second-order neurons of the trigeminal path; these nuclei project to the postcentral gyrus (areas 3-1-2); (*d*) n. lateralis dorsalis et posterior, the afferent fibers of which are unknown, which projects to the posterior parietal lobule (areas 5 and 7).

The posterior nuclei are situated laterally to the lamina, posterior to the ventral and lateral nuclei. The following are the main nuclei in this group: (*a*) the pulvinar, which projects to the posterior part of the parietal lobule and the peristriate cortex (areas 18 and 22); (*b*) the lateral geniculate body, a relay nucleus in the optic path, which projects to the striate cortex in the occipital lobe; (*c*) the median geniculate body, placed in the auditory path, which projects to the auditory area of the temporal lobe.

The thalamic nuclei can be classified into

1. Cortical relay nuclei placed in the ascending sensory system: the ventralis posteromedialis, which receives the trigeminal lemniscus and projects to the face and neck areas of the somatosensory cortex; the ventralis posterolateralis, which receives the spinothalamic tract (medial lemniscus) and projects to the somatosensory cortical areas corresponding to the leg, trunk, and arm; the lateral geniculate body, on which the optic tract ends and which projects to the striate cortex; the medial geniculate body, receiving the lateral lemniscus and projecting to Heschl's gyrus (auditory cortex); the lateral ventral nucleus, receiving fibers from the brachium conjunctivum and projecting to the precentral gyrus (areas 4 and 6).
2. The diffuse thalamic projection system[1] made up in the cat by five nuclear groups: (*a*) centromedian, (*b*) intralaminar nuclei, (*c*)

[1] Harzl, T. E., and H. W. Magoun, *J. Neurophysiol.*, **14**, 133, 1951.

anterior nuclei, (*d*) anterior ventral nucleus, and (*e*) anterior pole of the reticular nucleus. These nuclei form a functionally interconnected unit, and stimulation of any one of them evokes recruiting waves in the others. Their cortical projections are distinct from those of the previous group; they end in the association areas separating the somatosensory, visual, and auditory cortical areas, *i.e.*, in the prefrontal cortex (overlapping the motor cortex), the cingulate, orbital, and suprasylvian areas. The intralaminar and mid-line nuclei also project to the caudate nuclei[1] which take part in the recruiting responses evoked from the thalamus.

FIG. 401. Diagram of thalamocortical projections. 1, lateral geniculate body; 2, pulvinar; 3, n. lateralis posterior; 4, n. ventralis posterolateralis; 5, n. ventralis posteromedialis; 6, median geniculate body; 7, n. ventralis lateralis; 8, n. medialis dorsalis. (*Walker, A. E., J. Nerv. & Ment. Dis., vol. 85, p. 254, 1937.*)

3. Nuclei with no known cortical projections, *e.g.*, the mid-line nuclei, which do not show lesions of retrograde degeneration after removal of the cortex.

Lamination occurs in the cortical relay nuclei, and it is a prominent feature in the lateral geniculate body. Fibers from the macula of the retina end in the dorsal part of this nucleus in such a way that the corresponding points in the maculae in both eyes project to the same point in the geniculate body. Fibers from the peripheral retina end in the anterior third of the geniculate body; here also there is some degree of topographic organization, but with considerable overlapping of the different areas. Projection to the striate cortex also has a certain degree of point-to-point systematization. The retina is therefore projected first to corresponding points in the lateral geniculate bodies, and then to the occipital cortex.

Systematization of the posteroventral nuclei is such that the fibers of the median lemniscus and the spinothalamic tract end on the lateral nucleus, the different dermatomes placed in order so that the caudal segments are projected laterally to the cephalic segments. Impulses from the face and head are projected to the n. arcuatus (n. ventralis posteromedialis). Topographic organization in the cortex will be considered in detail farther on. The existence of lamination and point-to-point projection does not mean that there is no convergence and divergence; on the contrary, even in the optic pathway of macular vision there is a certain degree of overlapping of the different areas.

The areas of projection of the thalamic nuclei are represented in Fig. 401, and the density of projection in Fig. 402.

The cortex also projects to the thalamic nuclei. Thus the occipital (visual) cortex projects to the lateral geniculate body, the temporal (auditory) cortex to the median geniculate body, and the motor cortex to the lateroventral nucleus. The general rule is that each part of the cortex projects to the nuclei from which it receives impulses. Thus there is the possibility of the establishment of thalamocorticothalamic circuits similar to those which have been found to exist between the cortex and the striatus (see Chap. 82).
FIG. 402. Relative density of thalamocortical projection in different regions. Diagram of cerebral cortex of macaque. (*Walker, A. E., "The Primate Thalamus," University of Chicago Press, Chicago, 1938.*)

Sensory functions of the thalamus. Thalamic functions have been studied in animals after the

[1] DROOGLEEVER-FORTUYN, J., and R. STEFENS, *Electroencephalog. & Clin. Neurophysiol.*, **3**, 393, 1951.

whole cortex of one hemisphere has been removed. This procedure not only suppresses cortical activity, but also provokes degeneration and atrophy of the thalamic nuclei connected with the cortex, thus causing serious disturbance in thalamic function. Immediately after the operation there is complete anesthesia on the opposite side of the body. Gradually pain sensibility and, to a certain extent, tactile sensibility, are recovered, but accurate localization and discrimination are permanently lost. Visceral sensibility is not greatly altered, while proprioceptive sensations are definitely abolished. In primates the results are more severe than in lower animals. In cases of hemidecortication in man the syndrome is similar to that observed in experimental animals, *i.e.*, complete contralateral anesthesia, with gradual incomplete recovery of cutaneous sensibility.

Partial recovery of superficial sensibility may be due in part to bilateral cortical representation, owing to incomplete decussation of the spinothalamic tract. Thus, for the face there is considerable bilateral representation. That this is not the only reason for partial recovery of sensibility after hemidecortication is proved by the following experiment: the whole cortex is removed from one hemisphere, and after the animal has recovered, the cortex of the other hemisphere is removed. Complete contralateral anesthesia is observed after the second operation, but the partially recovered cutaneous sensibility on the other side is not disturbed.[1] Rudimentary cutaneous sensations (Head's "protopathic" sensibility) can therefore be integrated in the thalamus.

Localized strychninization of the posteroventral nucleus on one side causes bilateral hyperesthesia, more marked on the opposite side than on that of the treated nucleus. This experiment confirms the existence of bilateral representation of cutaneous sensibility. If strychninization is limited to a small part of the nucleus, hyperesthesia is observed only over a certain area of the skin, face, trunk, or limb, according to the part of the nucleus affected by the drug. This experiment confirms the existence of topographic organization revealed by anatomical studies.

Little is known about thalamic integration of visceral sensibility. The connections established by the anterior thalamic nuclei and the posterior hypothalamus (through the mammillothalamic tract) and the gyrus cinguli suggest the existence of a thalamic level of visceral integration, connected in some way with olfactory sensations.

Thalamic projection to cortical association areas (posterior parietal, prefrontal area) suggests that the respective thalamic nuclei play a part in the integration of complex visual and auditory sensations and in stereognosis, which is dependent on the correct integration of cutaneous and deep sensibility.

Thalamic syndromes. Obstruction of the thalamogeniculate artery provokes a thalamic syndrome first described by Déjerine in 1906. The posterior parts of the ventral and lateral nuclei are destroyed, and the following effects are observed: "hemianesthesia, more or less severe for cutaneous sensibility (touch, pain, temperature), but always marked for deep sensibility, with an exaggerated response to stimulation with painful or thermal stimuli, out of proportion to the strength of the stimulus. . . . Pain is felt, frequently intense, on the side where there is anesthesia; it is persistent, has the characteristics of central pain; it is felt deeply, there are paroxysms of lancing pain, which does not respond to treatment with analgesics."[1] The sensations are referred to the side opposite to the lesion, but they are imprecisely localized. There are also motor disturbances in the contralateral limbs (ataxia, choreoatetosis, etc.; see Chap. 82). The face is usually free from disturbances, because the median posteroventral nucleus is seldom damaged. In some cases the lesions are restricted to the entrance of the spinothalamic tract, and cutaneous sensibility alone is disturbed, because the impulses from deeply placed receptors (proprioception, deep pressure, touch) carried by the median lemniscus arrive normally to the thalamus.

Thrombosis of the perforating artery, which supplies the nuclei in the anterior part of the thalamus connected with the striatum, is followed by few sensory disorders, while motor disturbances such as tremor, ataxia, and choreoatetosis are prominent (see "The extrapyramidal motor system," Chap. 82).

Thalamic functions. The thalamus has several functions:

Sensory functions. It is a relay station in the ascending sensory paths. Visceral and somatic sensory impulses are relayed through the posteroventral nuclei; visual impulses through the

[1] WALKER, A. E., and J. F. FULTON, *J. Nerv. & Ment. Dis.*, 87, 677, 1938.

[1] DÉJERINE, J., "Séméiologie des affections du système nerveux," Masson et Cie, Paris, 1914, p. 922.

lateral geniculate body; auditory impulses through the median geniculate body; taste impulses through the median posteroventral nucleus; cerebellar impulses through the lateroventral nucleus; and possibly olfactory impulses through the mammillothalamic tract and the anterior nuclei to the gyrus cinguli.

Corticodiencephalic association, necessary for the integration of complex sensations, visual (pulvinar and peristriate cortex, area 18), auditory (pulvinar and temporal cortex, area 22), and general somatic, including stereognosis (dorsomedian nucleus with the prefrontal cortex, areas 9-10-12, and lateral dorsal nucleus with posterior parietal cortex, areas 5 and 7).

Regulation of cortical activity. The diffuse thalamic projection system, together with the reticular formation of the brain system, plays an important part in regulating the general level of cortical activity. Stimulation of these nuclei may depress the cortex, inhibiting spontaneous movements and evoking the electroencephalographic response of somnolence and sleep, or on the contrary may provoke a condition of alertness (see Chaps. 87 and 88).

CYTOARCHITECTURE OF THE CEREBRAL CORTEX[1]

The cerebral cortex is formed by a series of layers of cells and fibers organized according to a fundamental pattern common to the whole cortex, but with considerable variations in the shape, size, and number of the cells and the distribution of the fibers in the different areas. In all species that have so far been studied, in spite of variations in cell number, form, and size, "what remains constant is the arrangement of the plexuses of dendritic and axonal branches, *i.e.*, of the synaptic articulations through which nerve impulses are transmitted."[2] The comparative study of the cortex in different species is thus made possible.

General structural plan of the cortex. A vertical segment of the cortex may be considered as a "cortical unit" made up of neuron chains "in no way different from the chains of internuncial neurons in any part of the central nervous system."[1] These units, however, are not separated from each other, or placed simply side by side; they overlap and are closely interconnected, so that a single neuron forms part of more than one neuron chain.

Six layers of cells have been found in all parts of the cortex (Table 94 and Fig. 403). The

separation between layers IV*b* (5) and V (6) is clearly marked by a white line formed of myelinated fibers running parallel to the outer surface of the cortex, which is known as Baillarger's external band. It is highly developed in the occipital cortex, where it was first seen by Gennari (Gennari's line) and is the origin of the term "area striata" given to the visual cortex. Baillarger's band divides the cortex into an external lamina with four layers of cells and an internal lamina with two layers. The areas of greatest architectural differences are the relatively simple olfactory cortex and the far more complex pallium. The former, also called "allocortex," has a white external lamina, while the latter, known as "isocortex," has a gray external lamina.

Cortical neurons have been classified into four types according to the distribution of their axons: (*a*) cells with descending axons, some of which penetrate the white substance, which are fibers of projection to subcortical centers or of association with other parts of the cortex; (*b*) cells with short axons, which ramify in the proximity of the cell body (Golgi II cells); (*c*) cells with ascending axons, which ramify in one or more cortical layers; (*d*) cells with horizontal axons (Cajal's cells), which are found in the plexiform layer.

Cortical afferent fibers come from (*a*) the thalamus (thalamocortical projection fibers); (*b*)

[1] A detailed description of the cytoarchitecture of the cerebral cortex will be found in Chap. 15 of Fulton's "Physiology of the Nervous System," 2d ed., written in great part by R. Lorente de Nó.

[2] FULTON, J. F., "Physiology of the Nervous System," 2d ed., Oxford, New York, 1943, p. 280.

[1] *Ibid.*, p. 293.

other cortical areas (cortical association fibers). Projection fibers ramify mainly in layer IV, but all afferent fibers send branches to cells in all the cortical layers; therefore no single layer can be considered as the "receptor layer."

number of terminals from many other neurons, and its axon endings connect with several neurons. Even the axons of projection fibers may send out branches before entering the white matter.
Fig. 403. Cytoarchitecture of the cerebral cortex. On the left, cell layers; on the right, fiber layers. (*After Brodmann.*)

Cortical efferent fibers are sent out from cells in all the layers. The axons of the large pyramids (Betz cells) in the motor cortex (precentral gyrus) form the pyramidal tract. The main efferent fibers from the olfactory and occipital areas arise from the outer layers. Axons of cells in the outer layers ramify mainly within the cortex, but some penetrate into the white matter. No layer can therefore be considered as the "effector layer."

Synaptic connections of cortical cells do not differ from those of other cells in subcortical and spinal centers. Each neuron receives a large

The cell chains may be simple, formed by two cells, with only one synapse in the cortex. Most of the chains are more complex, with many intracortical synapses, and sometimes the chain forms a reverberating circuit. In man the absolute and relative number of neurons with short axons is much larger than in other species; according to Cajal, this is a sign of greater fineness in function.

Cytoarchitectural areas. (Fig. 404.) The differences in cytoarchitecture between two areas are not limited to a single layer, but usually extend to several. The passage from one area to

another is clearly marked; there are no transitional areas. The cytoarchitectural maps of the cortex that have been published are far from being complete, and intensive study of the different parts of the cortex continually shows new subdivisions in areas considered homogeneous. anatomic, but also physiologic and pathologic, significance; hence its importance.

Only the main cytoarchitectural areas will be mentioned here. When considering cortical integration of motor and sensory functions, the respective cortical centers will again be examined.
FIG. 404. Brodmann's areas. Diagrams of median (above) and lateral (below) aspects of the human cerebral cortex.

The first maps were constructed by Campbell, Brodmann, and the Vogts; since then there has been considerable and continuous progress in this field of neurology. The division of the cortex into areas with different structure has not only

Frontal lobe. The principal areas are (*a*) the motor area, Brodmann's area 4,[1] situated in the precentral gyrus, whose projection fibers form the pyramidal tract; (*b*) the premotor area (6),

[1] Brodmann's numeration is in general use.

placed in front of the motor area, which forms part of the extrapyramidal motor system; (*c*) the frontal eye field (8), in the posterior part of the second frontal convolution; (*d*) the prefrontal area (9-10-11-12), an association area occupying the rostral part of the frontal lobe.

Parietal lobe. The areas in this lobe are mainly related to general somatic sensations: (*a*) the postcentral area (3-1-2) receives projections from the posteroventral nuclei of the thalamus; (*b*) the preparietal (5*a*) area situated behind the postcentral area is also a sensory area, but contributes to the corticopontine and corticospinal projections; (*c*) the inferior parietal area (7), which includes the supramarginal gyrus (40) and the angular gyrus (39), is an association area in which are integrated somatic auditory and visual impulses of importance in the mechanism of speech.

Temporal lobe. The lower lip of the sylvian fissure (Heschl's transverse convolutions) is the area of projection of the median geniculate body. It is the primary auditory cortex (areas 41 and 42).

Occipital lobe. The visual centers are located in this lobe. There are three areas: (*a*) the striate cortex (17), which receives the lateral geniculate projection; (*b*) the occipital area (18), which surrounds area 17; (*c*) the preoccipital area (19), which extends into the parietal lobe and receives the projection from the pulvinar.

Olfactory cortex. The allocortex (Kölliker's rhinencephalon) is more highly developed in osmatic animals. It occupies the median aspect of the hemispheres. Cortical representation of smell is located mainly in the entorhinal (area 28) and retrosplenic (area 29) regions.

CORTICAL INTEGRATION OF AFFERENT IMPULSES. THE PARIETAL CORTEX

The cortical relay nuclei of the thalamus project to definite areas of the cortex, which have been shown to integrate sensory impulses. Cortical areas corresponding to the great cephalic receptors, *i.e.*, vision (occipital lobe), audition (temporal lobe), olfaction (hippocampus, gyrus cinguli), and taste (postcentral gyrus), will be considered in the respective chapters. Here only the cortical integration of superficial and deep somatic sensations of the body, which are relayed by the posteroventral nuclei to the parietal and frontal cortex, will be considered.

Relatively recent work has demonstrated the existence of two somatic receptor areas. One of these is the well-known postcentral sensory cortex (areas 3-1-2). The other was first reported by Adrian[1] in the cat, but was later found in several other mammals.[2] It is situated in the dorsal wall of the sylvian fissure in the monkey and in a homologous area lateral to the first somatic receiving area and rostral to the auditory area in other animals. Woolsey has proposed that they should be called somatic areas I and II, respectively. Visual and auditory cortical representations are also distributed in two areas, and two receiving and effector areas have been described in the cerebellum (see Chap. 83); therefore "it seems that a dual system of organization may pervade the afferent nervous system."[3]

Stimulation of the parietal cortex. Forty years ago, Cushing made a systematic examination of the parietal cortex, stimulating it electrically in conscious subjects in whom craniotomy had been performed under local anesthesia.

Stimulation of the postcentral gyrus (areas 3-1-2) evokes tactile or pressure sensations, sometimes cold and warmth, but not pain. These sensations are referred to the opposite side of the body. Those provoked by stimulation of the upper part are referred to the lower limb; they are referred to the trunk and upper limb when the middle part is stimulated, and to the neck and face when the lower part is stimulated (Fig. 405).

Stimulation of the precentral gyrus, especially of the rostral lip of the central fissure, provokes tactile sensations and the sensation of movements, although none are performed; occasionally thermal sensations are evoked, but pain is seldom felt. Reference to the periphery is made in a similar way to that observed when the postcentral gyrus is stimulated. Intense stimulation of areas 5 and 7 evokes sensory hallucinations also, which are sometimes visual or auditory. Visual sensations are felt more frequently when the stimulus is applied to more posterior areas, especially area 19. There are no specific areas for touch, thermal, or proprioceptive sensations; all are represented in the same areas. The cortex is not organized according to modalities of sensation, but by dermatomes.

[2] Woolsey, C. N., *Federation Proc.*, **2**, 55, 1943; **3**, 53, 1944; **5**, 116, 1946; Woolsey, C. N., and D. Fairman, *Surgery*, **9**, 684, 1946.

[3] Woolsey, C. N., *Ann. Rev. Physiol.*, **9**, 525, 1947.

Effects of strychninization of the cortex. The application of strychnine to a limited area of the parietal cortex provokes hyperesthesia, *i.e.*, an increased sensory response to peripheral stimulation, and paresthesia, *i.e.*, abnormal sensations. Disturbances in deep sensibility are always contralateral, while those in cutaneous sensibility are bilateral, but mainly contralateral. Three areas have been differentiated by this method: (*a*) an upper area, corresponding to the lower limb; (*b*) a middle area, corresponding to the trunk and upper limb; (*c*) a lower area, corresponding to the neck and face. These areas extend forward through the depth of the central fissure to the precentral gyrus (areas 4 and 6) and backward to the extreme limit of the parietal lobe. Strychninization of a single point in an area provokes responses corresponding to the whole area, but not to the other two areas; *e.g.*, strychninization of a small part of the arm area is followed by responses in all the upper limb but not in the leg or face. The effects of strychninization of the frontal cortex are not mediated by the parietal cortex; thus, in monkeys, strychninization of the precentral area corresponding to the arm produces its effects after bilateral extirpation of the whole parietal arm area.

Strychninization increases the electrical activity of the cortex; large spikes appear throughout the treated area, but they do not pass to the neighboring areas.[1] The cortex is "set on fire," according to the expression used by Dusser de Barenne, and the fire extends to the corresponding ipsilateral thalamic nuclei. The contralateral thalamus is not disturbed, a fact that is further evidence of the strictly ipsilateral nature of the thalamocortical connections.
FIG. 405. Motor and sensory localizations on the outer aspect of the cerebral cortex. Effects of stimulation. (*After Foerster.*)

Electrical activity of the cortex evoked by cutaneous stimulation. Stimulation of a limited area of the skin by a tactile stimulus evokes electrical activity (spikes) in a definite point of the contralateral parietal receptor area (areas 3-1-2).[2] If a threshold stimulus is applied, in order to avoid complications due to convergence and spatial summation, activity will

[1] Electrical hyperactivity of the three areas can be provoked by strychninization of area $6\alpha\beta$ in the premotor cortex. Electrical stimulation of this area provokes movements in the whole contralateral half of the body.

[2] WOOLSEY, C. N., W. H. MARSHALL, and P. BARD, *Bull. Johns Hopkins Hosp.*, **119**, 423, 1942.

be seen only in a small area of the cortex; by this method it has been possible to demonstrate that there is a dermatomal representation of the skin surface in the cortex (Fig. 406). Sacral dermatomes are represented in the upper part of the gyrus, and the other dermatomes downward in order of entrance into the spinal cord, except that the area of representation of the upper cervical dermatomes is placed next to that of the upper thoracic segments, and the eighth cervical segment lower down next to the trigeminal area. There is nevertheless a certain degree of overlapping of neighboring dermatomal areas. Representation is mainly contralateral except for the face, which is represented bilaterally. Some of the dermatomes are connected with a wide area of cortex, while others have a much smaller representation. The extent of cortical representation is related to the wealth of peripheral innervation; thus the hand area is large and the trunk area is small, in spite of the lesser area of skin covering the hand. Cortical representation is fixed, *i.e.*, there is no migration of an area from one part of the parietal cortex to another at different times. Therefore it is justifiable to accept the conclusion that the correspondence between skin and cortex is due to fixed fiber pathways.

FIG. 406. Diagrammatic frontal section through postcentral gyrus, showing distribution of dermatomes and sensory localization. Note that C_2 is next to T_1, and C_8 next to the centers corresponding to the face. The trunk has a small area of cortical representation, and the hand and face large areas. *Ophth.*, ophthalmic; *Man.*, mandibular; *Max.*, maxillary; *S.C.M.*, sulcus callosus marginalis. (*Woolsey, C. N., W. H. Marshall, and P. Bard, Bull. Johns Hopkins Hosp., vol. 70, p. 428, 1942.*)

The second somatic receptor area. This area is not distributed into dermatomal areas but is related to the whole surface of the body. It is possible, however, to differentiate three zones, corresponding to the face, arm, and leg. There is always a certain degree of overlapping, but differentiation of the zones is greater in the monkey than in the rabbit. Representation in somatic area II is bilateral, *i.e.*, stimulation of receptors on one side of the body evokes activity in both sides of the cortex, but in the ipsilateral area its amplitude is approximately half that in the contralateral cortex. Apical parts, such as the snout and digits, give an ampler response than other parts, such as the proximal end of a limb, and they are the only parts evoking a response in deeply anesthetized animals. In somatic area I richness of innervation is reflected by a large area of cortical representation; in somatic area II it is amplitude of response that increases with density of innervation.

Somatic area II is not dependent on somatic

area I; they each have independent afferent paths, and one of them can respond when the other has been rendered inactive. Area II is related bilaterally to the paramedian receptor-effector area of the cerebellum.

The functional significance of somatic area II is not yet well understood. Perhaps it plays a part in the integration of complex and widespread sensations, while area I is the site of the mechanism for precise localization and discrimination.

Destructive lesions of the parietal lobe. Destructive lesions of the parietal lobes, provoked experimentally or due to trauma or disease, cause sensory disturbances in the contralateral half of the body. Temperature and pain sensations show little or no change. Tactile sensibility shows the loss of precise localization and discrimination, and its differential thresholds are raised (*e.g.*, for two-point sensibility). Proprioceptive sensibility, *i.e.*, the sensation of active and passive posture and movement, is considerably disturbed, and maximum losses are observed in complex sensation patterns such as stereognosis. The patient responds irregularly and is easily fatigued when the side opposite to the lesion is stimulated, but responds normally to ipsilateral stimulation. According to Head's concept of the mechanism of sensation, epicritic sensibility is lost.

Experimental removal of the parietal cortex has been combined with the methods of analysis used by experimental psychologists, which have been applied to patients with cerebral lesions. Thus it has been possible to demonstrate that certain behavior patterns require cortical integration of somatic sensibility. The placing and hopping reactions (see Chap. 81) and responses learned by training to differentiate weights, or rough from smooth surfaces, or geometric shapes (stereognosis) are impaired by removal of the parietal cortex. The deficit increases according to the degree of "encephalization" of the species, *i.e.*, it is more pronounced in man and primates than in lower animals. There is a certain amount of recovery of function as time passes, especially if part of the parietal lobe remains. The hopping reactions and weight differentiation are recovered sooner and more completely than placing reactions and stereognosis.

Different methods of exploration in some cases apparently give contradictory results, but this is not really the case; each method shows a particular aspect of cortical function that is not made evident by other methods. Thus strychninization increases excitability and, by tending to spread the excitatory state, reveals the extent of interconnections between different centers, masking the finer aspects of these connections. On the other hand, stimulation of receptors and registration of electrical activity in paths and centers permits the exploration of more precise and intimate connections between the receptors and centers. This method reveals focal representation that is blurred by strychninization. Removal of parts of the cortex shows how in the integration of complex responses the whole cortex plays a part, and how one area may to a certain extent replace others.

CHAPTER 75

Chemical Senses. Smell and Taste

CERTAIN SUBSTANCES in solution stimulate special receptors and activate neurophysiologic mechanisms known as the chemical senses. Two of these, smell and taste, have differentiated receptors, but there are also free nerve endings in the nasal (nonolfactory), oral (nongustatory), respiratory, anal, and genital (vulva and glans) mucosae which can be stimulated by dissolved substances, giving rise to what is known as the general chemical sense.

THE GENERAL CHEMICAL SENSE

The skin of aquatic vertebrates (fishes and amphibians) is sensitive to chemical stimuli; acids placed on the skin of the frog or toad provoke remarkable defensive reactions. Other vertebrates develop a horny layer on the skin surface which protects them from the action of chemical agents, but if this layer is removed the free nerve endings can be stimulated by substances in solution. The mucosae that are in contact with the external environment (*i.e.*, those just mentioned) are less well protected and therefore respond to chemical stimuli. The general chemical sense forms part of the pain sense; it has the same receptors and afferent nerve paths and evokes painful sensations.

There are chemical receptors connected with visceral nerves; thus the aortic and carotid bodies are sensitive to variations in the partial pressures of O_2 and CO_2 and in hydrogen ion concentration, and to certain drugs. Stimulation of these receptors provokes the discharge of impulses along the nerves of de Cyon and Hering, which initiate reflexes regulating the circulation and respiration. Conscious sensations are not evoked by the stimulation of visceral chemoreceptors (see "Vascular reflexes," p. 195, and "Chemoreceptors," p. 296).

A given substance may stimulate the mucosae and the differentiated receptors, but each receptor needs a particular concentration (strength of stimulus); *e.g.*, the majority of people can detect ethyl alcohol by smell in a concentration of approximately 0.000125 *M*, but a 3-*M* solution is necessary to stimulate taste and a 5- to 10-*M* solution to excite the mucosae. The intact skin is not sensitive to alcohol, but if the horny layer is removed the nerve endings are made accessible and a smarting sensation is produced. Some substances stimulate only one type of receptor; *e.g.*, mercaptan has no taste, but it is a powerful stimulant of smell.

SMELL

Receptors. In the upper part of each nasal cavity there is an area of about 250 sq. mm. on the septum and the superior concha, where the nasal mucosa has a yellow color; this is the olfactory epithelium. This epithelium is made up of three kinds of cells: (*a*) *basal cells*, which are small, conic elements distributed in a single layer on the chorion; (*b*) *sustaining cells*, which are elongated and have a cuticle on the free surface joined to that of other cells so as to form a continuous membrane with perforations through which the cilia of the olfactory cells pass out into the nasal cavity; (*c*) *olfactory cells*, which are modified neurons distributed regularly among the sustaining cells.

The olfactory cells have a proximal and a distal process. The latter is a thick dendrite ending in 6 to 8 fine cilia of 2-μ length, which perforate the membrane formed by the sustaining cells and emerge on the surface of the mucosa. The proximal process is a slender axon 1 μ in diameter; this unmyelinated fiber passes through the cribriform plate of the ethmoid and ends synaptically on the mitral and tufted cells

of the olfactory bulb. Each one of the bulb neurons receives the fibers of several olfactory cells. Extirpation of the olfactory bulb causes retrograde degeneration of the olfactory cells in the mucosa which is complete within a week. Serial sections of the whole olfactory mucosa after ablation of different parts of the bulb in the rabbit show that the degenerated cells are distributed in a manner that indicates there is some degree of regional projection of the olfactory epithelium onto the bulb.[1] Topographic organization is not, however, as precise as in other sense organs, *e.g.*, the almost point-to-point projection of the fovea of the retina on the lateral geniculate body. Electrical methods have also shown there is some degree of localization in the bulb.[2] The olfactory cells are at the same time receptors and conductors; they are the first-order neurons of the olfactory path. This is the only sensory apparatus in which such a primitive structure, similar to that of invertebrates, is found.

Stimulation of the Olfactory Receptors

The olfactory cells are stimulated by small particles given off by aromatic substances. The particles are conveyed into the nasal cavity in the inspired air and by diffusion reach the olfactory area, where they are dissolved in the fluid secreted by Bowman's glands. These glands are situated under the olfactory epithelium, and they have a short duct opening on the surface of this epithelium. The dissolved odoriferous substances act on the cilia of the olfactory cells. The membrane of these cells has a lipoprotein structure; therefore the odoriferous potency of a substance is conditioned by its solubility in fats. The odorous particles are relatively heavy; they diffuse slowly, and the latency of the sensation is consequently lengthened. Stimulation by the first particles to arrive provokes an olfactory reflex—a short, sharp inspiration (a sniff), sometimes accompanied by extension of the neck, which directs the inspired air into the upper part of the nasal cavities, causing a greater number of particles to reach the sensory area. The weight of the particles makes them fall and lie on the ground, so that dogs and other animals with a well-developed sense of smell can follow a trail guided by the odor left by the prey.

Olfactory cells in fishes are sensitive to mechanical stimulation (gentle stroking). In mammals they seem to be sensitive to pressure; there is a burst of impulses at each inspiration, even when the inhaled air is odorless.

Olfactory thresholds. Several methods have been used to determine the threshold of sensation. The air inhaled must contain no odor except the one being tested, and it must be delivered at constant pressure. The *absolute threshold* is obtained by evaporating known quantities of the odorous substance in a given volume of air; the lowest concentration that can be detected by smell is the threshold. The *relative threshold* can be determined by means of Zwaardemaker's olfactometer. This instrument consists of a tube, one end of which is introduced into the nostril and the other into a second tube of greater diameter. The substance tested is spread on the porous inner surface of the outer tube. The air going into the nose must pass through this tube and is thus loaded with aromatic particles. The amount of these is proportional to the length of tube through which the air has passed, and it is measured in arbitrary units of length called olfacties. A double tube, one for each nostril, permits the combination of different substances by simultaneous application. Elsberg[1] has designed an olfactometer that pumps air saturated with the odorous substance into the nostril while the subject holds his breath. The force of the blast is controlled so that it is always the same. The threshold is the minimal identifiable odor, *i.e.*, the smallest amount of saturated air that provokes a sensation of smell.

Olfactory stimuli. The thresholds of different aromatic substances differ widely. Artificial musk is one of the most potent stimulants of smell; it can be perceived in a concentration of 0.04 μg per liter. Natural musk must be in a concentration 1,000 times higher to provoke a sensation, and ethyl ester can be detected only if there is 5 or 6 mg. per liter of air. The stimulating power of a substance is related to its boiling point, because the odoriferous particles are given off by evaporation. The more volatile substances are stronger stimuli than less volatile substances. Thus in the alcohol series the boiling point decreases and the odoriferous power in-

[1] Le Gros Clark, W. E., *Nature, London,* **165,** 452, 1950.

[2] Adrian, E. D., "Sensory Integration," University Press, Liverpool, 1949.

[1] Elsberg, C. A., in Glasser, "Medical Physics," Year Book Publishers, Inc., Chicago, 1944.

creases as the carbon chain lengthens; methyl alcohol produces the threshold sensation at a concentration of 1,000 μg per liter of air, ethyl alcohol at 250 μg, propyl alcohol at 5 to 10 μg, butyl alcohol at 1 μg, and isoamyl alcohol at 0.1 μg.

Classification of odors. Aromatic substances produce different sensations; they do not all have the same smell. Many attempts have been made to classify odors. Zwaardemaker's and Henning's classifications are among the best known, but none is satisfactory. It has not been possible to establish a definite relation between the chemical structure of a substance and its odoriferous properties. The position of the chemical groups OH, CH_2, NH_2, etc., on the ring or side chain of a substance in the cyclic series has a great importance in the determination of its odorific as well as other pharmacodynamic properties. In some cases substances with similar chemical structures have very different smells, while in others two substances with widely different chemical structures have the same or a similar smell.

Sensibility of the receptor. The threshold for a given substance varies within relatively narrow limits in different individuals, and it is fairly constant in the same subject. In women sensitiveness to smell increases before and during menstruation. Obstruction of the nasal cavities due to malformation, congestion of the mucosa, or inflammatory processes (*e.g.*, the common cold) raises the threshold by hindering the passage of odoriferous particles to the olfactory area. The olfactory epithelium is very sensitive to harmful agents, and once the olfactory cells are destroyed they are not replaced.

Difference thresholds. The capacity to distinguish one smell from another, or difference in the intensity of smells, is not easily determined because of the rapidity of adaptation and fatigue. It varies considerably in different subjects. Training is of great importance, but there are also inborn factors that condition the capacity to discriminate smells.

Localization. Olfactory sensations are not referred to the receptor or to any definite point of the environment. The origin of a smell can be localized only with the aid of other sensations.

Adaptation and fatigue. A given stimulus soon loses its efficiency on the olfactory receptor, especially if it is a strong one. This is due in part to adaptation (see Chap. 71) and in part to fatigue. Recovery, however, takes place very rapidly. Fatigue produced by one substance diminishes, but does not suppress, the effects of others of different odor. If fatigue is marked, there is a transitory partial anosmia for the substances that have produced fatigue.

Combination of stimuli. When several stimuli are applied simultaneously, at first one of them can predominate, but after a time, owing to adaptation and fatigue, it loses predominance and gives place to another stimulus. Sometimes the smell of one substance neutralizes that of another; thus by means of Zwaardemaker's double olfactometer it is possible to demonstrate that the smells of rubber and paraffin neutralize each other when applied in the proportion of 14:8.5. Some of the deodorizing substances act by either predominance or neutralization. Simultaneous application of two substances of similar strength but of different smell can produce a sensation completely different from that of either. The art of perfumery consists in finding novel and agreeable combinations. Frequently these are obtained by adding very small amounts of substances which in high concentration have a repugnant smell.

All the olfactory cells are apparently the same. There is no evidence that certain cells are specifically sensitive to odoriferous substances of a given chemical structure. Adrian has shown that the anterior part of the olfactory mucosa is more apt to be stimulated by substances soluble in water, and that impulses from this area are discharged with a shorter latency. The posterior part of the mucosa is stimulated preferentially by substances soluble in oil, and there is a longer latency in the discharge of impulses. "Discrimination depends in the main on differences in the sensitivity of different receptors to different kinds of smell, for when we use threshold concentrations we often find impulses are set up in different conducting units. Most of them, however, react to most smells when their concentration is much above threshold."[1] Different smells would, therefore, be due to the projection on the cortex of different patterns of excitation, arising not only in the olfactory receptors, but also in the nasal mucosa innervated by the fifth cranial nerve, *e.g.*, in the case of ammonia.

Enzymes (phosphatases, nucleotidases, esterases, etc.) have been found in the olfactory mucosa and in the mucous and serous secretion

[1] ADRIAN, E. D., *Nature, London*, **168**, 1021, 1951.

of Bowman's glands. They have been considered to have a part in the stimulation of olfactory receptors.[1]

Olfactory Pathway and Centers

Magendie and other physiologists in the nineteenth century believed that the trigeminal was the olfactory nerve. This is an erroneous conception, as is proved by the fact that extirpation of the gasserian ganglion does not abolish the sense of smell. The trigeminal nerve fibers ending in the olfactory area convey painful impulses. Congenital atrophy of the olfactory bulb, on the other hand, causes permanent and complete anosmia. In recent years several physiological methods have been used in the study of the olfactory paths and centers: (*a*) stimulation of the receptor or of the afferent paths by odorous substances or electrical stimuli, combined with the registration of the spread of the action potentials; (*b*) establishment of olfactory conditioned reflexes; (*c*) the discrimination method, in which animals are trained to distinguish a box with a given smell, containing food, from another, with a different smell, which has no food.
Fig. 407. Diagram of olfactory system (left side, from above). (*Allen, W. F., J. Comp. Neurol. vol. 88, p. 425, 1948.*)

The rhinencephalon or olfactory brain (Fig. 407) is greatly developed in fishes; in selachians it forms almost the whole of the forebrain. The development of the neopallium (the cerebral cortex corresponding to somatic sensation and motility) diminishes the importance of the rhinencephalon (archipallium) in mammals. Nevertheless in macrosmatic species, such as the rodents, in which olfaction plays an important

[1] Baradi, F. A., and G. H. Bourne, *Nature, London*, **168**, 977, 1951; *Science*, **113**, 660, 1951; Kistiakowsky, G. B., *Science*, **112**, 154, 1950.

part, the rhinencephalon is relatively large. Man is a microsmatic animal, and the olfactory cortex is therefore proportionately small.

The olfactory bulb is a diverticulum of the rhinencephalon, with a laminated structure similar to that of the rest of the archipallium. The central cavity has been filled by neuroglia, around which there are myelinated fibers, the axons of the mitral and tufted cells that form the olfactory tract. There are three kinds of neurons in the bulb: the mitral and tufted cells, which send their dendrites outward to the periphery, where they are joined synaptically to the unmyelinated fibers of the olfactory cells; and the deeply placed granules, which send short axons toward the surface of the bulb.

The olfactory tract is covered dorsally by a thin layer of gray matter; it is, therefore, a rudimentary gyrus. It lies on the orbital aspect of the frontal lobe and ends posteriorly in the olfactory tubercle, dividing up into three branches: (*a*) the *medial* olfactory tract, or gyrus, which merges into the paraolfactory area, communicating with the cingulum through the longitudinal striae; (*b*) the *lateral* olfactory tract, or gyrus, which passes into the amygdaloid nucleus and the uncinate gyrus (this anterior part of the hippocampus, together with the lateral tract, is known as the pyriform area); (*c*) the *intermediate* tract or gyrus, which is less distinct and passes directly into the anterior perforated space.

The olfactory cortex is made up of the hippocampus, the gyrus dentatus, the cingular gyrus, and the anterior perforated space. It forms an almost complete circle around the corpus callosum. The olfactory cortex receives fibers mainly from the amygdaloid nucleus and the pyriform area. The afferent olfactory pathway, unlike other sensory paths, does not pass through the thalamus; there is no primary thalamic projection, and no thalamocortical olfactory fibers are known. On the other hand the principal outgoing tracts from the olfactory cortex form the fornix, which goes from the hippocampus to the mammillary body of the hypothalamus. The mammillary body sends out fibers to the anterior nuclei of the thalamus (mammillothalamic tract) and the brain stem (mammillopeduncular tract). The anterior perforated space sends fibers to the habenula, which emits fibers to the mesencephalic nuclei. The anterior and the hippocampal commissures establish connections between both hemispheres. The olfactory centers are extensively connected with other cortical regions.

Stimulation of the olfactory epithelium with aromatic substances induces electrical activity in the olfactory tracts and the hippocampus. This activity is abolished if the olfactory epithelium is anesthetized. Fox, McKinley, and Magoun[1] have used a Horsley-Clark apparatus to place the electrode accurately in the deep brain structures and pyriform areas of the cat. They have carefully explored olfactory nerve centers in this animal and have found that stimulation of the olfactory bulb provokes electrical activity in the anterior perforated substance and the prepyriform and pyriform areas. They also observed spread of electrical activity from the olfactory areas to the putamen and globus pallidus, suggesting the existence of connections between the olfactory centers and the striatum. Stimulation of the pyriform area evokes electrical potentials in the prefrontal area, thus showing a connection between these centers.

If all the cortex except the olfactory centers, pyriform area, and anterior perforated space is removed in monkeys and cats, and the olfactory centers are stimulated electrically several months later, reactions are observed similar to those provoked by the smelling and ingestion of food, *i.e.*, sniffing, secretion of saliva, chewing, movements of the tongue, swallowing, and in monkeys the emission of guttural sounds.[2]

Allen,[3] in a remarkable series of studies, has employed the conditioned-reflex technique, associated with localized extirpation of certain areas. Conditioned reflexes to aromatic substances are not established, or are suppressed, if the olfactory bulb or the olfactory tract is removed. If these substances also have an irritating effect on the nasal mucosa (ether, chloroform, eucalyptus, camphor, etc.), reflexes can be established through the trigeminal nerve.[4] Large parts of the occipital, parietal, and tem-

[1] Fox, C. A., W. A. McKinley, and W. Magoun, *J. Neurophysiol.*, **7**, 1, 1944.

[2] Rioch, D. McK., and C. Brenner, *J. Comp. Neurol.*, **68**, 495, 1938; Smith, W. K., *Am. J. Physiol.*, **133**, 451, 1941.

[3] Allen, W. F., *Am. J. Physiol.*, **118**, 532, 1937; **121**, 657, 1938; **126**, 419, 1939; **128**, 754, 1940; **132**, 81, 1941.

[4] This would explain some old observations of cases of atrophy of the olfactory bulb, in which the sense of smell was reported as still present (Bernard, C., "Leçons sur le système nerveux," p. 229; Testut, "Anatomie humaine," 6th ed., vol. 3).

poral lobes and 90 to 100 per cent of the hippocampus of both sides can be removed in the dog without impairing the establishment or conservation of positive and negative olfactory conditioned reflexes and discrimination. Bilateral extirpation of the pyriform lobes and amygdaloid nuclei or of the prefrontal cortex hinders the acquisition of conditioned reflexes and especially of olfactory discrimination. None of these operations prevents the animals from recognizing meat when blindfolded. Allen[1] suggests that Ammon's horn functions as a mechanism for the amplification of simple olfactory reflexes.

The rhinencephalon does not have exclusively olfactory functions. Stimulation of the limbic lobe provokes respiratory, cardiovascular, and other visceral responses, *e.g.*, contraction of the bladder. Stimulation of the anterior cingulate gyrus has an inhibitory effect, although no paths from this area to the reticular formation have been described. Auditory and optic stimulation evokes electrical potentials in the cingulate gyrus and the hippocampus; the latter also receives somesthetic impulses[2] and intercortical fibers from areas 4, 6, 8, 9, and 10.

The rhinencephalon also takes part in the integration of emotional response and general behavior. Bard and Mountcastle[3] have shown that hyperirritability and sham rage, which appear in cats after removal of the greater part of the telencephalon, are not observed after extirpation of the neocortex if the rhinencephalon remains undamaged; on the contrary, the animals are remarkably placid.

Physiologic Significance

Smell is of fundamental importance in the search for food in many species. In man it has little significance in this respect, but it plays a part in digestion, as the smell of food stimulates salivary, gastric, and other digestive secretions and activates gastrointestinal movements. Smell is important in the initiation of sexual reflexes. In some animals it is an auxiliary in defense, as it gives warning of the proximity of an enemy. Olfactory sensations have a high affective tone of pleasure or displeasure; as a rule any strong smell is disagreeable. They also have a great capacity for awakening memory; possibly this is due to the numerous connections with other parts of the cortex. Through these connections the olfactory centers have an important nonspecific influence upon other cortical and subcortical areas, lowering the threshold and thus facilitating many reactions, or else increasing inhibition. In states of depression it is said that one has lost the taste for life; from a neurophysiological standpoint, it would perhaps be more appropriate to say that life has lost its perfume.

TASTE

What is commonly called "taste" is a complex sensory pattern made up not only of sensations arising in the specific taste receptors but also of those arising in general chemical, tactile, warm and cold receptors in the mouth, and especially of olfactory sensations. If the latter are suppressed, taste, and particularly taste discrimination, is considerably diminished. The gustatory sense only will be considered here.

Receptors. Taste receptors are distributed on the dorsal aspect of the tongue, the laryngeal aspect of the epiglottis, the pharynx, the soft palate (except the uvula), the anterior faucial pillars, and a few on the cheeks and the undersurface of the tongue. The taste organs appear in the course of the third month of fetal life. In the child they are not so widespread as in the fetus, but they are still found over the whole upper surface of the tongue and the mucosa of the cheeks. In the adult they diminish with age, first those on the middorsal region and then those on the tip of the tongue. They are mostly found in the fungiform, foliate, and circumvallate papillae. There are no taste buds in the filiform papillae. The small serous salivary glands that pour their secretion into the papillae are an important part of the mechanism of taste. They first dissolve sapid substances, thus facilitating their action on the receptors, and then wash them out, leaving the receptors in condition to receive another stimulus. The taste buds are made up of two types of cells, the sustentacular and the gustatory; the latter are spindle-shaped, and the peripheral end is drawn out into a ciliary process or gustatory hair, which projects through the pore of the bud. Both types of cells are innervated.

Thresholds. The taste receptors are stimulated by introducing into the mouth a certain

amount of the sapid substance in a solution of known concentration. Localized stimulation is provoked by placing a drop of the solution on the area examined, taking care not to let it spread. The thresholds vary considerably from one subject to another, but are fairly stable in the same subject. The threshold varies on the different areas of the tongue according to the distribution of the taste buds. In animals the thresholds can be determined by the conditioned-reflex method, the discrimination method, or the preference method. In the last method, the subject is given the choice of drinking tap water or a solution of the sapid substance; the minimum concentration that shows a differential consumption with water—either more, if the taste is preferred, or less, if it is rejected—gives the preference threshold, which is not equivalent to the absolute threshold. Distilled water at pH 7 is often considered the standard insipid substance, yet it has a peculiar taste similar to that of dilute alkali, owing to the fact that it has no CO_2. Saliva is the standard by which other tastes are judged (Moncrieff). An electric stimulus applied to the tongue provokes electrolysis, and usually a sour taste is perceived. The registration of action currents of the sensory nerves innervating the taste buds when these are stimulated has also been used to study the effect of different substances.

Taste receptors can also be stimulated by intravenous injection of a substance; *e.g.*, if "decholin," the sodium salt of dehydrocholic acid, is injected into a vein, a bitter taste is perceived when it arrives at the taste buds. This fact has been used to measure the circulation time.

Classification of tastes. Four tastes are recognized by the majority of normal human subjects: (*a*) salt; (*b*) acid or sour; (*c*) sweet; (*d*) bitter.

Salt taste. Dissociated salts stimulate the taste buds, but stimulation by nondissociated salts cannot be ruled out. The taste of common salt (NaCl) is the typical salt taste. Both the anion and the cation play a part in evoking this taste. Cl^-, Br^-, I^-, $SO_4^{=}$, NO_3^- have a saline taste, but all their salts do not taste the same. Thus NaBr has a salty taste, KBr tastes salt and bitter, and RbBr tastes bitter. Salts of cations of low molecular weight Na^+, Li^+, NH_4^+, taste salty, K^+ salts taste both salt and bitter, and salts of heavy cations such as Ca^{++}, Mg^{++}, Rb, and Cs taste bitter.

The absolute threshold of the saline taste of NaCl is given by a 0.087 per cent solution; some subjects perceive a saline taste in 0.02 per cent NaCl. If NaCl solutions are compared with distilled water, the salt-taste threshold is at 0.01 per cent, or even less (0.007 per cent).[1]

Sour taste. This is a property of all acids and is mainly dependent on the H^+ concentration. Mineral acids, such as HCl, H_2SO_4, H_2NO_3, etc., cannot be distinguished by their taste, and the strength of the sensation evoked is proportional to the H^+ concentration. The threshold is about pH 3.4 to 3.5. Organic acids, such as acetic, butyric, and citric, have a higher threshold if the minimum concentration of the acid is considered; *e.g.*, the threshold for HCl is 0.00125 *N* solution, and for acetic acid it is 0.005 *N*. Organic acids are weak acids, and less dissociated than mineral acids; in the example just given, the HCl solution has between four and five times the H^+ concentration of the acetic acid solution. Therefore organic acids are more efficient stimuli of taste buds than mineral acids. The threshold for organic acids is pH 3.7 to 3.9. Moreover, buffer solutions of weak acids evoke a sour taste at a much lower H^+ concentration, *e.g.*, the threshold for a buffer solution of acetic acid and sodium acetate is pH 5.6.[2] The undissociated salt plays a part in this case. The greater efficiency of organic acids as stimulators of taste has been attributed to their higher solubility in lipids, and it is supposed they can penetrate into the taste cells and increase intracellular H^+ concentration more rapidly than mineral acids.[3]

Sweet taste. Polyatomic alcohols, *i.e.*, substances which have several CH_2OH groups, have a sweet taste. The most common are glycerol, and sugars, such as hexoses (glucose, fructose, etc.) and their polymers (sucrose, lactose, etc.). The sweet taste is also a property of substances with a completely different chemical structure, *e.g.*, α-amino acids, lead acetate, chloroform, beryllium salts, saccharin (*o*-sulphobenzimide), and dulcin (*p*-ethoxy-phenylurea).

The threshold for the sweet taste of sucrose is given by 0.4 to 0.5 per cent solutions. The sweetness of a substance is usually compared with that of sucrose (Table 97). With the ex-

[1] RICHTER, C. P., and A. MACLEAN, *Am. J. Physiol.*, **126**, 1, 1939.

[3] TAYLOR, N. W., *J. Gen. Physiol.*, **11**, 207, 1928.

ception of fructose, most of the sugars are not so sweet as sucrose, but there are synthetic substances which are several hundred times sweeter. The relative sweetness of sugars varies with the concentration. Isosweet curves of several sugars (glucose, galactose, lactose, etc.) compared with sucrose are not lineal but exponential.[1]

Table 97. Relative Sweetness of Different Substances

Substance	Relative sweetness
Sucrose	1.0
Fructose	1.73
Glycerol	1.08
Glucose	0.74
Galactose	0.32
Maltose	0.32
Lactose	0.16
Dulcin	265
Saccharin	675
4-nitro-2-aminophenylpropyl ether	3,300

Sources: BIESTER, WOOD, and WAHLIN, *Am. J. Physiol.*, **73**, 387, 1925; GILMAN and HEWLETT, *Iowa State Coll. J. Sc.*, **4**, 27, 1929; BLANKSMA and VAN DER WEYDEN, *Rec. de trav. chim d. Pays-Bas*, **59**, 629, 1940.

Bitter taste. Alkaloids (quinine, strychnine' etc.), glucosides, salts with a high molecular weight (Ca, Mg, Rb, Cs salts), and other substances such as picric acid have a bitter taste. The threshold for quinine is given by a 0.0016 per cent solution; strychnine is about three times as bitter as quinine and brucine (dimethoxystrychnine) more than ten times as bitter.

Certain substances have more than one taste, *e.g.*, the salts with saline and bitter taste. Others, such as the glucoside dulcamarin, taste sweet and bitter; pyridine 2,5-dicarboxylic acid is sweet, bitter, and sour.

Solubility in water is an essential prerequisite for a substance to have taste. Solubility in lipids may also play a part in enhancing this property. Chemical structure is another essential prerequisite. This is not so apparent in the more primitive salt and sour tastes, in which acids and salts taste much alike; but it is of fundamental importance for the sweet and bitter tastes, which, according to Moncrieff, are a later and higher specialization. The capacity to stimulate a taste receptor is due to special chemical groups (saprophores), the loss or modification of which renders the substance tasteless or gives it another taste. Thus *p*-etoxyphenylurea (dulcin) is extremely sweet and *p*-etoxyphenylthiourea is very bitter; dimethoxystrychnine is three to four times more bitter than strychnine.

Distribution of the taste receptors. A taste bud is apparently stimulated exclusively by the substances in one of the four groups mentioned, but in the same papilla there can be buds corresponding to two or more tastes. In man, the salt taste receptors are more numerous in the tip and the anterior part of the lateral margins of the tongue, acid in the lateral margins, sweet in the tip, and bitter in the base, connected with the large circumvallate papillae. A given substance can stimulate two types of organs. Thus $MgSO_4$ tastes salt on the tip and bitter on the base of the tongue; hexamine is sweet and also bitter.

In the cat,[1] three types of taste organs have been discovered by registering the action potential in the chorda tympani after reducing it by dissection to only a few fibers: (*a*) those stimulated by acids; (*b*) those stimulated by acids and salts (NaCl); (*c*) those stimulated by acids and bitters (quinine). Sweet substances apparently do not stimulate any receptors. These experiments show that in the cat either a receptor is stimulated by substances of two tastes or else the final branches of one axon end in receptors of two different types; in the second case the sensory unit would not be homogeneous. The nerve impulses are the same whatever stimulus is used, a fact that proves conclusively that the quality of sensation is not dependent on differences in the nerve impulses. In this species salt receptors are more numerous in the anterior part, and bitter ones in the back, while acid receptors are distributed all over the tongue but are relatively scarce on the middorsal aspect. In the dog there are receptors for the four tastes. Sweet receptors are fairly widely distributed; they are stimulated by sucrose, glycerol, lead acetate, and other substances tasting sweet to man, but not by saccharine. Taste impulses are conducted by relatively fine fibers, 4 to 6 μ in diameter in the dog (calculated from the spike potential). Impulses arising in receptors stimulated by strychnine and other bitter-tasting substances are conducted in very fine fibers.[2] The initial frequency of the impulses depends on the

[2] ANDERSSON, B., S. LANDGREN, L. OLSSON, and Y. ZOTTERMAN, *Acta physiol. Scandinav.*, **21**, 105, 1951.

concentration of the sapid substance, *i.e.*, the strength of the stimulus. Adaptation is relatively slow. There are no morphologic differences between the taste buds sensitive to different kinds of sapid substances. Sensitiveness to different substances is probably due to differences in the chemical constitution of the receptors. Localized stimulation has shown that there are individual receptors that respond exclusively to one of the four types of stimuli. Pfaffmann's[1] experiments in the cat, recording the action potentials of single nerve fibers, also demonstrate the existence of receptors that respond to only one type of sapid substance. Moreover, cocaine applied on the tongue abolishes first the sensation of bitter, then sweet, then salt, and finally acid. Sweet and bitter tastes are selectively abolished by the local application of gymnemic acid, which leaves salt and sour unimpaired.

Taste sensibility. There are considerable individual differences in taste sensitiveness. Certain subjects cannot perceive any taste; they are "taste-blind," a condition known as ageusia. Loss of one taste, *e.g.*, sweet or bitter, leaving the others unimpaired has not been observed. The majority of individuals recognize as sweet a solution of 0.41 per cent of saccharose; for others even a 10 per cent solution is tasteless. Ethyl alcohol has no taste for some subjects, who drink it in concentrations of 50 per cent and more, while most subjects find it disagreeable at 10 per cent or even less.

Certain substances which taste bitter to the majority of individuals are tasteless to others, *e.g.*, *p*-ethoxyphenylthiourea. This substance and others, such as phenylthiocarbamide (PTC) and its derivates, which also have a bitter taste, have been widely used to investigate taste deficiencies. The threshold for PTC varies considerably; the minimum concentration that can be distinguished from water is 0.000005 per cent for some individuals and 0.1 per cent for others, with a maximum frequency at 0.0003 per cent.[2] A certain number of subjects (3 to 5 per cent) are practically "taste-blind" to this substance. In women the threshold was found to be slightly lower than in men, and when the response to 0.05 per cent PTC was tested, 22.2 per cent

[2] SALMON, T. N., and A. F. BLACKSLEE, *Proc. Nat. Acad. Sc.*, **21**, 78, 1935; RICHTER, C. F., and K. H. CLISBY, *Am. J. Physiol.*, **134**, 157, 1941.

were found to be nontasters; the corresponding figure for men being 25.9 per cent.[1] This type of "taste-blindness" is inherited according to the mendelian laws. When both parents are nontasters, the offspring are all nontasters.[2]

Diversity in taste has been remarkably demonstrated by the following experiment: At a meeting of scientists (*i.e.*, trained observers experienced in the objective consideration of phenomena), the taste of an unknown substance (maltose) was tested. The answers obtained were (*a*) sweet; (*b*) bitter; (*c*) acid; (*d*) salt; (*e*) insipid; (*f*) complex—that is to say, all the possible answers. The old Latin tag *ae gustibus non est disputandum* is apparently true in a literal as well as a figurative sense.

Taste threshold varies with the temperature of the solution used as a stimulus. It is at a minimum between 20 and 30°C. and rises at temperatures below and above these. Changes in the concentration in the blood, and therefore in the taste buds, of salts modify the preference threshold for these substances. Thus in adrenal insufficiency there is a decrease in blood sodium, and a specific appetite for sodium is awakened. Normal rats recognize and prefer a 1:2,000 NaCl solution; adrenalectomized rats distinguish and prefer a solution of 1:33,000 NaCl.[3] Adrenalectomized rats spontaneously increase their NaCl consumption, compensating for the excess loss of salt in the urine. Specific appetite for salt has also been observed in patients with Addison's disease (adrenal insufficiency). An increase in blood sodium causes the specific appetite for sodium of adrenalectomized rats to diminish. Parathyroidectomized rats with low blood calcium have a specific appetite for calcium. The mechanism of this process must be fairly complex; apparently, however, it does not involve a decrease in the absolute threshold of taste. Thus the minimum concentration of NaCl applied to the tongue evoking action potentials in the chorda tympani was found to be 0.008 per cent in normal and 0.010 per cent in adrenalectomized rats.

Fatigue soon occurs in taste. Persistence of a stimulus diminishes the sensitiveness of the taste stimulated. There is some evidence that sensi-

[1] FALCONER, D. S., *Ann. Eugenics*, **13**, 211, 1947.

[2] SNYDER, L. H., *Science*, **74**, 151, 1931; BLACKSLEE, A. F., *Proc. Nat. Acad. Sc.*, **18**, 120, 1932.

[3] RICHTER, C. F., *Endocrinology*, **26**, 367, 1939.

tiveness of other taste receptors is simultaneously increased.

Contrasts and masking. Simultaneous and successive contrasts are well developed in taste. Thus, sweet and acid reciprocally raise, and sweet and bitter lower, their thresholds. Neutral distilled water tastes like dilute alkali, but after an acid solution it tastes sweet. These contrasts are used to mask unpleasant tastes and to enhance pleasant ones. In lemonade, acid and sweet are combined in agreeable proportions. Aromatic substances are sometimes used to mask an unpalatable taste.

Fusion frequency. Repetitive electric stimulation of the tongue, with the cathode as the active electrode and the inactive anodic electrode on the lower surface of the tongue, gives rise to a sensation of sour taste. According to Allen and Weinberg,[1] if the frequency is sufficiently low, pulsating or discontinuous sensation is evoked, which becomes continuous when the frequency of stimulation is increased. The critical frequency, *i.e.*, the minimum necessary to evoke a continuous sensation, decreases as the voltage increases; a stronger stimulus prolongs the duration of the sensation. Plotting frequency against voltage, four curves are obtained which the authors attribute to the four tastes on the basis of experiments with gymnemic acid which abolishes the sweet and partly the bitter tastes. Jones and Jones,[2] however, have not been able to obtain discrete gustatory sensations; only continuous sensations were evoked with all voltages and frequencies. Tactile pulsating sensations were perceived which might be confused with gustatory sensations by untrained subjects. It is therefore premature to speak of fusion frequency in gustatory sensation.

Enzymes in taste organs. Histochemical methods have shown there are several enzyme systems in the taste buds or the neighboring epithelium of the papillae. Alkaline phosphatase has been found concentrated in all the cells of the taste buds, gustatory pores, and gustatory hairs in the bat and monkey; in man and rabbits it is found in the epithelium overlying the taste buds, gustatory pores, and gustatory hairs. Other enzyme systems have been found in the epithelium lining the folds between the papillae; they act on the following substrates: adenosinetriphosphate, hexose-diphosphate, adenylic acid, ribonucleic acid, long-chain fatty acids (lipase); acid phosphatase has also been identified. These enzymes have been

[1] ALLEN, F., and M. WEINBERG, *Quart. J. Exper. Physiol.*, **15**, 385, 1925.
[2] JONES, M. H., and F. W. JONES, *Science*, **115**, 355, 1952.

considered as part of the mechanism which stimulates taste receptors.[1]

Localization. Taste sensations are localized on the receptor. They are contact sensations similar in this respect to tactile sensations.

Peripheral and Central Pathways of Taste

Innervation of the receptors. The taste buds are innervated by fine fibers. In the cat 18 per cent, and in the dog 23 per cent, of the fibers in the chorda tympani (one of the gustatory nerves) are unmyelinated and less than 1.5 μ in diameter. Myelinated fibers range from 1.5 to 6 μ in diameter.[2] Not all are gustatory fibers; some of them conduct pain and tactile impulses. The following nerves include fibers which innervate taste receptors.

1. *The lingual nerve* innervates the anterior two-thirds of the tongue. The taste fibers in this nerve arise in the geniculate ganglion of the facial nerve. In most subjects they join the lingual nerve through the chorda tympani; in others they follow a different path, leaving the geniculate ganglion through the greater superficial petrosal nerve and passing through the otic ganglion into the chorda and lingual nerves.
2. *The glossopharyngeal nerve* innervates the posterior third of the tongue. The fibers arise in the petrosal ganglion.
3. *The vagus nerve* sends a few fibers to the taste buds of the epiglottis and pharynx. The neurons of these fibers are situated in the ganglion nodosum (Fig. 408).

Section of the lingual and glossopharyngeal nerves increases considerably the threshold for salt and quinine, but complete ageusia is not observed even though the taste buds of the tongue degenerate completely after denervation. Taste buds innervated by the vagus may be responsible for the remnant of sensation, or else the strong solutions employed stimulate nongustatory receptors (the common chemical sense).[3]

Central pathways and nuclei. The fibers conducting impulses from the taste buds, which enter the pons and medulla with the seventh, ninth, and tenth nerves, form part of the descending tractus solitarius and end in the nucleus of this tract. The facial and glossopharyngeal gustatory fibers end in the rostral and the vagal fibers in the caudal part of the nucleus. Lesions in the tractus solitarius (guinea pig, rabbit) produce degeneration in the dorsal part of the medial lemniscus, medial to the ventral trigeminothalamic tract. These fibers end in the n. ventralis posteromedialis, or arcuate nucleus of the thalamus. Lesions in the dorsal part of the medial lemniscus raise the threshold for quinine in the rat.

FIG. 408. Diagram representing the peripheral and central pathways of taste (highly schematic).

The thalamic relay neurons of the gustatory paths are situated in the dorsomedial tip of the arcuate nucleus. The following observations are evidence for this assertion: (*a*) bilateral localized lesions in the arcuate nucleus in the monkey are followed by permanent disturbances in taste; the threshold for quinine is raised, and the animals drink a bitter-tasting solution as if it were water;[1] (*b*) hemiageusia has been reported in a patient with a tumor destroying the medial tip of the arcuate nucleus;[1] (*c*) tactile stimulation of the body surface in the cat and monkey evokes potentials in the arcuate nucleus, except for a discrete area in the medial tip of this nucleus; (*d*) extensive lesions of the inferior rolandic cortex which do not cause disturbances in taste provoke severe retrograde degeneration in the arcuate nucleus except in its dorsomedial tip.

Cortical representation. It has been commonly supposed that the cortical centers of taste were situated in the olfactory area. This opinion was founded on the following facts: (*a*) taste and smell are "chemical" senses; (*b*) the receptors of both senses are frequently stimulated at the same time, and the sensations provoked by one and the other are closely associated; (*c*) stimulation of taste and smell produce motor and secretory reflexes in the digestive tract. In spite of this close functional association, the senses do not have a common or even neighboring cortical representation. Removal of olfactory centers (pyriform area, amygdaloid nucleus, and hippocampus) is not followed by disturbances in taste.[2] Extirpation of the olfactory bulb does not suppress gustatory reactions in animals, nor are the

[1] ADLER, A., *Ztschr. Neurol. & Psychiat.*, **149**, 208, 1934.
[2] ALLEN, W. F., *Am. J. Physiol.*, **132**, 1941, *loc. cit.*

taste thresholds modified when olfactory capacity is diminished, as occurs in the common cold and other cases of nasal obstruction.[1]

The central pathways and the thalamic and cortical representations of taste are not close to those of smell, but are associated with those of the somatic sensations of the tongue, the impulses of which are conducted in the trigeminal nerve.[2] The exact area of cortical representation of taste has not yet been definitely located, but there is the following evidence that it is not situated on the surface of the brain, but in the sylvian fissures in the parainsular region, or in the insula: (*a*) removal of the precentral and postcentral parainsular cortex with minimal damage to the surface cortex produces disturbances in taste in monkeys and chimpanzees as severe as those provoked by wide and deep lesions in the opercular region;[3] (*b*) stimulation of the chorda-lingual trunk, after section of the lingual component, evokes surface potentials in the cortex of the sylvian fissure (Woolsey's somatosensory area) rostral to the face area;[4] (*c*) in the rabbit, extirpation of Bremer's "masticatory" area, the cytoarchitectural homologue of the insula in primates, abolishes taste and provokes retrograde degeneration in the posteroventral thalamic nucleus (homologue of the primate arcuate nucleus);[5] (*d*) epileptic seizures with gustatory aura and disturbances in taste have been observed in patients with tumors involving the insula. Cortical representation of taste is, therefore, situated in the inferior extension of the sensory cortex, below the somatosensory representation of the face, corresponding to the extreme medial localization of the thalamic relay of the gustatory path.[6]

[1] Frequently it is said that food becomes tasteless when one suffers from a cold, because the olfactory sensations, which are diminished or absent, are mistakenly identified with those of taste, which are not impaired.

Physiologic Significance

Stimulation of taste receptors provokes salivary, gastric, and other digestive secretions and gastrointestinal motility. Taste thus plays an important, although not indispensable, part in normal digestion.

Taste, however, has a more fundamental physiologic significance; it regulates the ingestion of food and in this way has an important part in the maintenance of the constancy of the *milieu intérieur*. This fact has only recently been brought to light, mainly by the work of Richter.[1] Food is distinguished from harmful substances. Thus rats prefer nutritive solutions of sugars and electrolytes, below certain concentrations (8 per cent saccharose, 10 per cent maltose), and will drink them instead of distilled water; they also refuse toxic solutions, such as those of $HgCl_2$ and AsO_2, or substances without nutritive value. When given a choice between water and alcohol, they prefer alcohol in concentrations of 1 to 6 per cent but not in higher concentrations; they reduce the ingestion of food in quantities equivalent to the calories of the alcohol ingested. Rats on deficient diets show a marked preference for foods that contain the required substance. Thus rats suffering from vitamin deficiency will eat selectively foods containing the missing vitamin.

The intimate nature of this process is not yet known, but taste plays a fundamental part, because after section of the taste nerves preference thresholds and discriminative ingestion of food are considerably disturbed.

CHAPTER 76

Vision

Knowledge of the size, shape, color, and luminosity of objects in the environment, together with their position and movements in space with respect to other objects and to the observer, is obtained by means of sight. Vision also plays an important part in postural reflexes and in the maintenance of postural equilibrium. These results are obtained by a complex process. Light from the objects in the environment is focused on the retina by the dioptric system of the eye, and an image is formed. The receptor cells in the retina are thus stimulated, and nerve impulses arise, which are conducted along the visual pathway to cortical centers. There the mental image of the object is formed. The process will be examined in this order in the course of this chapter and the following ones.

THE FORMATION OF IMAGES BY THE EYE

Light rays that enter the eye are focused on the retina by the dioptric surfaces in the eye according to the physical laws of optics.[1]

Refraction of light. Light rays, on passing obliquely from one transparent medium to another of different optical density, are deflected from their path, *i.e.*, they are refracted. According to the laws of refraction, when a ray of light passes from a rarer to a denser medium, refraction is made toward the perpendicular, and away from the perpendicular when the ray passes from a denser to a rarer medium. For example, the incident ray, on passing from air into a sheet of glass of greater optical density, is deflected toward the perpendicular; on passing out of the glass into air at the opposite surface, it is again deflected, but this time away from the perpendicular (Fig. 409). The incident ray forms an angle with the perpendicular to the surface which is called the *angle of incidence;* the refracted ray forms with the perpendicular the *angle of refraction*. The ratio of the sine of the angle of incidence to the sine of the angle of refraction is the *index of refraction* of the medium into which the ray enters.

[1] The student is advised to refresh his knowledge of optics in a textbook of physics.
Fig. 409. Refraction of light passing from one medium to another of different density. *i*, angle of incidence; *r*, angle of refraction.

If a light ray falls obliquely on a transparent medium with parallel surfaces (*e.g.*, a sheet of glass), on again passing out of the medium into air it will follow a path that is parallel to the incident ray. If a ray falls obliquely on the surface of a prism, on again emerging into the air it will be deflected toward the base of the prism. If the ray passes through a lens, the deflection will depend on the form of the lens, *i.e.*, convex, concave, cylindrical, or complex.

Refraction by convex lenses. The principal axis of a convex lens with two spherical surfaces is a straight line that passes through the centers of curva-

ture of these spheres; therefore it is perpendicular to the principal plane of the lens. Rays that fall on the lens traveling along the principal axis are not refracted; they pass through the lens without being deflected. Rays parallel to the principal axis are refracted and on emerging converge to a point situated on the principal axis behind the lens; this is the *principal focus* (Fig. 410). The distance from the principal focus to the lens is the *principal focal distance;* it varies with the curvature and the refractive index of the lens. The focal distance is a measure of the refractive power of a lens.

If a luminous object is placed on the principal focus, the rays emerging from the lens follow a parallel course. If a luminous object is placed on the principal axis between the principal focus and the lens, the rays emerging from the lens follow a divergent course and are not focused. If a luminous object is placed on the principal axis at a greater distance than the principal focal distance, the rays on emerging from the lens converge to a point on the principal axis which is farther away from the lens than the principal focus. These two points are known as *conjugate foci,* because a luminous object placed on either of them will be focused on the other. For example, if a luminous object is placed at twice the principal focal distance, a real image, inverted and smaller than the object, will be formed at twice the principal focal distance behind the lens.

The *optical center* of a biconvex lens is situated on the principal axis equidistant from the surfaces if these are of equal curvature, and nearer one of the surfaces if they are of unequal curvature. All straight lines passing through the optical center, other than the principal axis, are called *secondary axes;* these cross the principal axis at the optical center. Rays of light coincident with a secondary axis do not suffer a change in direction; they emerge from the lens and follow a path that is parallel to the incident ray. A luminous point not on the principal axis will have its conjugate focus (*i.e.,* image) on the secondary axis drawn from this point through the optical center, at the place where the prolongation of the line of the refracted ray passing through the principal focus cuts the secondary axis.

Fig. 410. Refraction of light by convex lenses. *A*, refraction of parallel rays; *B*, refraction of divergent rays; *C*, refraction of divergent rays from a light placed between the lens and the principal focus; *f* and *f'*, conjugated foci; *a* and *a'*, inverse principal planes; *b* and *b'*, focal planes; *c*, direct principal plane.

The Refractive Surfaces of the Eye

The *cornea* and *aqueous humor* have approximately the same index of refraction; they can therefore be considered as forming a system of concavoconvex lenses. When this system is separated from the organism, its refractive index is lower than that of the crystalline lens, but in the intact eye it has a higher refractive power because light rays pass from the air into the much denser medium of the cornea. Two-thirds of the

total refractive power of the eye is due to this system (42 D.).[1]

Table 98. Refractive Properties of the Eye

	Refractive index	In the organism		Radius of curvature, mm.	Distance to cornea, mm.
		Refractive power, D.	Focal distance, mm.		
Cornea	1.34	42	24	8	
Aqueous humor	1.33				
Crystalline lens	1.42	23	44	Ant. surf. 10	3.6
				Post. surf. 6	7.6
Vitreous humor	1.33				
Retina	....	..	..	....	22.6

The *crystalline lens* is a biconvex lens which has a high refractive index but which *in situ* does not refract the light rays so much as when isolated from the eye, because the rays pass into it from the cornea and aqueous humor, which also have high optical density. After the crystalline lens has been removed because it has become opaque (cataract), a lens of 10 D. corrects the defect produced. The cortex of the lens has a lower refractive power than the nucleus, a circumstance that is useful for the correction of spherical and chromatic aberration produced especially in the periphery of the lens. The shape of the lens can be altered, thus modifying its refractive power. This can increase up to 10 D. when an object is displaced from a distance greater than 6 m. (20 ft.) from the cornea (far point) to a distance of 10 to 20 cm. (4 to 8 in.) from the cornea (near point). This accommodation of the lens, according to the distance at which the object is placed, permits clear focusing of the image on the retina. It is governed by a special mechanism, which will be considered later.

The reduced eye. The path of the light rays through the eye can be deduced from the refractive index and the surface curvature of the different media and the distance between them (Table 98). This is a laborious task, and a fair approximation can be obtained by employing an optical system, introduced by Listing and modified by Donders, known as the "reduced eye." The principal numbers in this system are easily remembered, and there is no difficulty in tracing the path of the light rays. Light is considered as being refracted only on entering the eye, which is supposed to be a homogeneous optical medium with the same index of refraction as water, 1.333. The center of curvature and optical center of the system is situated on the principal axis, 5 mm. behind the cornea; the retina is 15 mm. behind the optical center. The distance from the cornea to the retina is 20 mm., and parallel rays that enter the reduced eye are focused exactly on the retina. The total refractive power is 65 D. (Fig. 411).

[1] The refractive power of lenses is expressed in diopters, *i.e.*, the reciprocal of the focal distance in meters. Thus a lens with a focal distance of 1 m. is considered as having a refractive powerof 1 D., if the focal distance is 0.5 m. the refractive power is 2 D., and if the focal distance is 0.1 m. the refractive power is 10 D.

Retinal Image

A real, inverted image, smaller than the object, is formed on the retina. Scheiner observed this for the first time in 1625, using the eye of a white rabbit, which has no pigment and therefore has a translucid sclera. If the eye of any animal is placed at one end of a tube made out of black paper, with the cornea facing outward so that the light enters the eye, on looking through the tube at the other end, the observer will see the image of the objects before the eye formed on the retina. After scraping off the sclera, the result is even more striking. The retina can be examined *in vivo* by means of the ophthalmoscope.[1]

[1] The ophthalmoscope was invented by Helmholtz in 1851. The primitive model consists of a small mirror that reflects a ray of light into the eye. In the center of the mirror there is a small orifice through which the observer looks into the fundus of the eye.

Visual angle. Size of the retinal image. The path of the light rays forming the retinal image is given in Fig. 411. The visual angle is formed at the optical center by the limiting rays from *A* and *B*. This angle increases as the object is placed closer to the eye, *i.e.*, the visual angle is inversely proportional to the distance between the object and the eye. These same lines prolonged beyond the optical center form the retinal image. There are, therefore, two triangles joined at their apexes, the bases of which are respectively the object and its image. From the size of the object and its distance from the eye, it is easy to calculate the size of the image, because the distance of the image from the optical center is always 15 mm. Therefore,

$$\frac{\text{Size of object}}{\text{Size of image}} = \frac{\text{Distance from object to optical center}}{\text{Distance from image to optical center}}$$

For example, the image of an object of a diameter of 100 m. at 1,000 m. distance will measure 1.5 mm., since

$$\frac{100}{x} = \frac{1{,}000}{0.015}$$

$$x = \frac{0.015 \times 100}{1{,}000} = 0.0015 \text{ m. } (1.5 \text{ mm.})$$

Fig. 411. Formation of the retinal image in the reduced eye. Distances in millimeters. (*Donders.*)

Characteristics of the image perceived. Images are perceived "erect" and "projected." The retinal image is inverted with respect to the object, but it is seen in the correct position. The "righting" of the image is a psychological process, which is begun in childhood by the association of the visual image with other, especially with tactile, sensations.

Projection consists in the localization of objects at a distance from the receptor; touch and taste, unlike vision, are localized on the receptor. Thus if the eyes are closed and a finger presses on the eyeball, a visual sensation, called a "phosphene," is awakened; a dark spot surrounded by a light halo is perceived. The sensation is localized at a distance in a direction opposite to that of the stimulating pressure, *e.g.*, on the nasal side if the temporal side is stimulated.

Lecat's experiment is another illustration of the same process. A pinhole is made in a card, which is then placed at a distance of 2 cm. from the eye, *i.e.*, within the near point. The head of a pin is placed between the card and the eye, and they can be so adjusted that in the light passing through the pinhole an inverted pinhead will be seen. The pin casts an erect shadow on the retina, and an image is formed which corresponds to that of an inverted pin.

Entoptic images. Objects within the eye form what are known as entoptic images. Thus foreign bodies in the vitreous humor are seen as flying shadows when one looks at the sky or on a luminous surface. Defects on the cornea or crystalline lens appear as colored halos. The vascular network of the retina can also be perceived by looking at a bright luminous surface through a pinhole in a card which is moved so that the shadows of vessels on the retina are displaced (Purkinje's images). The erythrocytes in the retinal vessels can be seen by looking through a blue-violet glass onto a bright surface, or even better with Fortin's apparatus, which consists of a bright blue-violet light placed laterally to the eye and moved backward and forward.

Optical Defects

The eye has defects common to all optical systems. These are, however, corrected to a certain extent by the iris, which eliminates marginal rays (the cause of the majority of these defects), and by the low sensitiveness of the peripheral retina, where the distorted images are mostly formed. There are also psychological processes

which contribute to improve the appearance of the images.

Spherical and chromatic aberration. Diffraction. Presbyopia. *Spherical aberration* in a lens is due to focusing of marginal rays in front of the focus of the central rays, thus blurring the image. In a camera this defect is corrected by forming the lens with two substances of different refractive indexes. In the eye it is corrected in part by elimination of the peripheral rays (constriction of the iris) and by the greater optical density of the nucleus of the lens with respect to that of its cortex.

Chromatic aberration is due to the different dispersion of the light rays by the lens, according to their wavelength, so that the focus for violet rays is placed nearer the lens than that of red rays, with a series of intermediate foci for the other colors of the spectrum. This type of aberration is corrected by joining a concave lens to a convex one of a different type of glass, so that the composite lens is achromatic. In the eye yellow rays are focused on the retina so that 70 per cent of the spectrum is utilized. Colors at both ends of the spectrum are not perceived separately, nor is the image blurred. The mechanism of this is not well understood.

Diffraction consists in the deviation of part of the rays by the edge of the iris or by colloidal particles in the cornea or the crystalline lens. This blurs the retinal image. The ultraviolet rays are those which suffer the most dispersion; thus they are deviated from the retina, on which they have a harmful effect.

Presbyopia consists in the decrease of the power of accommodation of the lens for objects at different distances. This power diminishes fairly rapidly between forty and fifty years of age, and the near point of distinct vision is situated at increasingly greater distances from the eye. It is easily corrected by lenses that replace the diopters lost.

Emmetropia and ametropia. In the normal eye, when the lens is at rest, parallel rays are focused on the retina. This is due to the existence of an adequate relation between refractive power and axial length, which is called emmetropia. Normally the far point is situated at 6 m. (20 ft.), and rays of light from that or a greater distance can be considered as coming from infinity and entering the eye parallel to the principal axis.

If there is an abnormal relation between refractive power and the axial length of the eye, the condition is known as ametropia. The far point is not placed at infinity, and parallel rays are not focused on the retina. Ametropia may be due to the fact that the axis is too long, in which case it is called *myopia*, or too short, in which case it is *hyperopia* or *hypermetropia* (Fig. 412).
FIG. 412. Hyperopia, emmetropia, and myopia. Course of light rays and formation of retinal image in the normal eye (center), hyperopia (above), and myopia (below). Mechanism of correction by appropriate lenses.

Myopia. In "short-sighted" people the axial length of the eye is too long with respect to the refractive power of the eye. Parallel rays are focused on some part of the vitreous humor, and a blurred image is formed on the retina. Only divergent rays from an object placed near the eye are focused on the retina. The far point and the near point are close to each other, and accommodation does not play an important part; therefore the ciliary muscle tends to atrophy. The defect is corrected by the use of concave lenses.

Hyperopia. In this case the eye is too short for the refractive power of the eye, and parallel rays are focused behind the retina. The retinal image is blurred, and the individual must accommodate even to focus distant objects. This, together with the effort of accommodation required for near objects, leads to hypertrophy of the ciliary muscle and eventually to eyestrain. The defect is corrected by convergent lenses.

At birth the majority of eyes are hyperopic. Later the eye increases in length more rapidly than it decreases in refractive power, and it tends to become less hyperopic or even myopic. Hyperopia is therefore gradually corrected with age, while myopia increases.
Fig. 413. Astigmatic chart of Lancaster-Regan. The normal eye sees all the meridians clearly. In astigmatism some of the meridians appear blurred.

Astigmatism. In a spherical lens all parallel rays converge to a single focus. In toric lenses, *i.e.*, those with one meridian of smaller curvature than that of the meridian placed at right angles to the former (similar in shape to the outer surface of an automobile tire), a single focus is not formed. The rays falling on the meridian with greatest curvature converge to a point placed in front of those falling on the meridian of smallest curvature. The image is therefore distorted. The cornea of certain individuals is not perfectly spherical but to a certain extent toric in shape. These individuals see clearly lines placed on one of the meridians, but not those on others (Fig. 413). This defect is known as regular astigmatism. It is corrected by cylindrical lenses placed at an adequate angle. If there is considerable irregularity of the surface of the cornea (irregular astigmatism), it is sometimes impossible to obtain a satisfactory correction.

VISUAL SENSIBILITY

The sensibility of the eye as a receptor of light rays is so great that it approximates the maximum theoretically possible.

The Receptor. Dark and Light Adaptation

The eye undergoes certain gradual changes when it passes from light to darkness or vice versa, which give it peculiar properties adapted for vision in either circumstance.

Dark adaptation. Scotopic vision. When an individual passes from a well-lighted environment to a dark one, at first nothing is seen, but after a few minutes there is a certain degree of vision, *i.e.*, the outline of objects is distinguished. The improvement in vision is due to a considerable increase in the sensitiveness of the retina, especially of its peripheral extrafoveal part. The minimum amount of light that can be perceived by a fully dark-adapted retina is 1:10,000,000,000 of the maximum stimulus in full daylight.

Curve of dark adaptation. In the course of dark adaptation the pupil dilates, the visual purple increases, and the chromatosomes are concentrated. The green part of the spectrum appears more luminous, with a maximum of 5150 A, while in a bright light maximum luminosity corresponds to the yellow part of the spectrum (6100 A).

If the threshold for light is measured at intervals after passing from bright light into darkness, it will be seen to fall sharply during the first 5 min.; then, after a short interval during which the curve tends to flatten, it again falls gradually, becoming stable after 20 to 30 min. (Fig. 414). The first drop is due to an increase in the sensitiveness of the cones, the threshold of which remains stable at this level. The second, gradual fall, which is more marked, is due to an increase in the sensitiveness of the
Fig. 414. Curve of dark adaptation. Ordinate, logarithm of threshold intensity in millilamberts. Abscissa, time in minutes.

rods. Nocturnal vision is due mainly to stimulation of the rods, and maximum sensitiveness corresponds to the peripheral part of the retina, not to the fovea. For this reason objects are perceived better in a slightly lateral position than when they are looked at directly.

Factors influencing dark adaptation. A dark-adapted eye loses its adaptation if a bright light falls on the eye even for only a brief instant. raising the hands to cover the eyes. A series of changes opposite to those of dark adaptation takes place (Table 99), and after a few minutes the eyes become light-adapted. The process is much shorter than that of dark adaptation.

The double function of the retina. The retina functions differently in daylight and at night. Schultz in 1866 was the first to observe this.

Table 99. Adaptation of the Eye to Light and Darkness

Adaptation	*Pupil*	*Retina*				*Sensitiveness*				*Avitaminosis A*
		Visual purple	*Melanosomes*	*Part used*	*Receptors*	*To light*	*Visual acuity*	*To luminosity of spectrum (Purkinje phenomenon)*	*To radiant energy (apex of visibility curve)*	
Light-adapted......	Myosis (3 mm.)	Decreased	Dispersed	Fovea	Cones	Diminished	Great	Yellow	554 mμ	Normal vision
Dark-adapted......	Mydriasis (8–9 mm.)	Increased	Concentrated	Peripheral retina	Rods	Increased	Small	Green	510 mμ	Night blindness

Aviators who have to fly at night are advised to wear red goggles for some time before the flight, because these permit central vision by means of the cones without interfering with the process of dark adaptation. Light has a considerable effect on this process, which is greatly delayed if the eye has been previously submitted to intense or prolonged illumination.

Anoxia raises the threshold for light. Thus an ascent of 5,000 m. (16,500 ft.) increases the threshold two and a half times. On the contrary, hyperventilation at sea level causes a drop in the threshold to half the normal value.

Vitamin A deficiency causes great difficulty in nocturnal vision. The whole curve of dark adaptation is raised. This is due to a disturbance in the formation of visual purple, which is cured by the administration of vitamin A if the deficiency has not been excessively prolonged.

In a rare condition, often hereditary, called "nyctalopia," there is also a disturbance in dark adaptation and night blindness. It is not improved by vitamin A.

Light adaptation. Photopic vision. On passing from a dark or poorly lighted environment to a bright light, there is a disagreeable sensation of dazzling, which may be painful and provokes defensive reflexes, such as blinking and

Daylight vision, which gives color and detail, is performed by the cones, mainly in the fovea, and has special nerve paths. Nocturnal vision gives only a colorless outline of the objects, but a minimum amount of light energy can stimulate the receptors, *i.e.*, the rods, especially in the peripheral part of the retina. Visual purple plays an important part in this type of vision, which also has special nerve paths. Other differences between daylight and nocturnal vision are given in Table 99. In the eye of higher animals, therefore, there are two different, but correlated, visual processes.

The Stimulus. Intensity, Functions

Light is the specific stimulus for the visual receptor, but the eye is sensitive only to rays of certain wavelengths (as will be seen when considering color vision), and within those wavelengths the stimulus must have a certain intensity. The intensity of the visual stimulus, brightness, which can be accurately measured by physical methods, should be distinguished from the intensity of the visual sensation, luminosity, which is a complex psychological fact. The intensity of the latter is related to that of the former, but is not exclusively dependent on it.

Three thresholds must be considered: (*a*) the absolute threshold; (*b*) the difference threshold; (*c*) the critical fusion frequency.

The absolute threshold is the minimal amount of light that can be perceived. It is dependent on several factors, among which are the wave-
Fig. 415. Luminosity curves of spectra for the eye adapted to light (photopic) and darkness (scotopic). Ordinate, coefficient of visibility. Abscissa, wavelength in millimicrons.

length of the rays and the state of adaptation of the eye. This is well demonstrated by the determination of visibility or luminosity curves for different wavelengths, using a constant amount of energy (Fig. 415). These curves show that the eye is most sensitive to the middle part of the spectrum, although the maximal point is different in daylight and nocturnal vision. The curves in the figure have been adjusted so that the maximum in each of them corresponds to a conventional value of 1. The minimal threshold for nocturnal vision is far below that for daylight vision. The sensitiveness of a dark-adapted eye is the maximum theoretically possible. The duration of the stimulus, which should not be less than ⅛ sec., and the size of the area of retina stimulated modify the absolute threshold. Several laws (Ricco's law, etc.) define the relations between the duration of the exposure, the size of the area stimulated, and the absolute threshold.

The difference threshold is the minimal difference of intensity that can be perceived. The same factors that modify the absolute threshold have an influence on the difference threshold.

The critical fusion frequency is the minimum frequency at which intermittent flashes of light produce a continuous sensation. For example, if a disk, out of which a sector has been cut, is placed before a source of light and rotated at a slow rate, intermittent flashes of light will be perceived; if the rate of rotation is increased, a continuous brightness will be experienced. The minimum speed of rotation, *i.e.*, the minimum frequency at which the flashes become fused into a continuous sensation, is the fusion frequency. Fusion frequency, therefore, measures the maximum number of stimuli that can be perceived separately in unit time. Several factors condition fusion frequency; it is constant for a given intensity but rises with the increase in intensity (Fig. 416). Fusion frequency is not dependent on color; therefore it can be used to compare the brightness of lights of different color. Critical fusion frequency diminishes with age, fatigue, hypoxia, certain drugs (*e.g.*, alcohol), etc.

The curve obtained by plotting critical fusion frequency against intensity (Fig. 416) is smooth when the light falls on the fovea. When it falls on other parts of the retina, the curve has two limbs; the lower limb is interpreted as corresponding to the response of the rods and the upper limb to the response of the cones.

Visual Acuity

Visual acuity is the preciseness with which the detailed form of objects is perceived. It is a
Fig. 416. Curves of critical fusion frequency for the fovea and at 5° and 20° from the fovea. Abscissa, logarithm of light intensity in photons; ordinate, fusion frequencies. (*Hecht and Verrijp.*)

function of daylight vision and is closely dependent on good illumination.

There are two ways of measuring visual acuity: (*a*) the determination of the *minimum visible;* (*b*) the determination of the *minimum*

separable. The minimum visible is expressed by the narrowest line that can be distinguished on a homogeneous background. The minimum separable is the smallest distance that must separate two parallel lines so that they can be clearly distinguished from each other. It is expressed by the *visual angle, i.e.*, the angle formed by the rays converging from the lines to the optical center. Most normal subjects have a visual angle of 1′, but in certain individuals with greater visual acuity, it measures less. The visual angle increases as visual acuity diminishes.

Factors modifying the visual angle. Three groups of factors modify the visual angle: (*a*) factors dependent on the stimulus; (*b*) dioptric factors; (*c*) retinal factors.

Factors dependent on the stimulus. Illumination is a most important condition for visual acuity. Visibility increases when the brightness of the object contrasts with the brightness of the background. It also increases with the intensity of illumination, but only up to an optimum, because excessive illumination produces glare. These factors can be demonstrated by varying the size, contrast, and illumination of black letters drawn on a white background.

Dioptric factors. The normal retinal image is not perfect; it is distorted by spherical and chromatic aberration and by diffraction by the optic media of the eye. In abnormal conditions, errors of refraction are added (myopia, hyperopia, astigmatism). Constriction of the pupil by excluding the marginal rays diminishes these errors and increases visual acuity. Monochromatic light improves visual acuity by diminishing chromatic aberration. A yellow light is the most favorable, then green, red, and blue light in decreasing order.

Retinal factors. The light-adapted eye has very great visual acuity for rays falling on the fovea. The acuity diminishes to one-half on the margin of the macula lutea and to one-fortieth in the extrafoveal parts of the retina. The dark-adapted eye has no visual acuity in the fovea and a low visual acuity in the extrafoveal parts of the retina (Fig. 417).

Visual acuity is mainly a function of the cones. It is at a maximum in the fovea, where the cones are closely packed, and in daylight, when the cones are functioning. Nocturnal visual acuity is probably due to the rods. It does not exist in the fovea, where there are no rods, and is found only in the peripheral retina.

Retinal-grain theory. This theory, proposed by Hecht, endeavors to explain the sensibility of the retina. The sensitiveness of a photographic plate depends on the size of the grains on its surface. By analogy, sensitiveness of the retina would be dependent on the size of its "grains," *i.e.*, the cones and
FIG. 417. Relative visual acuity curve in the central and peripheral retina.

rods. According to this theory, visual acuity depends on the difference in the illumination of neighboring rows of cones (granules), which would then be analyzed by the nerve centers. Thus, to perceive the minimum separable of parallel lines, two rows of cones would have to be in the shadow cast by these lines, and the cones between them would have to be brightly illuminated. In the case of the minimum visible, the thread or line would have to throw a shadow on a row of cones while the neighboring rows on both sides would be brightly illuminated. Visual acuity would therefore be due to a process of discrimination between light and shadow falling on the cones.

Careful measurements made by Polyak in 1941, on the distance between the cones in different parts of the retina, have shown that these distances are in agreement with the respective visual acuity only in the fovea. In other parts of the retina, visual acuity is not dependent on a single cone or rod but on the group of photoreceptors innervated by a single nerve fiber, *i.e.*, a sensory unit. The retinal-grain theory therefore should be based on functional, not on anatomic, units or "granules."

Clinical tests of visual acuity. Snellen's chart is commonly used to measure visual acuity in man. This chart consists of lines of letters of decreasing size, so that when read at distances of 60, 24, 18, 12, 9, 6, 5, and 4 m. the visual

angle measures 1′. The width of the lines forming each letter is one-fifth the total size of the letter.

The subject tested is placed at a distance of 6 m. (20 ft.) from the chart and indicates the smallest type of letter he can read. Visual acuity
FIG. 418. Blind spot in the retina. The left eye is shut and the cross is looked at with the right eye. The figure is slowly moved away from and toward the eye. At a distance between 15 and 20 cm., the white disk is not seen

is expressed by the formula $V = d/D'$, in which V is the visual acuity, d is the distance of 6 m. and D' is the distance in meters corresponding to the line and noted on one side of the chart. For example, if the smallest type that can be read at 6 m. is that corresponding to 12 m., visual acuity will be equal to $6/12 = 1/2$. If the smallest line is that corresponding to 24 m., visual acuity will be $6/24 = 1/4$.

VISUAL FIELDS AND BINOCULAR VISION

The visual field of each eye is the extent of the environment that can be seen by a subject without moving the eye. It extends approximately 160° in the horizontal plane and 145° in the vertical plane. It is limited by the prominence of the nose on the mid-line or nasal plane, by the brow of the eye in an upward direction, and to a lesser extent by the cheek in a downward direction.

Objects within the visual field form an image on the retina. Those on the right of the subject are projected upon the left side of the retina, those above upon the lower half of the retina, and so on; *i.e.*, the visual field is inverted upon the retina. Therefore a subject with a blind right half of the retina loses the left half of the visual field.

The point in the retina at which the optic nerve enters the eye has no cones or rods; it is a blind spot. This spot is situated 3 mm. from the mid-line and 0.5 mm. below the fovea centralis (15° toward the temporal side of the fovea in the visual field). It is easy to demonstrate by a simple experiment that there is no vision when the image of an object is formed on this spot (Fig. 418).

Different parts of the surface of the retina are not equally sensitive to color (see "Color vision," below).

The visual field can be charted by means of the instrument known as the perimeter. The chin of the subject is placed on a support, and the eye is fixed on a point in front of it. A white or colored disk is moved along an arc, which can be fixed in any of the meridians of the eye field. The disk is moved along the meridian, and the subject indicates the moment when it enters the eye field. The results obtained from different meridians are marked on a chart, and the whole field can thus be plotted (Fig. 419).
FIG. 419. Normal visual fields. On the left, visual field of right eye. On the right, binocular visual field.

Binocular vision. The visual field of one eye overlaps that of the other over an area of approximately 120°. Outside the area common to both eyes, each eye has a field, not visible to the other eye, which has the shape of a crescent con-

cave toward the nasal plane (monocular crescent or temporal half-moon) (Fig. 419).

Objects placed in the area common to the fields of both eyes form images on both retinas. They produce a single or a double visual sensation according to the position in the retinas on which the images are formed. The images produce a single visual sensation when they are formed on corresponding points of the retinas. Symmetrically placed points on the retina are corresponding points. Thus the half of the retina on the right of the fovea of one eye corresponds to the right half of the other; the two left halves, the two upper halves, and the two lower halves are corresponding. The movements of the eye are made so that the images of objects will fall on corresponding points of both foveas.

When the images are formed on noncorresponding points a double visual sensation, called "diplopia," is produced. Diplopia can be easily provoked by exerting light pressure with a finger placed on one of the eyeballs so that its axis of fixation is displaced. Objects within the field of vision will be seen double. In cases of strabismus (squint) the images fall on noncorresponding points, but there is no diplopia because one of the images is suppressed or ignored.

Binocular rivalry. When a different image falls on each eye, the images are not fused; one prevails over the other and is the only one perceived. Sometimes the images are seen alternately, or parts of the images prevail over the reciprocal parts of the others. This phenomenon is known as binocular rivalry. It does not obtain in certain cases of color vision in which fusion of the images gives rise to a different color (see "Color vision," below).

Stereoscopic vision. The images on corresponding points of the retinas are not absolutely identical. This slight difference is one of the elements used by the cortex to build up the notion of depth or solidity (*i.e.*, the third dimension) of the objects seen. Other data are also used for this purpose, *e.g.*, the size of the shadows or parallax, *i.e.*, the apparent displacement of near objects in the opposite direction to the movements of the observer, and of distant objects in the same direction. The notion of depth can be given by monocular, but is far more perfect in binocular, vision.

FIG. 420. Optical illusions. 1, the different segments of the vertical lines are all of equal length, although some appear to be shorter than others; 2, both figures are perfect squares of the same size, although they appear to be rectangles; 3, the distance from *A* to *B* is equal to that from *B* to *C*; 4, the white and black disks have the same diameter, but the white disk appears to be larger than the black one (irradiation); 5, the long horizontal lines are straight parallel lines.

PERCEPTION OF MOVEMENT

Perception of a moving object is maximal in light and when the image falls at a distance 10 to 15° from the fovea. It is a well-known fact

that the lateral vision of an object gives a better idea of its movements than central or foveal vision. In this case the smallest movement perceived is a displacement at an angle of 1 in 1 sec. if there are stationary objects in the neighborhood. If there are no other objects, the movements must be 10 to 20 times greater to be perceived.

If the eyes are fixed and the head or the whole body is moved, objects in the visual fields seem to move, owing to the displacement of their images on the retina. Thus when the observer is traveling in a train, stationary objects near the track seem to move in the opposite direction, and objects farther away in the same direction, as the train.

Optical Illusions

Errors of appreciation are committed with respect to the size, shape, and distance of objects if they are presented in certain ways. Figure 420 gives several examples of optical illusions.

The error known as "irradiation" is of special importance. It consists in the apparent increase in size of the image of a brightly illuminated object when placed next to one of the same size that is poorly illuminated. Thus in Fig. 420 the white circle seems to be larger than the black circle, although their diameters are equal. This effect is due to diffusion of stimulation around the edges of the image of the brightly lit object, owing to chromatic and spherical aberration.

COLOR VISION

Color vision is one of the most interesting aspects of the sensibility of the photoreceptor. It is a function of the light-adapted eye and is dependent on the acuity of the cones. Certain physical properties of light must first be examined in order to facilitate the understanding of the physiology of color vision.

Properties of Light as a Visual Stimulus

Light consists in radiations which on stimulating the photoreceptor give rise to sensations of color, which vary according to the intensity of the stimulus, the wavelength of the different radiations, and the combination of radiations of different wavelength.

The chromatic series. All visible colors are found in the solar spectrum with the exception of purple, which is the only extraspectral color. Colors are disposed in the spectrum according to their wavelength, forming the chromatic series. Every color has three physical attributes, *i.e.*, tone or hue, brightness or luminosity, and saturation[1] or purity.

Tone or hue. This attribute is due to the spectral distribution (*i.e.*, the wavelength) of the stimulus. The tones or colors have the following limiting wavelengths (in mμ): red, 723 to 647; orange, 647 to 585; yellow, 585 to 575; green, 575 to 492; blue, 492 to 455; indigo, 455 to 424; violet, 424 to 397. Light from a limited portion of the spectrum is known as monochromatic light.

Brightness or luminosity. A tone or hue varies in brightness according to the intensity of radiation. Excessive brightness causes an unpleasant sensation (glare). Brightness is measured by determining the critical fusion frequency, considered above. In daylight vision, yellow is the brightest color.

Saturation or purity. This attribute is dependent on the amount of accompanying white sensation. The purity or saturation of a color increases as the amount of white diminishes. Thus red is more saturated than pink. Probably in the retina a saturated color unsaturates other colors.

The degree of saturation is determined by means of the spectroscope. A saturated color gives out radiations within narrow limits of wavelength. If the color is not saturated, *i.e.*, if it is mixed with white, the dominant radiation is accompanied by radiations of other wavelengths. Thus pure red gives out radiations corresponding to the red part of the spectrum only, while unsaturated red gives out these radiations and those corresponding to other colors.

Color mixture or fusion. Color mixture refers here to the combination or fusion of spectral color, *i.e.*, of light radiations of different wavelengths, not to mixtures of pigments or paints

[1] The Optical Society of America has given the following definitions of these characteristics: Tone is the attribute of certain colors by which they differ in a characteristic way from gray of equal brightness and which classifies them as reddish, yellowish, greenish, or bluish. Brightness is the attribute of all colors by which a color may be classified as the equivalent of a given member of the series of grays going from black to white. Saturation is the attribute of all colors with a hue, which determines the degree by which they differ from gray of equal brightness (*J. Optic. Soc. America*, **6**, 527, 1922).

that may react chemically with each other and give rise to substances with new colors. In optics colors are mixed by means of lenses or mirrors that converge two or more light rays of different color (*i.e.*, wavelength) on a reflecting surface. When radiations corresponding to different colors fall on the same point of the retina, they produce a sensation that differs from the sensations produced by each radiation acting separately.

Primary colors. If a ray of sunlight is dispersed by a prism, the spectral colors can be recombined, and white light is again obtained without any loss of brightness (Abney's law). White light and any of the intermediate colors of the spectrum can also be obtained by fusion of red, green, and blue in certain proportions; these three are therefore called primary colors.

Complementary colors. Certain pairs of colors combined in adequate proportions give rise to a sensation of white; they are known as complementary colors. There is a complement for every color of the spectrum, *i.e.*, light radiations of a certain wavelength which, combined with the spectral color, give white light. Thus the following pairs are complementary colors: red (656 mμ) and greenish blue (492 mμ); yellow (595 mμ) and indigo blue (433 mμ); greenish yellow (563 mμ) and violet (less than 433 mμ). The complementary color for green is extraspectral purple, formed by the fusion of red and violet.

Fusion of pairs of noncomplementary colors. Complementary colors are separated by a fairly wide interval in the spectrum. Fusion of colors separated by a shorter interval gives rise to an intermediate color; *e.g.*, red and yellow give orange, red and blue give yellow.

The site of color fusion. Fusion of light rays of different colors apparently takes place in the brain, not in the eye. Thus if a ray of one color is made to fall on a certain spot of the retina of one eye, and a ray of another color on the corresponding point of the retina of the other eye, the colors are fused; this is known as binocular fusion. It is not yet clear which nerve centers are responsible for fusion; probably the geniculate bodies or the occipital cortex play a part in this phenomenon.

Achromatic series. White, black, and intermediate grays formed by mixtures of different proportions of white and black constitute the achromatic series. White is always obtained by fusion of radiations of different wavelengths: (*a*) by the resynthesis of the whole spectrum; (*b*) by fusion of the three primary colors; (*c*) by fusion of a pair of complementary colors. The origin of the sensation of black is not quite so clear. Some observers consider that black is not a sensation, because a black object does not reflect light. The sensation of black would therefore be due to the absence of stimulation of the retina. The image of a black object must, however, fall on some part of the retina to give rise to the sensation of black; if it falls on the blind spot, not black but nothing is seen. Moreover, black can be mixed with other colors and changes them. When the light stimulus ceases, the retina sends out electrical discharges; blackness, therefore, seems to be due to activity provoked by the cessation of the light stimulus.

Characteristics of the Receptor

The eye as a receptor. Each one of the primary colors is perceived from a definite part of the retina. If the visual fields for the different colors are determined by means of a perimeter, four concentric ringlike areas can be differentiated around the fovea. The innermost area corresponds to green, and the outer areas to red, blue, and white in that order, the white area extending to the ora serrata. The green area is trichromatic; all colors are perceived within this area. The red area is dichromatic; green is not perceived within it. The blue area perceives only blue (except for a narrow inner ring, which also perceives yellow).

The component rays of white light are refracted differently according to their wavelength. In the eye yellow light is focused exactly on the retina; rays of shorter wavelength are focused in front, and those of longer wavelength behind. This chromatic aberration is corrected in part by constriction of the pupil, thus eliminating the more peripheral rays, which undergo a greater degree of deviation than central rays.

Sensibility of the eye. The following aspects of the sensibility of the eye will now be considered: (*a*) spectral limits of visibility; (*b*) intensity threshold.

Spectral limits of visibility. The eye perceives all the colors in the solar spectrum between red (720 mμ) and violet (350 mμ). It is therefore sensitive to radiations of wavelengths differing by approximately one octave. The ear can

perceive sound waves within a range of approximately 10 octaves.

Beyond the red end of the spectrum, there are the infrared rays, which are not visible, *i.e.*, do not act on the retinal pigments but can be demonstrated by their thermic effect (*e.g.*, by means of a thermocouple). Beyond the violet rays there are ultraviolet radiations, which are also invisible but produce photochemical effects (*e.g.*, on a photographic plate). Rays with a wavelength between 350 and 320 mμ cause fluorescence in the eye media and thus become visible. With age the lens yellows, causing the violet end of the spectrum to become progressively invisible. If the lens is removed, violet is again perceived.

FIG. 421. The Purkinje phenomenon. Luminosity curves for spectra of different intensity. Abscissa, wavelength in millimicrons; ordinate, luminosity. (*König.*)

The difference threshold for color, *i.e.*, the capacity to discriminate color tones, varies for the different colors. Small differences in wavelength are perceived in the yellow part of the spectrum; the difference must be much greater in the red or violet parts to be perceptible. The normal human eye distinguishes approximately 165 tones or hues.

Intensity threshold. The Purkinje phenomenon. If luminosity is gradually diminished, the colors of the spectrum do not disappear all together, but one after the other. There is a chromatic threshold. Red and violet are the first to disappear and yellow, green, and blue the last. The threshold is therefore higher for the former colors than for the latter. The threshold for each color is constant. If the intensity is gradually increased above this threshold, 660 degrees of brightness can be distinguished for each hue.

If the brightness of the chromatic spectrum is diminished progressively, the colors gradually fade out, beginning at the ends of the spectrum; only a gray luminosity persists, more marked in the green part of the spectrum. This is known as the scotopic spectrum (dark spectrum), while the chromatic spectrum is also called the photopic spectrum (light spectrum). The brightest part of the photopic spectrum corresponds to the yellow wavelengths, while that of the scotopic spectrum corresponds to the green. This displacement of maximum brightness from the yellow (610 mμ) to the green (535 mμ) wavelengths, as illumination decreases, is called the Purkinje phenomenon (Fig. 421). This explains why yellow flowers appear the brightest at midday and blue flowers in the evening.

After-images. This term is applied to images that remain after the stimulus has ceased to act on the retina. They are especially notable after looking at a bright object. The after-image at first increases in intensity, then gradually disappears (Fig. 422).

FIG. 422. Diagrammatic curve of visual sensation following stimulation by a flash of light. (*After Hartridge.*)

There are two kinds of after-image according

to the conditions that obtain after the primary stimulus has ceased to act. If, after looking at a brightly illuminated object, the eyes are closed or fixed on a black surface, the after-image appears to be bright and of the same color as the object. This is a positive after-image, due apparently to a persistent effect of the stimulus. If, after looking at the object, the eyes are fixed on a white surface, the after-image takes on the complementary color. For example, if a bright red object is looked at for 20 sec. or more, the after-image will appear bluish green. This is a negative after-image, due to fatigue which causes an increase in the threshold for light of the wavelength of the stimulus and lowers the threshold for the complementary wavelength in the white light reflected by the surface. The retina therefore persists in an excited condition for a short time after the stimulus has ceased (positive after-image); the excited area is, however, less sensitive to the same stimulus and more sensitive to the complementary stimulus.

Contrast phenomena. A ray of light not only stimulates the retina; it also modifies the sensibility of the stimulated and neighboring areas.

Simultaneous contrast (*spatial induction*). Stimulation of a definite area of the retina causes an increase in sensitiveness to certain other stimuli in the neighboring areas. The maximum effect is produced with respect to the complementary color. Thus if a blue disk is placed on a yellow background both colors appear to be heightened by the contrast; if they are seen separated by a wide space they appear to be paler, *i.e.*, less saturated. The influence of color contrast is of importance in painting and in the employment of colors for decoration.

Successive contrast (*temporal induction*). Stimulation of the retina modifies its sensibility for successive stimuli. Thus after looking at a bright red disk, a green disk will appear to be more saturated. This is due to an increase in sensitiveness to the complementary color, as was mentioned in the discussion of after-images.

The Young-Helmholtz Theory of Color Vision

Many theories have been proposed to explain the phenomena of color vision, but none gives a completely satisfactory explanation of all the facts. In 1801 Thomas Young proposed a theory which was later expanded and modified by Helmholtz. It is known as the Young-Helmholtz theory and has wide acceptance.

According to this theory there are three different chemical substances in the cones, which are sensitive to red, green, and violet light respectively. Each one of these substances is specifically disintegrated by light of the corresponding color; other colors have a less considerable effect. The photochemical response stimulates the endings of different nerve fibers and sends impulses along the optic nerve to different parts of the occipital cortex according to the nature of the receptor that has been excited.

The sensations of red, green, or violet are due to the specific effect of the colored light on the corresponding chemical substance. The sensations of white and other colors of the spectrum are produced by the combined decomposition of the three substances in varying proportions. Black is due to the absence of stimulation.

This theory gives a good explanation for many facts. Thus, blindness to one color would be due to the absence of one of the photochemical substances. Color mixture would be produced by simultaneous decomposition of two of the three substances. The positive after-image would be due to the continuation of the process of decomposition of the substance after the stimulus has ceased. The negative after-image would be due to a decrease in one of the substances (the one corresponding to the color of the stimulus) while the other two are found in normal quantities; white light would, therefore, provoke a greater response from the latter and a smaller response from the former. However, not all the facts observed are explained by this theory. It gives no explanation of the sensations of gray and white, which arise in the peripheral retina where there is no sensitiveness for color, or for the sensation of yellow given by stimulation of an area outside the part of the retina sensitive to red and green (according to the theory, yellow is the result of combined stimulation by red and green). Finally, it has no satisfactory explanation for total color blindness with persistence of the vision of form. Observations made on the electrical phenomena of the retina and optic nerves by Granit have brought forward further evidence in favor of this theory (see Chap. 78).

Hering's theory. According to Hering there are three photosensitive substances, which on decom-

position or resynthesis provoke different sensations by stimulation of different nerve fibers. These sensations are those of red-green, yellow-blue, and white-black. White light breaks down the substance sensitive to white, which on being resynthesized provokes impulses which produce the sensation of black. The existence of this substance sensitive to white would explain vision in cases of total color blindness. According to this theory complementary colors (*e.g.*, red and green or blue and yellow) have opposite and antagonistic effects.

Several other theories of color vision have been proposed. Motokawa and his associates,[1] observing the effects of electric stimulation of the eye, conclude there are four different types of receptors. Four principal photosensitive substances have been identified (see Chap. 78).

Disturbances in Color Vision

Dalton, the English physicist, discovered color blindness in himself and in his brother, and he gave a classic description of the anomaly in 1794. Blindness to one or more colors is frequently observed. According to certain statistics 8 per cent of otherwise normal males and 0.5 per cent of females are color-blind. It is a hereditary sex-linked character; the defective factor responsible for its appearance is found in the X chromosome, and hereditary transmission takes place in the same way as for hemophilia. A color-blind person often does not realize his condition or may discover it only late in life. There are many simple tests that quickly reveal its existence. Color blindness is of importance in persons such as engine drivers, pilots, etc., who are guided by colored traffic lights, as they may unknowingly commit errors with disastrous consequences. Normal color vision is also necessary in other professions and trades, *e.g.*, painting, dyeing, printing, color photography and television, horticulture, etc.

Classification of color blindness. Usually a color-blind person is said to be blind to a given color, *e.g.*, red, green, etc. This is not strictly true, because there is not always total blindness to a color, and the defect, although it is predominant for one color, always extends to others. The classification now used was proposed by von Kries and is based on the Young-Helmholtz theory of the existence of three specific color receptors. According to this classification, normal vision is trichromatic; deficiency in color vision may affect one, two, or all three types of color receptors.

Trichromats	*Dichromats*	*Monochromats*
Normal	Protanopia	
Protanomalous	Deuteranopia	
Deuteranomalous	Tritanopia	

Anomalous trichromatic vision. Individuals with this type of vision see the three primary colors and synthesize white and the other colors of the spectrum by fusion of the primary colors. They are therefore trichromats. They perceive red and green differently from normal subjects, although they are not blind to these colors. In mixing red and green to form yellow, they use proportions different from those chosen by normal subjects. Protanomalous individuals are deficient in vision of red (they require more red), and deuteranomalous ones are deficient in vision of green.

Dichromatic vision. Individuals with this type of vision do not see one of the primary colors, supposedly because the corresponding receptor is missing. They see the two other primary colors, although with certain deficiencies. They learn, however, to recognize the color of usual objects from their brightness and from previous experience. The diagnosis can be made because these subjects attempt to synthesize white and all the colors of the spectrum by combining only two colors.

In protanopia, the most common anomaly, there is blindness to red; green is deficiently perceived, and blue is seen normally. In deuteranopia there is blindness to green; red is deficiently perceived, and blue is seen normally. In tritanopia there is blindness to blue, but red and green are perceived. Tritanopia is much less frequent as a congenital anomaly; about 1 in 65,000 persons suffer from it.[1] Jaundice, intoxication by santonin, and dislocation of the retina may provoke it. According to König, there is normally a small tritanope point in the center of the fovea, which can be easily demonstrated.

Monochromatic vision. Achromatopsia or total color blindness. Individuals with monochromatic vision do not perceive color; they see only white, black, and different shades of gray. They distinguish colors exclusively by differences in brightness.

[1] Ebe, M., K. Isobe, and K. Motokawa, *Science*, **113**, 353, 1951.

[1] Wright, W. D., *Nature, London*, **170**, 904, 1952.

Night vision is normal. In these individuals apparently there is only rod vision; the cones do not function. Achromatopsia is an extremely rare congenital anomaly.

The spectrum in color blindness. Subjects with anomalous color vision see the scotopic spectrum (*i.e.*, in the dark) normally. The daylight or photopic spectrum is seen normally by deuteranomalous subjects and in deuteranopia. For protanomalous subjects and in protanopia, the spectrum is shortened at the red end and the brightest part is in the blue wavelengths (540 mμ), instead of in the yellow (554 mμ).

Tests of color vision. There are many tests of color vision. In the Holmgren test the subject is given a skein of colored wool and told to choose from skeins of assorted colors those of similar hues. Another test consists in showing lights of different colors and intensity which the subject must recognize. Ishihara's test (a modification of Stilling's test) consists of a series of plates in which a digit formed of spots of one color is "hidden" in a field of other colored spots. Subjects suffering from different forms of color blindness do not see the digit. By an adequate choice of colors and shades the test can be made diagnostic for the different forms and intensity of color blindness.

The most accurate method consists in asking the subject to match spectral colors; *e.g.*, to match yellow by mixing red and green. The proportions of each color used are compared with those used by normal subjects. The range of the visible spectrum and the point of maximum brightness in the spectrum are also determined, and the subject is asked to discriminate between different spectral hues.

BIBLIOGRAPHY

See page 976.

CHAPTER 77

The Physiology of the Eyeball and Its Appendages

THE EYEBALL IS a complex structure formed by closely integrated parts, each one fulfilling a special function. The eye is protected by the secretion of the lacrimal glands and the eyelids, and it is moved by the extrinsic muscles of the eye. The physiology of the cornea, iris, crystalline lens, and ocular fluids will also be considered in this chapter; the retina and the optic pathway will be dealt with in the following chapter.

LACRIMAL SECRETION

The secretion of tears together with the eyelids forms a protective mechanism for the eyeball.

Anatomy. There is a principal orbital gland situated in the upper external part of the orbital cavity, and there are several small glands distributed along the fundus of the conjunctiva. Histological examination shows that they are formed by acini of secretory cells, the ducts of which converge to one or more excretory ducts opening into the fundus of the conjunctiva. The cells show different phases of secretion, with formation and excretion of granules.

Normal lacrimal secretion. It is not possible to measure accurately the total amount secreted during the day. Schirmer (1904) calculated that 13 drops are excreted every 16 hr., of which 7 drops are evaporated and the rest flow into the nasal cavities.

Irritation of the conjunctiva or the nasal mucosa increases lacrimal secretion. The afferent fibers of this reflex form part of the trigeminal nerve. Vomiting, sneezing, and coughing are accompanied by increased lacrimal secretion. In man and the anthropoids, lacrimal secretion increases in certain psychic states. Weeping forms part of the expression of sorrow and extreme hilarity. It can also be provoked by a conditioned reflex, *e.g.*, when actors simulate painful emotions.

Mechanism of lacrimal secretion. Tears are secreted by a mechanism similar to that of salivary secretion. Sympathetic and parasympathetic nerves play a fundamental part in this process. The glands are innervated by parasympathetic secretory and vasodilator fibers which arise in a nucleus of small motor cells situated in the pons near the upper salivary nucleus. These fibers form part of the seventh cranial (facial) nerve, from which they diverge at the level of the geniculate ganglion. They end in the sphenopalatine ganglion. Postganglionic fibers from this ganglion travel to the lacrimal gland in the maxillary division of the trigeminal nerve. Parasympathomimetic drugs such as pilocarpine, muscarine, and acetylcholine stimulate lacrimal secretion, which is inhibited by parasympatholytic drugs, such as atropine.

Sympathetic fibers arise in the intermediolateral cell column of the upper thoracic segments of the spinal cord. The preganglionic fibers travel in the cervical sympathetic and end in the superior cervical ganglion. Postganglionic fibers arising in this ganglion ascend in the carotid plexus. They provoke vasoconstriction and have a secretory effect which is less marked than that of parasympathetic fibers.

TEARS

The chemical composition of tears is given in Table 100. Lysozyme has been found in tears; it

has a bacteriostatic effect which prevents the growth of bacteria. Lysozyme concentration diminishes in cases of eye infection and again increases when the condition of the patient improves.

Table 100. Chemical Composition of Tears

Constituent	*Per Cent*

Tears flow to the inner angle of the eye, where they are collected in the lacrimal sac and pass through the lacrimal canals into the nasal cavity. Contraction of the orbicularis plays an important part in the circulation of tears. Paralysis of this muscle causes the tears to flow down the cheek. Normally the orbicularis, on contracting, compresses and empties the lacrimal sac, but the sac can be extirpated without disturbing the circulation of tears, which continue to flow by capillarity into the lacrimal canals.

THE EYELIDS

The movements of the eyelids, by closing and opening the eyes, regulate the entrance of light into the eye. These movements protect the eyes from excessive illumination and the action of foreign bodies. They also spread the tears secreted by the lacrimal gland over the exposed part of the eyeball, thus preventing desiccation of the cornea and conjunctiva.

Neuromuscular apparatus of the eyelids. The eyelids have two muscles, the orbicularis and the levator palpebrae. The former closes the eyelids; the latter raises the upper lid. These muscles are reciprocal antagonists; when one contracts, the other relaxes. The postural tone of these muscles varies considerably. Relaxation of the levator palpebrae is a sign of sleepiness. During sleep the tone of the orbicularis is predominant and the eyes are closed. In the waking state the levator is tonically contracted and it keeps the eye open.

The orbicularis is innervated by the facial nerve and by sympathetic fibers, and the levator by the oculomotor nerve and parasympathetic fibers. The nerve centers of the sympathetic and parasympathetic fibers are situated in the hypothalamus. The facial nuclei and the oculomotor nuclei give rise to the motor fibers for the orbicularis and the levator palpebrae. Cortical centers for the movements of the eyelids are found in the lower part of the precentral gyrus.

MOVEMENTS OF THE EYELIDS

Movements of the eyelids are associated with movements of the head and eyes: (*a*) certain movements are accompanied by movements of the eyelid, *e.g.*, when the head and eyes are lifted upward, the upper lids are raised; (*b*) movements of the eyelids are associated with other movements, *e.g.*, the pupil contracts and the eyeball is rotated upward and outward on closing the eyelids; (*c*) the movements of one eyelid are usually associated with those of the other eyelid, and they also take an important part in facial expression.

There are three principal movements of the eyelids: voluntary blinking, reflex blinking, and spontaneous blinking.

Voluntary blinking. The eyes cannot be kept open without blinking for more than a few minutes, but they can be kept voluntarily closed for an indefinite time. One eye alone can be closed while keeping the other open. Voluntary blinking is a very rapid movement. It takes only 0.2 sec., about one-half the time taken by spontaneous blinking.

Reflex blinking. A large number of stimuli, mainly acting on receptors innervated by the second (optic), third (trigeminal), and eighth (acoustic) cranial nerves, provoke defensive reflex closure of the eyelids. For example a bright light that suddenly illuminates the eye, a loud noise, or physical contact with the cornea, conjunctiva, eyelashes, or the nasal mucous membrane cause reflex blinking.

Spontaneous blinking. This is the most frequent movement of the eyelids. It consists in rhythmic involuntary closing and opening, at a rate of 10 to 20 movements per minute. The tears are thus spread over the eye, and desiccation of the cornea and conjunctiva is prevented. The movement consists of very rapid closing, followed by the opening of the eye. The whole movement lasts 0.3 to 0.4 sec., and it is repeated after an interval of 2 to 10 sec. Slow-camera cinematography shows that the upper lid falls like a curtain; the lower lid remains almost motionless. The eye closes progressively from the outer to the inner angle, sweeping tears and

foreign bodies toward the lacrimal sac. Lawson[1] has pointed out that owing to blinking there is a blackout during 10 per cent of the time the eyes are active, which increases if the rate of blinking is greater. This causes a certain degree of inaccuracy in the observation of very rapid phenomena and also in controlling movements where speed is essential (*e.g.*, when playing tennis or boxing) or in handling very fast machines; *e.g.*, a jet-propelled plane travels several hundred yards in the time taken by a single blink.

The cause of spontaneous blinking is still unknown. It is not due to drying of the cornea, because it persists after the eye has been anesthetized or in an atmosphere saturated with water vapor in which the cornea is not dried. Neither is blinking due to light reflexes, because it persists in the dark and in blind persons. Perhaps it is a reflex arising in proprioceptive receptors in the eye muscle, or it may be due to rhythmic automatic discharge of the nerve centers.

THE MOVEMENTS OF THE EYE

Each eye performs several fast and precise movements which are closely associated with the movements of the other eye. Any eye movement involves at least two muscles of each eye. These movements are controlled by accurately integrated nerve impulses.

Anatomy. Six extrinsic muscles move each eyeball.

The four recti muscles are inserted on a fibrous ring (tendon of Zinn) attached to the margin of the optic foramen. Their fibers are directed forward, opening out, so as to form the four sides of a pyramid. The *external and internal recti* end near the margin of the cornea on a flat tendon; the lines of insertion of these tendons are parallel to the corneal margin. The *superior and inferior recti* end on tendons that are inserted lateral to the middle axis of the eye, behind the corneal margin; the lines of insertion are not parallel to the corneal limbus.

The superior oblique arises in the depth of the orbit and passes to its upper and inner side. There the muscle forms a tendon which passes through a fibrous ring, acting like a pulley. The direction of the fibers of the muscle changes, and they pass backward and downward under the superior rectus and end on the superior posterior and external aspect of the eyeball.

[1] Lawson, R. W., *Nature,* **161,** 154, 1948.

The inferior oblique arises in the inferior and internal angle of the orbit and passes outward, under the eyeball, ending on its inferior posterior and external aspect.

The oculomotor (third cranial) nerve innervates all the extrinsic muscles of the eyes except the external rectus, which is innervated by the sixth cranial nerve (n. abducens), and the superior oblique, which is innervated by the fourth cranial nerve (n. trochlearis). The nuclei of the third and fourth nerves are found in the midbrain. The oculomotor nucleus consists of a series of nuclei, one for each muscle. The nucleus of the sixth nerve is found in the pons.

Movements of the Eyeball

Since the middle of the nineteenth century many methods have been applied to the study of the movements of the eyeball, *e.g.*, direct observation of the eyeball, photographic or cinematographic registration of its movements, and the mechanical and electrical registration of the contraction of the different muscles.

The eyes at rest. Fixation of the eyeball. Absolute rest is obtained only by section of all the nerves of the eye muscles; the eyes then look forward in a slightly divergent outward direction. The eyeball is physiologically in the resting position when it is not submitted to any stimulus that provokes accommodation or fusion of images, but it is still under the control of muscles with their innervation intact. In this position the eyes look forward, and their axes are parallel. When the eyes are fixed on an object, both are displaced from the physiologic resting position so that the images are formed on corresponding points of the retinas of both eyes. They are kept in that position by a sustained contraction of the eye muscles made up of rapid, asynchronous twitches of their fibers.

Rotation and torsion. All the movements of the eye are rotations around several axes. The eyeball behaves as if it were a condyle in a condyloid articulation, the socket formed by the orbital fat. The theoretical center of rotation of the eyeball is placed 14 mm. behind the center of the cornea. A frontal plane passing through the center of rotation (Listing's plane) is used as a reference for the primary axes of rotation, *i.e.*, the vertical and horizontal axes. Rotation around the vertical axis moves the cornea to the right and to the left. Rotation

around the transverse axis moves the cornea up and down. These two types of rotation are known as cardinal movements and are the only pure voluntary movements. Rotation around the horizontal (sagittal) axis, *i.e.*, the line passing through the center of rotation and the object
FIG. 423. Demonstration of torsion movements of the eyeball by means of the after-image. (*Ruete.*)

(fixation point) produces wheellike movements of the cornea. Rotation around the oblique axes, which pass through the center of rotation at oblique angles to the horizontal axis, produces involuntary torsion movements that cause the cornea to rotate like a wheel. These movements can be easily followed by tattooing a point near the corneal margin. Torsion movements can be appreciated subjectively in the following way: A bright red cross is placed on a gray background, and the eyes are fixed on it for 20 sec. or more. The eyes are then quickly turned to the right or left, or up or down (cardinal movements); the after-image is always that of a vertical cross. If oblique movements are made, by looking at an angle, the cross of the after-image appears to have rotated more or less to one side, owing to the torsion of the eyeball (Fig. 423). Donders, Helmholtz, and Listing have made detailed studies of torsion movements and expressed their results in the laws that bear their names.[1]

Movements of the Extrinsic Muscles of the Eye

The eyeballs are moved by striated muscles which have a very short contraction time and a permanent postural tone that fixes the eyeball. Reciprocal innervation is prominent in the functioning of these muscles. Relaxation of the antagonist on contraction of the protagonist can be easily demonstrated as follows: All the extrinsic muscles of one eye are cut except the external rectus. The animal is shown an object, which is then displaced toward the opposite side. The eyeball follows the object until the pupil is situated in the mid-line, *i.e.*, in the resting position. This movement is due exclusively to relaxation of the external rectus, all the other muscles (including the internal rectus) having been cut.

The central nuclei of these muscles situated in the pons and brain stem are joined together and to the nuclei on the opposite side by many association fibers, which assure a closely coordinated action. The oculomotor nuclei are also connected to the vestibular nuclei and cortical centers in the second frontal convolution and the occipital lobe. These cortical centers govern the associated movements of the head and eyes; if they are stimulated, conjugate movements of the eye are provoked.

Individual action of each muscle. The isolated contraction of an extrinsic muscle causes the eyeball to rotate around the center of rotation and the cornea is displaced. If the lateral recti contract, the cornea moves horizontally to the right or to the left according to which muscle has contracted. If any one of the four other muscles contracts, the cornea undergoes a triple displacement, because these muscles are inserted obliquely with respect to the axis of the eyeball. Thus the superior rectus causes not only an upward movement but also a slight inward displacement and torsion of the eyeball. When the oblique muscles contract the main displacement is one of torsion. In Fig. 424 the movements of the eyes are diagrammatically represented.

Associated movements. The movements of the eyes are normally the result of the simultaneous contraction of two or more muscles. Associated contraction results in the reciprocal annulment of opposite effects. It can be seen

[1] Donders' law (1847) states that for every position of the visual axis with respect to the head, there is a definite and constant angle of torsion independent of the observer's will and of the manner in which the eyes are focused on the fixation point.

in Fig. 424 that the eye can be directed outward (*a*) by contraction of the external rectus; (*b*) by the associated contraction of the superior and inferior oblique muscles; (*c*) by associated contraction of the three muscles.

Bilateral Movements

The movements of both eyes are coordinated so that they are "symmetrical and equal," as Hering stated in 1879. They are moved reflexly or voluntarily.

uniform; the eyes are rotated and fixed alternately. In reading, for example, a group of letters is fixed and after a short pause (0.2 sec.) the eyes are rapidly moved (0.025 sec.) to the next group.

Coordination of voluntary movements is a complicated process. Electrical stimulation of the posterior part of the second frontal gyrus provokes conjugate movements of the eyes toward the opposite side. Destruction of these cortical centers does not cause paralysis of the eye muscles, but conjugate movements are lost.

Fig. 424. Movements of the cornea produced by the contraction of each one of the eye muscles, according to Terrien. The line indicates the inclination of the vertical meridian (torsion).

Voluntary eye movements. When the eyes are directed upward or downward, to the right or to the left, the visual axes are always parallel to each other and the movements are known as conjugate. The area of fixation is limited by the maximum range of these movements made in all directions, without moving the head. It is determined by keeping the head fixed and following an object which is displaced in the visual field in all directions and as far as it can be clearly distinguished. The summated area of both eyes is given by a rotation of approximately 40° in an upward direction, 60° downward, and 50° outward.

When the visual axes of both eyes are not parallel but converge to a point, the movements are known as "convergent." They are called "divergent" or "disjunctive" movements when the visual axes pass from a convergent to a parallel direction. Both eyes take part in convergent movements even when the point of fixation is situated on the visual axis of one eye; this eye undergoes slight oscillatory and torsion movements. If the fixation point is approximated to the observer, convergence increases. It is at a maximum at 8 cm. from the eye (near point); at lesser distances a double image is formed.

When the movements of the eye are registered photographically or cinematographically, it is seen that the movements are not smoothly

Reflex eye movements. Reflex movements of the eye are involuntary but are accompanied by a certain degree of consciousness.

The reflex movements for fusion of the images prevent the formation of blurred images by directing the visual axes so that the images will be formed on corresponding points of the retina. For example, if a weak prism is placed before one eye at first there is diplopia, but soon a correcting reflex develops which assures the formation of a single image.

Fixation reflexes, which rapidly focus on the fovea an image formed on the peripheral part of the retina, are also accompanied by a certain degree of consciousness.

Postural reflexes of the eye are outside the sphere of consciousness. They contribute to the maintenance of bodily equilibrium. Stimulation of certain proprioceptors provokes reflex eye movements such as nystagmus (see Chap. 81).

Disturbances in eye movements. In certain cases movements of both eyes are not harmoniously combined; convergence to a point of both visual axes may be impossible (strabismus) or obtained only with effort (heterophoria). In both cases muscular synergy does not exist. Visual images are not formed on corresponding parts of both retinas, and there is *diplopia, i.e.,* two images of the object are perceived. In strabismus one of the images is suppressed by a psychologic process.

THE CORNEA

The cornea is a membrane covering the anterior part of the eyeball; it is a continuation of the sclera. It has no blood vessels. It is transparent and acts as a lens of 41 to 45 D., because it is placed between the air and the aqueous humor. It has a special type of sensibility.

Anatomy and histology. The cornea is like a watch glass fixed in the sclera. Its diameter is 11.6 mm., and its thickness 0.8 mm. in the center and 1 mm. in the periphery. The anterior aspect has a curvature with a radius of 7.84 mm. and the posterior aspect a curvature with a radius of 6.8 mm. In the adult it weighs 180 mg.

Microscopical examination shows that the central or optical part differs from the peripheral part or limbus. The optical part is formed by five layers: (*a*) stratified epithelium, 50 to 100 μ thick, continuous with the epithelium of the conjunctiva; (*b*) Bowman's anterior lamina, which is structureless and 10 μ in thickness; (*c*) the substantia propria of the cornea, consisting of fibers arranged in parallel rows forming approximately 60 laminae separated by cell spaces or lacunae (it forms 60 per cent of the whole corneal thickness); (*d*) the posterior lamina of Descemet with a thickness of 5 to 7 μ; (*e*) a single layer of flat endothelial cells, which is in contact with the aqueous humor. The peripheral part of the cornea is transitional to the sclera. It has large arterial and venous loops, lymphatic vessels, and nerve endings.

The epithelium of the cornea is covered in the living eye by a thin fluid film, which can be seen with the ocular microscope, especially when fluorescein has been instilled in the eye. This precorneal film has its origin in lacrimal and conjunctival secretions; it is a colloid dispersion which is being continuously renewed. It protects the corneal epithelium and dissolves drugs which after instillation penetrate into the eyeball.

Chemical Composition

The chemical composition of the cornea is given in Table 101. The water decreases with age, so that the other components of corneal tissue become more concentrated. The ash contains Cl, K, Na, Mg, Ca, sulfate, and phosphate. Fats are neutral fats, phospholipids, and cholesterol. Protein forms 98 per cent of the solids. There is a mucoprotein which has mucoitin–sulfuric acid and is similar to the mucoproteins in the vitreous humor and in the umbilical cord. There is also collagen, which gives gelatin on boiling, and a small amount of elastin. Radioactive iodine injected into the organism is found in greater proportion in the cornea than in other eye tissues.

A relatively large amount of acetylcholine has been found in the cornea. It diminishes after the trigeminal nerve has been cut, in proportion to the degree of ulceration of the cornea following the operation.

Source: Krause, 1934.

In certain pathologic conditions, urates, hemosiderin, and other foreign substances are deposited in the cornea.

Physical Properties

Hydration. When the cornea is placed in water, it swells and increases up to five times its normal weight (imbibition or turgescence). The sclera does not have this property, although its histologic structure is similar to that of the cornea. Moreover, the cornea does not take up water from the aqueous humor *in vivo*, but swells when placed in aqueous humor *in vitro*.

Permeability. The permeability of the cornea *in vivo* is shown by the rapidity with which substances in solution placed on the cornea are absorbed into the eye and rapidly produce their effects. Cogan and Kinsey[1] have shown that *in vitro* water can flow through the cornea in both directions without producing edema. The posterior endothelial and anterior epithelial surfaces behave as semipermeable membranes. Rupture of either of these membranes is followed by edema. The normal epithelium is impermeable to NaCl in both directions.

Transparency. The transparency of the normal cornea *in vivo* is apparently perfect. However, if it is examined with an ocular microscope it appears to be gray because of the reflection

[1] Cogan, D., and E. V. Kinsey, *Arch. Ophth.*, **27**, 466 and 696, 1942; **28**, 272, 449, and 661, 1943; **31**, 408, 1944.

of light by its parenchyma. In the 5 months' fetus it is opaque, and it becomes opaque a few hours after death.

The transparency of the cornea is dependent on the water it contains; if it is dehydrated it becomes opaque and regains its transparency on rehydration. The sclera has a microscopic structure similar to that of the cornea, and on being hydrated it becomes transparent.

Cornea
Anterior chamber
Lens
FIG. 425. Diagram of circulation of fluids in the cornea. (*Kinsey and Cogan.*)

According to Kinsey and Cogan, the normal transparency of the cornea depends on an equilibrium between the processes of hydration and dehydration. Hydration is due to the continuous flow of fluid from the lymph vessels in the corneal limbus. Dehydration is due to the fact that the anterior and posterior aspects of the cornea are in contact with hypertonic fluids (tears and aqueous humor), which draw water from the cornea through the semipermeable membranes that line it. The surface of hydration in the corneal limbus measures 0.4 sq. cm. and that of dehydration 2 sq. cm. If the normal equilibrium between the processes is disturbed, the cornea becomes opaque (Fig. 425).

Reflection of light. Light rays are partially reflected when they pass from one medium to another with different optic density. This occurs on the anterior and posterior aspects of the cornea and is the origin of the well-known phenomenon called "Purkinje's images," which will be considered in the discussion of the lens. The amount of light reflected by the different surfaces, according to Raeder (1922), is as follows: anterior surface of the cornea, 2.5 per cent; posterior surface of the cornea, 0.024 per cent; anterior surface of the lens, 0.036 per cent; posterior surface of the lens, 0.030 per cent. Images reflected from the anterior surface of the cornea are therefore approximately 100 times as bright as those from the posterior surface, and 70 times as bright as those from the surface of the lens.

By means of the ophthalmometer (invented by Helmholtz and later considerably improved) it is possible to measure the curvature and determine the regularity of the anterior and posterior surfaces of the cornea, and also to measure its thickness.

PHYSIOLOGY

Circulation. In the normal adult cornea the blood vessels do not penetrate beyond the limbus. Section or destruction of half the limbus does not provoke opacity of the cornea, but if the limbus is totally destroyed the cornea loses its transparency. Fluid passes out of the capillaries in the limbus and seeps through the lacunar spaces between the laminae of the cornea, not through special ducts. This centripetal flow can be demonstrated in the following way: The cornea is pricked with a rusty needle in several places, and potassium ferricyanide is injected intravenously. The peripheral points are stained blue before those placed nearer the center. This demonstration has been confirmed by injecting radioactive ions and following their appearance and movements in the cornea.

Metabolism. Friedenwald[1] has recently made an important contribution to the knowledge of the metabolism of the cornea. The isolated bovine cornea takes up oxygen at the rate of 70 cc. per hr.; 90 per cent of the oxygen consumption is due to the activity of the epithelium. The rate of oxygen consumption varies in different species.[2] CO_2 is given off, and the RQ is 1.

Glucose is completely oxidized by the epithelium, but the substantia propria converts glucose into lactate or pyruvate, which is afterward oxidized by the epithelium.

Sensibility. The sensibility of the cornea is due to the many nerve fibers that end in it. They can be observed *in vivo* by means of the ocular microscope. If the nerves in the limbus are cut, the cornea loses its sensibility for a time, but soon recovers it because the nerves regenerate fairly rapidly. When a corneal graft is made, the fragment grafted becomes sensitive in approximately a year.

These fibers make the cornea sensitive to pain, temperature, and touch, and give rise to reflexes such as the corneal reflex, which provokes closure of the eyelids. Sensibility to pain is more

[1] FRIEDENWALD, J., *Bull. Johns Hopkins Hosp.*, **82**, 1948 (the whole volume).

[2] EPSTEIN, M., *Vest. Oftal.*, **29**, 22, 1950; DE ROETTH, A., *Arch. Ophth.*, **44**, 666, 1950; **45**, 139, 1951.

developed in the central part of the cornea than in the peripheral parts. Each one of the fibers penetrating from the periphery innervates a quadrant of the cornea, which in part overlaps the area covered by neighboring fibers.

The peripheral part of the cornea is sensitive to cold and touch. There is still some discussion as to whether the center also gives rise to tactile as well as painful sensations. Franceschetti[1] has observed that after anesthetizing the cornea there are two thresholds of recovery, which he interprets as due to the reappearance of tactile and painful sensations respectively. Local application of cocaine or cocaine derivatives rapidly produces anesthesia of the cornea but causes some damage to the epithelium.

THE IRIS AND PUPIL

The Iris

The iris is a pigmented disklike membrane placed in the anterior part of the eye. It is perforated in the center, the orifice being called the pupil. The size of the pupil varies according to the state of contraction or relaxation of the muscle fibers of the iris, thus regulating the amount of light that enters the eye. The aqueous humor is also formed at the level of the iris, and the reticuloendothelial cells in the iris take up cell debris and foreign bodies in the aqueous humor. The pigment in the iris prevents the penetration of light rays into the eye except through the pupil.

The Pupil

In man the form of the pupil is circular and it is placed almost in the center of the iris, but its form varies in different species. In the shark and other fishes it is oval; in saurians it is a vertical slit with dentate borders, which interlock when the pupil contracts. Among the mammals it is oval in the horse and sheep, a vertical slit in the cat, and a horizontal slit in the goat.

The size of the pupil varies according to the physiologic circumstances. Contraction of the pupil is known as *myosis* and dilatation as *mydriasis*. In women the pupils are usually larger than in men; in children and old people they are often small. In young men of twenty the average diameter is 4 mm., which is reduced to 2.5 mm. between the ages of forty and fifty.

[1] Franceschetti, A., *Ber. über die XLIX Zusam. der Deuts. Ophth. Ges.*, Leipzig, p. 242, 1932.

The pupil is contracted to a diameter of 1 mm. in a bright light, and dilates to 8 mm. in poor light. In emotional states such as fear, the pupil dilates. It contracts during natural sleep and narcosis produced by anesthetics; simulation of sleep can thus be detected. Immediately after death there is marked mydriasis, but after a time the diameter of the pupil diminishes.

Movements of the Iris

Changes in the diameter of the pupil are due to the contraction and relaxation of two muscles in the iris, the sphincter and the dilator. These muscles arise from the pigmented epithelial layer of the retina. They are smooth muscles and are not under voluntary control.

The sphincter is the stronger of the two. It forms a ring 0.8 mm. thick around the pupil. On contraction its fibers can shorten their length as much as 87 per cent. Such intense contraction is not observed in any other muscle in the organism.

The dilator is formed by radial fibers, which go from the ciliary muscle to the margin of the pupil. These are myoepithelial fibers which have not been completely transformed into muscle fibers. They had passed unnoticed until Langley and Anderson observed local retraction of the margin of the pupil when the iris was stimulated electrically at different points. This observation led to the search for the fibers responsible for this movement and the discovery of the dilator muscle.

Innervation

The pupil is innervated by fibers of the two divisions of the visceral nervous system. The sympathetic innervates the dilator, and the parasympathetic the sphincter. Centers of pupillary activity have been localized in the hypothalamus and the spinal cord, and stimulation of the frontal eye fields of the cortex (area $8\alpha\beta\delta$) is occasionally accompanied by mydriasis.

Sympathetic. Karplus and Kreidl discovered a center in the hypothalamus that controls the movements of the iris, and Budge described a pupillodilator (the so-called "ciliospinal center") in the spinal cord, almost a century ago. This center is situated in the intermediolateral cell column of the spinal cord from the last one or two cervical segments to the first three or four thoracic segments. The preganglionic fibers emitted from this center leave the spinal cord

in the white rami of the corresponding ventral roots and travel up the cervical sympathetic to the superior cervical ganglion, where they end. The postganglionic fibers form part of the trigeminal and long ciliary nerves and end on the fibers of the iris (Fig. 426).
Fig. 426. Diagram of innervation of the pupil.

In the course of his classic observations on the cervical sympathetic, Claude Bernard described the effects produced on the eye by section of this nerve in the rabbit, *i.e.*, myosis, enophthalmia, narrowing of the palpebral fissure, and vasodilatation. Stimulation of the cervical sympathetic produces the opposite effects, among which is pupillary dilatation (mydriasis), due to the contraction of the dilator.

Parasympathetic. Contraction of the sphincter causing myosis is governed by parasympathetic fibers. Section of these fibers causes dilatation of the pupil; they are, therefore, antagonistic to the sympathetic fibers.

There is a hypothalamic vasoconstrictor center, and situated close to the oculomotor nucleus in the brain stem is the well-known Edinger-Westphal nucleus. Fibers from the latter emerge together with the fibers of the oculomotor nerve and end in the ciliary ganglion. The postganglionic fibers form part of the short ciliary nerves and end on the fibers of the sphincter (Fig. 426).

Pharmacology

Several drugs modify the diameter of the pupil (Table 102). They act by stimulating the effectors of the sympathetic or parasympathetic or paralyzing one or the other division of the autonomic nervous system, thus disturbing the equilibrium that normally exists between the two divisions (see Chap. 84).

Pupillary Reflexes

The diameter of the pupil is modified reflexly by stimuli that act on several receptors; there are also changes in the size of the pupil associated with other eye movements. Strong stimuli such as a foreign body causing damage to the cornea or conjunctiva, a very bright light, a loud noise, etc., cause mydriasis. The most important of the pupillary reflexes is the light reflex.

The light reflex. Light falling on the retina of one eye causes contraction (myosis) of the pupils of both eyes. The stimulus is white or monochromatic light, which must reach a certain threshold. The minimal strength of the stimulus increases as the point stimulated is further from the fovea. It must also last a certain time and be produced with relative suddenness.

The receptor is the retina, and the light reflex is abolished by destruction of the retina. Dark and light adaptation modify the sensibility of the retina to light with respect to this reflex. The threshold is lowered proportionally to the area of the retina stimulated. After repeated application of the stimulus, the response diminishes owing to fatigue.

Ranson and his associates have made important contributions to the knowledge of the path followed by the impulses that provoke this reflex (Fig. 427). The centripetal impulses travel along the optic nerve, chiasma, and optic tract to the pretectal region, where they have their first synapse. Fibers from this region cross over to the other side in the posterior commissure and end in the Edinger-Westphal nucleus. Efferent fibers leave this nucleus and reach the iris through the oculomotor and short ciliary nerves. Ranson's work has shown that the path of the light reflex does not pass through the lateral geniculate body or through the colliculi. Visual sensations and the light reflex do not have a common path, and it is still doubtful whether they have a common afferent fiber that branches out, or whether there are separate sensory fibers for each kind of impulse. The latter supposition is based on the fact that there are cases of blindness due to injury of the optic nerve in which the light reflex is not abolished.

FIG. 427. Nerve path of light reflex.

The response takes place in the pupil of the illuminated eye (direct light reflex) and of the opposite eye (consensual light reflex). There is at first a rapid constriction of the pupil, which then gradually dilates to the habitual size, as the retina becomes adapted to the higher level of illumination. The latent period of the initial constriction is 200 to 500 msec., considerably greater than the latent period of the knee jerk (60 msec.); therefore the reflex path is obviously made up of several neurons.

Associated movements. When the eyes are fixed on an object nearer than infinity (*i.e.*, within 20 ft.) the following movements take place: (*a*) the visual axes of both eyes converge; (*b*) the lens undergoes accommodation; (*c*) the pupil is constricted. Myosis is bilateral and dependent on accommodation and convergence, mainly on convergence; but either accommodation or convergence can be suppressed by appropriate lenses or prisms, and myosis is then related solely to one or the other process.

Myosis is also associated with reflex or voluntary closure of the eyelids.

THE CRYSTALLINE LENS

The lens is biconvex and is placed in the path of the light rays that enter the eye. It is elastic, and its shape can be changed so as to focus the image on the retina, whether the rays are emitted from an object placed at infinity or from one near the eye. The lens is thus the most important dioptric medium of the eye; it assures the formation of a clear image on the retina at whatever distance from the eye the object is placed.

Anatomy. The lens is a transparent and elastic structure which has no blood vessels or nerves. It is suspended between the posterior chamber and the vitreous humor by the zonula, a suspensory ligament formed by fibers attached on the one hand to the ciliary body and on the other to the margin and the neighboring parts of the anterior and posterior surfaces of the lens.

The lens is biconvex; its posterior surface has a

greater curvature than the anterior surface. It has a slight yellow tint in young subjects, which becomes more marked in old age. Its weight increases gradually throughout life; at thirty years of age it weighs approximately 180 mg.

Histological examination of the lens shows that it is formed by concentric layers of fibrous cells, covered by a thin, elastic, permeable membrane. The central nucleus is formed by the older fibers. With age it loses water and hardens; the elasticity of the lens is then diminished, and its dioptric properties change.

Chemical Composition

Krause has carefully analyzed the chemical composition of the lens and has determined the content of water, salts, protein, and fat (Table 103).

Table 103. Chemical Constituents of Crystalline Len

Constituent	*Per Cent*
Water	60–70
Ash	0.5–1
Lipids	3–6
Protein	35

In mammals, including man, the lens has 60 to 70 per cent of water; in fishes, only 50 to 60 per cent. With age this percentage diminishes and is less in the nucleus (60 per cent) than in the periphery (75 per cent), which is considered to be the youngest part of the lens. In the process of cataract formation, water at first increases and then diminishes when the cataract is "mature."

The ash of the lens represents 0.5 to 1 per cent of the total weight and has a composition similar to that of other tissues. There are relatively large amounts of potassium, corresponding to the large amount of intracellular water, and sulfur from cystine and glutathione. There are also Na, Cl, and small amounts of Mg and calcium. The calcium is a factor in its permeability and increases considerably in cases of cataract.

Berzelius (1825–1831) mentioned the existence of fats in the lens. In man the fat content increases up to 6 per cent at the age of twenty years and then remains stationary. Phospholipids form 80 per cent of the total fat; they are found together with protein mainly in the capsule. Cholesterol crystals are also found; they can be identified because they are doubly refracting.

Specific proteins, called "crystallins" by Berzelius, form 35 per cent of the weight of the lens. No other tissue has such a high protein content. There are six types of protein (Table 104). The amino-acid content of these proteins has not been accurately determined, but it is known that they do not contain glycin.

Table 104. Proteins in the Crystalline Lens of One-year-old Oxen

Protein	*Per Cent*	*Reported by*
Albuminoid	12.50	Mörner (1894)
α-Crystallin	31.74	Mörner (1894)
β-Crystallin	53.39	Mörner (1894)
Albumin	1.46	Mörner (1894)
Nucleoprotein	0.07	Krause (1933)
Mucoprotein	0.84	Krause (1933)

Source: Krause.

These proteins undergo *in vitro* and *in vivo* a process of autolysis which consists in disintegration with the release of a large quantity of amines (NH_2). Autolysis is produced by acids and enzymes. Kraus has extracted two proteases (α and β) from the normal lens, which act in acid medium. They are important in the genesis of cataract.

Proteins in the lens have peculiar antigenic properties. When injected they provoke the formation of antibodies specific for the lenses of all mammalian species (Uhlenhuth, 1903). The proteins contained in the lens of amphibians and birds differ in this respect from those of mammals. The so-called "α-crystallins" have a high antigenic power and the "β-crystallins" a low one.

The maintenance of normal structure in the lens is conditioned by dietary factors; thus tryptophane-free diets provoke in young rats the formation of cataracts and vascularization in the cornea.[1]

Physical Properties

The osmotic pressure of the lens is similar to that of blood. The freezing point varies from −0.51 to −0.63°C. Submerged in 1 per cent NaCl solution, the lens does not change in volume. The pH of the lens is 7.4, the same as that of other tissues.

The capsule of the lens is permeable to crystalloids but not to colloids. Glucose, lithium

[1] Schaeffer, A., and J. Murray, *Arch. Ophth.*, **43**, 202 and 1056, 1950.

salts, and even alcohol injected subcutaneously or given by mouth are found in the lens a few hours later. If the lens is submerged in water or a hypotonic fluid, it swells in proportion to the degree of hypotonicity of the fluid. Calcium salts diminish edema thus produced.

Light rays are partially absorbed as they pass through the lens. Approximately 8 per cent of the visible spectrum is absorbed, but not all wavelengths are absorbed equally. Infrared and ultraviolet rays are absorbed in a considerable proportion and can produce damage to the lens. The proteins of the lens are responsible for this absorption.

Physiology of the Lens

The lens plays an important part in accommodation, which will be dealt with further on. It has an active metabolism, which has been the object of a considerable amount of work.

Respiration. The lens takes up oxygen from the aqueous humor, which absorbs it through the cornea and from the ciliary bodies. If the lens is removed, oxygen pressure in the aqueous humor increases. The oxygen consumption of the lens of the dog *in vitro* is 0.2 to 0.5 cc. per min., approximately one-tenth that of resting muscle.

Ascorbic acid and glutathione seem to play an important part in the respiratory processes of the lens. There are considerable amounts of both these substances. The concentration of glutathione in the lens of the sheep has been found to be 343 mg. per 100 gm. of fresh substance; therefore much higher than in other tissues. It is found in the oxidized and reduced forms. The concentration of both these substances is greater in the peripheral part of the lens than in the central part; it diminishes with age. The lens forms glutathione, but not ascorbic acid, which comes from the ciliary body.[1]

Glutathione takes up oxygen and passes it to β-crystallin, both substances forming an oxidation-reduction system. If all the glutathione is removed from the lens, the latter no longer takes up oxygen, but respiratory processes again take place if glutathione is added and at a rate proportional to its concentration.

Ascorbic acid is taken up from the aqueous humor in its oxidized form and is returned in the reduced form, oxygen remaining in the lens. The concentration of ascorbic acid in the lens is higher than that of the aqueous humor, which in turn has a higher concentration of ascorbic acid than the blood. Synthesis of this substance is supposed by some workers to take place in the lens. Glutathione and ascorbic acid diminish in a lens with cataract.

[1] Kinsey, E. V., *Arch. Ophth.*, **46**, 441, 1951.

Intermediary metabolism. Energy is set free in the lens by the oxidation of glucose, which diffuses from the blood into the aqueous humor and is taken up by the lens, where it is found in a concentration of 60 mg. per 100 gm. After removal of the lens, the concentration of glucose in the aqueous humor increases up to the level of the blood sugar. The low content of glucose usually found in the aqueous humor is therefore due to sugar consumption by the lens. The concentration of glucose in the aqueous humor and the lens increases in diabetes. Approximately one-quarter of the total amount of sugar metabolized by the lens is completely oxidized to CO_2 and water; three-quarters of it is converted into lactic acid. There is a cycle similar to that found in muscle. Lactic acid formed accumulates in the lens and diffuses out into the aqueous humor, where it reaches a higher level than that of the blood. After removal of the lens, the concentration of lactic acid in the aqueous humor falls to the same level as in blood. Flavoprotein and the cytochrome–cytochrome oxidase system have been found in the lens (see Chap. 34, Cell Respiration).[1]

ACCOMMODATION OF THE EYE FOR OBJECTS AT DIFFERENT DISTANCES

A clear vision of objects placed at different distances from the observer is obtained by a series of changes in the eye, known as accommodation. The crystalline lens plays a fundamental part in this process.

The Need for Accommodation. Scheiner's Experiment

When an object that is focused on the plate or film of a photographic camera is moved nearer to, or farther from, the camera, the distance between the lens and the plate must be changed, because the focus is displaced in the same direction as the object. When an object is brought nearer to the eye, the light rays coming from the object are progressively more diver-

[1] Kinsey, E.V., and C. Frohman, *Arch. Ophth.*, **46**, 536, 1951.

gent, and they would be focused at a point behind the retina if the eye remained unchanged. The displacement of the focus is insignificant when the object is moved from infinity to a distance of 6 m. (20 ft.) from the eye, but at nearer distances and up to 12 cm. from the eye, changes (*i.e.*, accommodation) take place which focus the object clearly on the retina (Table 105).

Table 105. Distance of Object from Eye and Image from Cornea

Distance of Object from Eye, M.	*Distance of Image from Cornea, Mm.*

Source: Luciani.

Scheiner in 1614 demonstrated accommodation by means of the following experiment: A needle is held at arm's length and looked at through two pinholes made in a black card distant 2 to 3 mm. from each other. The needle will be seen double if the eye is focused nearer or farther away, because the retina is in front of the focus of the needle in the first case and behind the focus in the second (Fig. 428).

Fig. 428. Illustration of Scheiner's experiment.

The Importance of the Crystalline Lens

Demonstration of the role of the lens in accommodation. Indirect proof of the role of the lens has been obtained by showing that the cornea and retina are not displaced in the process of accommodation; therefore the lens must be modified in order to change the focus.

Young (1801) pointed out that individuals who had no crystalline lens had no power of accommodation and had to use lenses of 3 D. to see clearly objects placed near the eyes. Direct proof of the changes that occur in the lens in the process of accommodation was given by observation of the Purkinje images by Langenbeck (1849), Cramer (1851), and especially Helmholtz (1851–1853). If a subject in a dark room has a lighted candle placed on one side at approximately 50 cm. from the eye, an observer placed on the other side, so as to see the light reflected by the subject's eye, will see three images of the candle:
Fig. 429. Purkinje images. *A*, eye at rest; *B*, eye accommodated for near objects; *a* and *a'*, images reflected on the cornea; *b* and *b'*, images reflected on the anterior surface of the lens; *c* and *c'*, images reflected on the posterior surface of the lens.

1. The brightest image is reflected by the anterior surface of the cornea and is upright.
FIG. 430. Mechanism of accommodation. Left half, eye accommodated for near objects; right half, eye during vision of distant objects. 1, substantia propria of the cornea; 2 and 3, epithelial layer on the anterior surface of the cornea; 4, epithelial layer on the posterior surface of the cornea; 5, pectineal ligament; 6, spaces of Fontana; 7, sclera; 8, chorioid; 9, retina; 10, ciliary body; 11, ciliary muscle; 12, circular fibers of the ciliary muscle; 13 and 14, iris; 15, ora serrata; 16, ciliary processes; 17, hyaloid membrane; 18, zonula; 19 and 20, anterior and posterior surface of the zonula; 22, intra-zonular space; 23, lens accommodated for near vision (increased curvature of the anterior surface); 24, lens accommodated for distant vision.

2. The second image, also upright, is much dimmer but of larger size. It is reflected by the anterior surface of the lens.
3. The third image is the smallest of the three. It is bright and inverted, and due to reflection on the posterior surface of the lens, which acts like a concave mirror.

If the subject looks at an object near the eye, the first and third images do not change, the second image diminishes in size and approaches nearer to the first, owing to an increase in the curvature of the anterior surface of the lens (Fig. 429). This increase in the curvature of the lens pushes the iris forward toward the cornea, the anterior chamber of the eye diminishes, and the angle formed by the iris and the cornea becomes more acute.

Changes in the lens in accommodation. Changes in the Purkinje images have been accurately observed by means of the ocular microscope and registered photographically. If a near object is looked at, the curvature of the anterior surface increases in the middle part of the lens, but diminishes in the peripheral parts; the posterior surface also becomes slightly more convex. The diameter of the lens diminishes, and its anteroposterior axis increases (Fig. 430); the dioptric power increases by 12 D.

The speed with which these changes occur is greater when the eye is focused from a distance to a near object (0.39 to 0.82 sec.) than when accommodation takes place in the opposite sense (0.5 to 1.16 sec.).

The range of accommodation is measured in diopters, which give the refractive power of the eye. It decreases with age, especially after forty years (Fig. 431), when reading or any work that
FIG. 431. Amplitude of monocular accommodation in man at different ages. Average, thick line; extremes, thin lines. Abscissa, age in years; left ordinate, diopters; right ordinate, distance of near point in centimeters. (*Duane, 1922.*)

requires near sight becomes difficult. This defect is known as presbyopia.

Associated phenomena. The pupil is constricted for near vision; thus marginal rays are eliminated and aberration is corrected. The increase in the depth of the focus also improves sight. The visual axes converge so that the images are formed on corresponding points of the retina.

Accommodation and convergence are closely associated and strengthen each other, but they can be artificially separated and are dissociated in certain diseases. Pupillary constriction is dependent on accommodation and convergence, but more on the latter than the former.

Action of the Zonula

Anatomy. The zonula is a fibrous ligament that extends from the ciliary body to the margin of the lens, being inserted on its anterior and posterior surfaces near the margin. Between the fibers there is jellylike substance which is easily permeable to fluids in both directions. The zonula separates the posterior chamber from the vitreous humor.

Physiologic action. The changes in shape of the lens are dependent in great part on the action of the zonula. In cases of congenital absence of the iris, the zonula can be observed with the ocular microscope, and it will be seen to relax on looking at a near object or when eserine is applied. The lens can then move slightly (0.3 to 2 mm.) when the subject's head is moved.

Action of the Ciliary Muscle

Anatomy. A transverse section of the eye shows the ciliary muscle as a triangle with its base on the iris and its apex in the chorioid at the level of the ora serrata. In man it is formed by two sets of smooth fibers. In one set the fibers are disposed in a radial or meridional direction; in the other, lying central to the first, the fibers follow a circular course. Each set has its own innervation.
Fig. 432. Hansen and Volkers' experiments.

Physiologic action. The action of the ciliary muscle was first demonstrated by Hansen and Volkers in 1868; recently their work has been confirmed and developed by Sachs (1942). The muscle has been observed in dogs, cats, monkeys, and man directly through an opening made in the sclera for that purpose. On stimulation of the ciliary ganglion, the muscle will be seen to move approximately 0.5 mm. forward toward the cornea. This movement is also demonstrated by passing a pin through the sclera so that its point touches the muscle; when the latter contracts the head of the pin is displaced backward. If another pin is placed so that it passes over the anterior surface of the iris to the anterior surface of the lens, its head moves in the same direction as the first (Fig. 432). These experiments show that contraction of the ciliary muscle approximates it to the cornea and coincides with an increase in the convexity of the lens.

Innervation. Helmholtz maintained that accommodation to near objects was an active process, and accommodation to distant objects a passive one. There are, however, several proofs that both are active processes dependent on autonomic innervation. Olmsted's[1] experiments are conclusive in this respect. Stimulation of one of the divisions of the autonomic nervous system, after section of the fibers corresponding to the other division, in rats, dogs, rabbits, monkeys,

[1] Olmsted, J. M. D., *J. Nerv. & Ment. Dis.*, **99**, 794, 1944.

etc., has shown that the cervical sympathetic (through the long ciliary nerves) has a tonic effect, producing hypermetropia by flattening the anterior surface of the lens, thus accommodating the eye for distant vision. The parasympathetic (through the oculomotor and the short ciliary nerves) increases the convexity of the lens, producing myopia, thus accommodating the eye for near vision. The two divisions of the autonomic are reciprocal antagonists, but the effect of the parasympathetic is greater, being equivalent to 10 D., than that of the sympathetic, which is equivalent to 1.5 D.

Pharmacology. Drugs that act on visceral nerves modify the process of accommodation. Parasympathomimetic drugs, such as eserine, muscarine, and pilocarpine, produce accommodation for near vision, the intensity of their effect being in the order given. Parasympatholytic drugs, such as atropine and its derivatives, homatropine, euphthalmine, etc., paralyze accommodation. Both types of substances are often used by ophthalmologists.

Theories of Accommodation

Several theories have been proposed to explain accommodation. The Young-Helmholtz theory is widely accepted. According to this theory, when the eye is resting, the zonula is under tension and maintains the elastic capsule of the lens distended. When the eye is accommodated for near vision, the following changes occur: (*a*) the ciliary muscle contracts and pulls the chorioid forward; (*b*) the zonula is therefore relaxed; (*c*) the lens, owing to the elasticity of its capsule, takes on a more rounded shape. All these facts have been satisfactorily demonstrated, but the theory does not explain certain other facts; *e.g.*, the fact that the anterior surface of the lens takes on a hyperbolic and not a rounded shape. Moreover, Fincham has seen that the capsule is not of uniform thickness over all the lens, but is thinner over the central part of the anterior surface, so that the curvature can increase more at this level than in the periphery.

INTRAOCULAR FLUIDS AND INTRAOCULAR PRESSURE

The intraocular fluids, *i.e.*, the aqueous and vitreous humors, are of similar chemical composition, and both are contained in the eyeball under pressure.

Aqueous Humor

Aqueous humor is a colorless fluid, similar to water, which circulates in the anterior and posterior chambers of the eye. It is a nutrient fluid for the lens and the vitreous humor, and it serves to regulate intraocular pressure.

The amount of aqueous humor in different species and its relation to the volume of the eyeball are given in Table 106. In man normally there is approximately 150 cu. mm., and in myopic eyes there is 250 cu. mm. Its chemical composition is given in Table 107. It has much less protein and more water than the blood plasma. Other substances are found in more or less the same concentration in the aqueous humor as in blood plasma, except that there are less glucose, amino acids, and urea, and more salts, especially chlorides. There is also oxygen and CO_2 in solution.

Table 106. Amount of Aqueous and Vitreous Humors of the Eye in Different Species

Species	*Aqueous humor, cu. mm.* (*Magitot,* 1921)	*Vitreous humor, cu. mm.* (*Emmert,* 1896)	*Anterior chamber, % volume of eyeball* (*Wessely,* 1921)

Formation of aqueous humor. The aqueous humor is formed from blood plasma in the same

way as other tissue fluids. Thus diffusible substances injected into the blood (fluorescein, potassium ferricyanide, etc.) or taken by mouth (potassium iodide) are found soon after in the auqeous fluid. The process of formation is still a subject of discussion.

Aqueous humor is formed on the surface of the iris, the ciliary body, and the cornea, according to the work of Kinsey and Cogan previously discussed. There is now definite proof that all these structures contribute to the formation of the aqueous humor.

An experiment performed by Ehrlich in 1881 showed that aqueous humor is formed on the surface of the iris. Fluorescein (2 to 3 cc. of a 20 per cent solution) is injected intravenously into a rabbit, and 2 or 3 min. later a greenish cloud is seen to form on the anterior surface of the iris. In some cases aqueous cysts are formed on this surface. The iris is not the only site of formation of the aqueous humor, because this fluid continues to be produced after extirpation of the iris and in cases of congenital aniridia (absence of the iris).

Aqueous humor is also formed on the surface of the ciliary body. If the pupil is closed, experimentally or by disease, aqueous humor accumulates in the posterior chamber, which is again filled after it has been evacuated by puncture. Aqueous humor continues to be formed in cases of congenital absence of the ciliary body; therefore it is not formed exclusively on these structures.

The mechanism by which the aqueous humor is formed (secretion by the ciliary body or filtration or dialysis) has been the object of much discussion. According to Duke-Elder,[1] some substances are filtrated and others are dialyzed.

Intraocular circulation. Aqueous humor circulates through the chambers of the eye and is evacuated by three routes: (*a*) the posterior route; (*b*) the iris; (*c*) the canal of Schlemm. The posterior route through the zonula, the canal of Cloquet (which extends from the posterior surface of the lens to the disk), and the sheath of the optic nerve accounts for only 1 per cent of the total fluid. The crypts of the anterior surface of the iris near its blood vessels also reabsorb part of the aqueous humor.

The canal of Schlemm is a venous sinus which surrounds the cornea like a ring at the level of the angle formed by the iris and the cornea. It is separated from the anterior chamber by trabeculae which come from the cornea and form the spaces of Fontana, which communicate with the anterior chamber but not with the canal of Schlemm. Small particles, such as those of India ink, injected into the anterior chamber accumulate in the iridocorneal angle, also known as the filtration angle. According to some observers, the canal of Schlemm is continuously reabsorbing aqueous humor, but according to others it is a safety mechanism that functions only when the intraocular pressure increases, the eyelids contract, etc.

The circulation of the aqueous humor is carried out at a relatively fast rate. This has been demonstrated by the injection of "labeled" substances (*e.g.*, isotopes) which can be followed in their passage through the eye. The aqueous humor has thus been seen to be completely renewed several times per day. Kinsey and Cogan maintain that all the water is renewed every 3 min. In the cat and rabbit renewal of the aqueous humor takes place at a rate of 1 to 2 per cent per min.[1] Stains can also be seen to disappear rapidly, but many factors other than the circulatory rate (*e.g.*, phagocytosis) condition the reabsorption of these substances. If the anterior chamber is evacuated, it is refilled in 40 to 50 min. by a fluid that has a higher protein concentration and less chloride than the normal fluid.

There is also a thermal current of fluid, which flows up the anterior surface of the iris and down the posterior surface of the cornea. It is due to the difference in temperature between the iris and the cornea; the latter has a temperature 7°C. below that of the former. This current is clearly seen after the injection of fluorescein.

Vitreous Humor

The vitreous humor is a colorless, transparent, jellylike fluid which fills the space between the posterior surface of the lens and the retina. It contains a network of thin fibers, which can be seen *in vivo* with the ocular microscope. They form the hyaloid membrane on the surface of the retina. If the vitreous humor is centrifuged, the fibers fall to the bottom and a fluid identical to aqueous humor is separated.

[1] Duke-Elder, W. S., Nature of the Aqueous Humor, *J. A. M. A.*, **137**, 1285, 1948.

[1] Langham, M., *Brit. J. Ophth.*, **35**, 409, 1951; Ross, E., *Brit. J. Ophth.*, **36**, 41, 1952.

The density of vitreous humor (1.005 to 1.008) and its freezing point are similar to those of the aqueous humor. Its chemical composition (Table 107) differs from that of aqueous humor by its higher protein content. Two proteins have been separated, a mucoprotein (mucoid) and vitrein, similar to gelatin, which is highly hygroscopic and forms fibers. These proteins give the vitreous humor the consistency of a gel, which is denser near the retina and less dense on the posterior surface of the lens. Hyaluronic acid is found in relatively large amounts. This mucopolysaccharide probably forms part of the mucoid. It absorbs great quantities of water and contributes to give viscosity to the fluid. Hyaluronidase, which is found in the ciliary body, iris, cornea, etc., disintegrates hyaluronic acid and fluidifies the substances which contain it. Piris injected this enzyme in the vitreous humor of living rabbits and observed liquefaction of the vitreous humor and a fall in intraocular pressure which lasted for several days.

Intraocular Pressure

The fluids in the eye are contained in a cavity formed by the inelastic sclera. They are under pressure, which results from an equilibrium between the inflow and outflow. The pressure falls rapidly after death or if the eye is separated from the body.

The normal intraocular pressure and its physiologic variations. Intraocular pressure can be measured directly by introducing a needle into the eyeball and connecting it with a manometer. It can also be determined by digital pressure or by means of tonometers. The latter are instruments that measure the pressure needed to flatten the cornea or sclera. The normal pressure in the human eye, measured by a tonometer, is usually 20 to 25 mm. Hg, the extreme values being 12 and 35 mm. Hg.

Intraocular pressure diminishes gradually throughout life, from childhood to old age. It is 3 to 5 mm. higher in the morning than in the evening. Respiratory movements and the arterial pulse cause slight rhythmical oscillations in intraocular pressure. When the lids are closed, the pressure rises approximately 10 mm. Hg.

Causes of intraocular pressure. Intraocular pressure is due to the pressure in the blood capillaries of the chorioid membrane, which depends on the general arterial blood pressure.

Arterial blood pressure. Intraocular pressure is related to the arterial blood pressure and rises and falls with it. The relation between intraocular pressure and arterial blood pressure in different species is given in Table 108. If the blood pressure in the chorioid capillaries falls, *e.g.*, owing to clamping of the carotids, hemorrhage, bradycardia (stimulation of the vagus nerve), removal of the eyeball from the body, or death, intraocular pressure also falls. If the blood pressure rises, *e.g.*, owing to clamping of the abdominal aorta, or intravenous injection of a large quantity of fluid, intraocular pressure also rises.

Table 108. Intraocular Pressure and Blood Pressure in Different Species

Species	*Intraocular pressure, mm. Hg*	*Blood pressure, mm. Hg*
Guinea pig	10–15	110–120
Rabbit	18–25	100–140
Cat	23–30	130–150
Dog	15–25	140–180
Man	15–30	110–120*

* In femoral artery.

Circulation in the chorioid. Variations in the pressure and flow in the chorioid vessels have a direct influence on intraocular pressure. The circulation in the eye is divided into two systems: (*a*) the retinal vessels, which are branches of the central artery of the optic nerve; (*b*) the chorioid vessels, which are branches of the ciliary arteries. The latter is the only system of importance for intraocular pressure. The chorioid is a vascular membrane situated between the almost rigid sclera and the retina. Its thickness is approximately 300 μ. The ciliary arteries enter this membrane and immediately branch out, forming a rich network of large capillaries (their diameter is approximately 10 times that of other capillaries in the organism). The pressure in the ciliary arterioles is approximately 80 mm. Hg; owing to the large size of the capillaries, a relatively great part of this pressure is transmitted to the veins, where the blood pressure is approximately 26 mm. Hg. The pressure in the capillaries lies between these two figures. This pressure is maintained by the rigid sclera; therefore any increase in the pressure within the capillaries causes an increase in intraocular pressure,

and vice versa, a fall in capillary pressure is followed by a fall in intraocular pressure. Ligature of the ciliary arteries provokes a fall in the pressure of the capillaries in the chorioid and in intraocular pressure. On the other hand, ligature of the veins increases capillary and intraocular pressure.

Variations of intraocular pressure with respect to variations in the diameter of the chorioid capillaries are related to the changes in capillary pressure. Thus if the capillaries are dilated by subconjunctival injection of hypertonic NaCl solution, intraocular pressure rises slightly, but if later pituitrin is injected so that a considerable rise in arterial blood pressure occurs, the intraocular pressure also rises considerably. On the other hand, if the chorioid capillaries are constricted by adrenaline, intraocular pressure does not rise even if the general blood pressure rises. Changes in the diameter of the capillaries therefore influence intraocular pressure in so far as they modify capillary pressure.

Effects of innervation. Nerve impulses modify intraocular pressure only through the changes they provoke in capillary pressure. Stimulation of the cervical sympathetic causes vasoconstriction, and the intraocular pressure falls considerably. Section of the cervical sympathetic causes a slight transitory rise in intraocular pressure

Stimulation of the trigeminal nerve raises intraocular pressure, and section of this nerve lowers it. Axon reflexes take place through the endings of this nerve. After it has been cut, stimulation of the iris with a needle (Magitot) or subconjunctival injection of hypertonic solution provokes an increase in intraocular pressure, which is annulled by the injection of adrenaline, causing vasoconstriction.

Drugs that act on autonomic effectors also cause changes in intraocular pressure by modifying the pressure in the chorioid capillaries. Thus the following substances instilled into the conjunctiva modify intraocular pressure: (*a*) adrenaline diminishes it after a slight transitory increase; (*b*) eserine increases it; (*c*) atropine has no effect on it in normal subjects, but increases it in patients with glaucoma[1] and should not be used in these cases.

BIBLIOGRAPHY

See page 976.

[1] Glaucoma is a disease of the eye in which there is a high intraocular pressure, which disturbs the nutrition of the eye and usually ends in blindness.

CHAPTER 78

The Retina. The Visual Pathways and Centers

THE STUDY OF THE embryology and histology of the retina shows that it is a specialized part of the central nervous system.

THE RETINA

In recent years the classic work of Cajal on the histology of the retina has been considerably developed; the observations of Polyak are particularly important in this respect. The photochemical processes and electrical phenomena that take place in the retina have been studied intensively and have thrown much light on the physiology of the organ of vision.

Anatomy and histology. Histological examination of the retina shows that it is formed by two concentric parts: (*a*) under the chorioid membrane there is a pigmented epithelium; (*b*) below this epithelium, in close contact with the vitreous humor, there is the pars optica. The pigmented epithelium is formed by a layer of pigmented cells, which convert the interior of the eyeball into a camera obscura.

The pars optica is the sensory part of the retina, and it is transparent in the living eye. Its thickness is 0.6 mm. at the back of the eye and diminishes toward the anterior part, so that it is only 0.1 mm. in the ora serrata, where it ends. It is perforated by the entrance of the optic nerve. Slightly above (1 mm.) and 3 mm. toward the nasal side of this entrance, on the visual axis of the eye, there is a small yellowish area (approximately 3 sq. mm.), called the macula lutea. In the center of the macula there is a depression, the fovea centralis, which is the most sensitive part of the retina for daylight vision. The pars optica is formed by nine layers, in which there are three fundamental types of cell: (*a*) photoreceptors; (*b*) association cells; (*c*) ganglion cells (Fig. 433).

The photoreceptors are in the outermost layer of the pars optica in contact with the pigment layer and placed vertically with respect to this membrane. There are two kinds of photoreceptors, the cones and the rods, which nevertheless have a common embryonic origin. These cells are formed by three parts, an external photosensitive process, similar to a cilium; a middle part, which contains the nucleus; and an internal process, which is connected with the association cells (Fig. 434). There are approximately 7,000,000 cones in the human retina. They are the only type of receptor in the fovea, where their length is 80 μ. Toward the ora serrata they diminish in size and number, and are surrounded by rows of rods. The external process is short except in the fovea, where it is almost as long as that of the rods. There are approximately 130,000,000 rods in the human retina; they increase in number toward the ora serrata. They have a long, fine, external process which contains 10 per cent rhodopsin. The fine internal process is connected with association cells.

There are three types of association cells distributed in the middle layers of the pars optica. The bipolar cells have two processes; the external process is connected with the internal process of the photoreceptors, and the internal process ends on the ganglion cells. Other association cells are the horizontal and amac rinal cells, which are also connected with the photoreceptors and the ganglion cells.

The ganglion cells are placed in the innermost layer of the retina. They have a short process connected with the bipolar cells and a long process which is a naked axon forming the optic nerve.

The cells in the retina, therefore, form a chain with three links, *i.e.*, the photoreceptor (cone or rod), the bipolar cell, and the ganglion cell. Most of the bipolar and ganglion cells have multiple connections whereby

they receive impulses from several, in some cases many, photoreceptors (Polyak's "polysynaptic" cells). A few of the bipolar cells are much smaller (midget, or monosynaptic, bipolar cells); they are found in the fovea centralis and are connected with only one cone and one ganglion cell. In the fovea there are also small ganglion cells which receive impulses from only one or two cones by way of the midget bipolar cells (Fig. 433).

Fig. 433. Principal connections of the cells in the retina.

Structural Changes Produced by Light

In fishes, amphibians, reptiles, and birds, light provokes in the retina photomechanical changes which involve the pigment cells and the photoreceptors. If a frog or toad is exposed to a bright light, the pigment granules in the pigment cells are rapidly dispersed so that within a few minutes they surround the external processes of the photoreceptors. When the animals are placed in a dark environment, the pigment granules are slowly concentrated around the nucleus of the pigment cells (Fig. 435).

Dispersion and concentration of the melanosomes (pigment granules) are controlled by a complex neuroendocrine mechanism in which the pars intermedia of the hypophysis plays an important part (see Chap. 52).

In fishes and amphibians, and to a lesser extent in reptiles and birds, the rods are shortened when the animals are exposed to light. This process is even more marked in the cones, which are sometimes shortened to one-tenth their resting length. This shortening is due to the contraction of the middle part of the cell, which has a myoid structure. Apparently the shortening serves to focus the light on the photoreceptor. In these species the external processes of the rods are dilated on exposure to light, and they may come into contact with the neighboring rods.

Chemical Changes Produced by Light

The discovery of photography led to the belief that a similar process took place in the eye. The change in the color of the retina produced by light, which was reported a few years later (1877) by Boll, seemed to confirm the idea. Kühne (1879) then discovered rhodopsin and carefully investigated the part it played in visual processes. Recent advances in the physics and chemistry of photosensitive substances have given new and more accurate knowledge on this subject.

Origin of visual pigments. Photosensitive substances, which play a part in the visual processes of animals and in phototropism in plants, form part of the group called carotenoid pigments; one of these,

β-carotene, is closely related to vitamin A (see Chap. 49).

Carotenoids vary in color from yellow to red. Phototropic plants have large amounts of carotenoid pigments in the parts sensitive to light. There are no carotenoid pigments in plants that are not phototropic. These pigments are sensitive to the blue radiations of the spectrum, while the chlorophyll system is sensitive to yellow-orange radiations.

Wald[1] has drawn attention to the fact that these substances are utilized by plants and animals (in phototropism and visual processes, respectively) but only plant organisms synthesize them. Animals cannot synthesize carotenoids; they obtain them from plants and utilize them after only slightly modifying their structure. Animals are, therefore, dependent on plants for the supply of these pigments.

FIG. 434. Photoreceptors in the retina. Diagram of a rod (left) and a cone (right).

There are several visual pigments in the cones, the rods, and the macula. The best known are the pigments of the rods, rhodopsin and porphyropsin.

Rhodopsin. This red pigment, also called "erythropsin" or "visual purple," is bleached by exposure to light and recovers its color in the dark. It is found in the external segments of the rods.

Rhodopsin plays a fundamental part in nocturnal or twilight vision,[2] which is a function of the rods. The different radiations of the spectrum have the same effect on the dark-adapted eye as on visual purple. Thus the sensibility curve of the dark-adapted eye coincides with the absorption curve of a pure solution of visual purple (Fig. 436).

Bleaching. When rhodopsin is exposed to light it is rapidly bleached, passing through a series of

[1] WALD, G., *Harvey Lect.*, **39**, 117, 1945–1946.

[2] Nocturnal or twilight vision is given by illumination such that objects are seen in outline or as shadows, without any distinction of color.

FIG. 435. Retina of normal toad [*Bufo arenarum* (Hensel)] kept in the light and in darkness. Dispersion of pigment in light (left) and concentration in darkness (right).

colors, transitory orange and visual yellow, until it becomes white. These changes are easily followed not only *in vitro* in solutions of rhodopsin, but also *in vivo*, by cutting out part of the sclera. The process can also be demonstrated by the following experiment: A rabbit is kept in the dark for several hours and then placed in front of a brightly lighted window for a few minutes. The animal is then killed and the eye submerged in alum. A white patch will be seen in the retina where the image of the window was formed, and if the window had bars that threw shadows, these will appear as dark lines on the white patch.
FIG. 436. Corrected curves of scotopic vision of the human eye and absorption curve of a solution of visual purple. Abscissa, wavelength in millimicrons; ordinates, luminosity and absorption. (*Hecht and Pirenne.*)

Rhodopsin can be extracted by bile salts from the retina of an animal which has been kept several hours in darkness.[1] It is made up of a large protein molecule (molecular weight 270,000), *opsin*, which is specific for each animal species. It has a carotenoid group, equivalent to one-tenth of the weight of the whole molecule, to which it owes its red color and photosensitiveness. Absorption spectra of rhodopsin show three bands, α, β, and γ at 500, 350, and 278 mμ. The α band is the highest; it is due, together with the β band, to the carotenoid. The γ band is due to the opsin.
FIG. 437. Chemical cycle of rhodopsin.

Exposure to light causes profound physical and chemical changes in rhodopsin.[1] In the first stage the carotenoid is separated from the opsin (Fig. 437). Rhodopsin is rapidly converted to *lumi-rhodopsin*, with the absorption spectrum shifted 5 mμ toward the ultraviolet; then to *meta-rhodopsin*, with a further shift of 5 mμ in the spectrum, and finally it is split up into opsin and retinene$_1$, which has a characteristic absorption spectrum (Table 109). This substance is an aldehyde of vitamin A_1.[2] This stage ends with the formation of visual yellow.

Retinene$_1$ is converted by reduction into vitamin A_1. The enzyme system of this reaction is constituted by *retinene reductase* with DPN (diphosphopyridine nucleotide) as coenzyme. At the end of this stage visual white appears.

Table 109. Absorption Maxima of Photosensitive Substances in the Eye

Substance	*Maximum, mμ*	*Substance*	*Maximum, mμ*	*Substance*	*Maximum, mμ*
Pigment	467	*Porphyropsin*	522	*Iodopsin*	555
Rhodopsin	500	Retinene$_2$	405		
Retinene$_1$	387	Vitamin A_2	355		
Vitamin A_1	328				

Note: Rhodopsin and porphyropsin are dissolved in 1 per cent aqueous solution of digitonin. Retinenes and vitamin A are dissolved in chloroform.

[2] MORTON, R. A., and T. W. GOODWIN, Preparation of Retinene in Vitro, *Nature, London*, **153**, 405, 1944.

Regeneration. Retinene$_1$ and vitamin A$_1$ produced by the decomposition of rhodopsin are mainly in the form of the *trans* isomer, which cannot be used in the regeneration of rhodopsin. The process of conversion of vitamin A$_1$ into the *cis* isomer is still unknown. This *cis* isomer of vitamin A$_1$, coming from the retinal cycle, together with some taken from the blood, is converted into retinene$_1$ by oxidation of the alcohol into aldehyde. The above-mentioned enzyme system activates this reaction. The *cis*-retinene$_1$ combines in darkness with the SH groups of opsin, and rhodopsin is regenerated.[1]

Subjects suffering from avitaminosis A$_1$ have a more or less marked deficiency in dark adaptation, which is quickly improved by the ingestion of vitamin A$_1$. Night blindness or a deficiency in twilight vision is a serious handicap in certain occupations (*e.g.*, aviators flying at night).

Other factors also condition regeneration of visual purple. Among these, oxygen partial pressure can be mentioned. When there is a low oxygen pressure, *e.g.*, when flying at great heights, regeneration is retarded and twilight vision is deficient.

Porphyropsin. In fresh-water fishes the rods contain porphyropsin instead of rhodopsin. This is a purple pigment which is bleached by light and is regenerated in darkness. It differs from rhodopsin in setting free retinene$_2$ instead of retinene$_1$ when it is bleached. Crystalline retinene$_2$, identical with that obtained from the retina, has been prepared from vitamin A$_2$ extracted from fresh-water fishes.[2] Given by mouth to rats suffering from avitaminosis A, it is rapidly stored in the liver; signs of deficiency decrease and the animals improve, but normalization is not complete. The part played by vitamin A$_1$ is taken on by vitamin A$_2$; otherwise the process is the same. There are slight differences in the chemical composition of vitamin A$_2$ and retinene$_2$ with respect to those of vitamin A$_1$ and retinene$_1$. There are also differences in the absorption spectra (Table 109).

Comparison of rhodopsin and porphyropsin. The two systems are very similar in their chemical aspects, but they are distributed among different species. Porphyropsin is found only in the eyes of fresh-water fishes, while rhodopsin is found in salt-water fishes and all other species. Wald has examined fishes that at certain stages of their life cycle are found in salt water and at others in fresh water (eels, salmon, etc.). He concludes that these animals have both systems but that the system corresponding to the place of ovulation is predominant. Wald has observed a transition from one system to the other in *Rana catesbiana,* which like other amphibians ovulates and completes its larval development in fresh water. Porphyropsin is found in the eyes of the larvae, rhodopsin appears in the course of metamorphosis, and in the adult form porphyropsin disappears and only rhodopsin is found.

[2] Cama, H., R. Morton, *et al.*, *Biochem. J.*, **52**, 535, 540, and 542, 1952.

Other visual pigments. Wald has extracted two pigments from the retina of the chicken, in which cones are predominant. One is probably rhodopsin; the other is called "iodopsin" because of its purple color. The chemical structure of this substance has not yet been definitely established, but it appears to be related to vitamin A and similar to rhodopsin. It has maximum absorption at 555 mμ, *i.e.*, the wavelength to which the light-adapted eye is most sensitive.

A pigment with maximum photosensitiveness at 467 mμ, and insensitive to red light, has been extracted from the retina of a fresh-water fish, the tench (*Tinca tinca*).[1]

In the macula lutea of men and monkeys a yellow pigment, distributed in all the layers of the retina, has been found. It acts as a filter absorbing blue and violet radiations, thus correcting chromatic aberration. This pigment is one of the xanthophyll group, similar to others in the group found in many plants and the outer covering of crustacea.

Electrical Activity of the Retina

The development of sensitive and accurate methods for registering electric potentials of very low voltage and short duration has advanced the knowledge of the functions of the retina, as in other nerve structures.

Resting potential. The eyeball *in situ* or separated from the organism shows a steady corneoretinal potential of 7 to 9 mv., the back of the eye being electronegative with respect to the cornea. The potential is apparently due to the retina, since it is suppressed by destruction of the retina and persists after degeneration of the optic nerve.

Action potentials. Electroretinogram. If the retina is stimulated by light, a phasic po-

[1] Dartnall, H., *J. Physiol.*, **116**, 257, 1952.

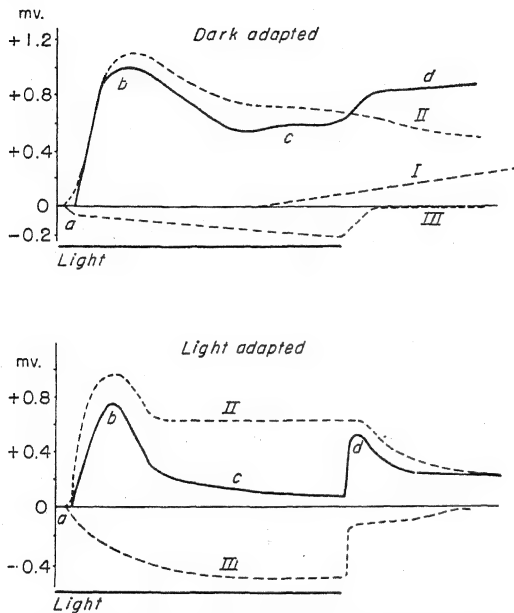
tential variation is observed which is known as the electroretinogram (ERG). Einthoven, who was the first to register this phenomenon, distinguished four waves, *a*, *b*, *c*, and *d* (Fig. 438).


Fig. 438. Electroretinogram in light and darkness.

The first wave (*a*) is a small negative deflection which appears 0.01 to 0.05 sec. after the application of the light stimulus. The other three waves are positive deflections. *b* is a large positive wave followed by a second prolonged positive wave (*c*). When the stimulus ceases, a third positive wave (*d*) is seen on the slowly declining potential curve.

The *b* wave varies considerably. Its threshold coincides with that of scotopic vision. It increases with the intensity of the stimulus. It is large when the eye is stimulated after having been kept in the dark, and small when provoked by an increase in illumination. It is modified by several drugs.

The electrical activity of the retina begins when, in the course of embryonic development, the photoreceptors are formed. It is not dependent on the optic nerve.

In man the ERG can be recorded by applying the electrodes to the tissues surrounding the eyes. The *b* and *c* waves are well marked, but the *a* and *d* waves are not found. The latent period may be as long as 60 sec. (Bernhard).

Action potential of the optic nerve fibers. Hartline and his associates have registered the potentials of a single optic nerve fiber in the retina of the horseshoe crab (*Limulus*). They removed the cornea, lens, and vitreous humor and under the microscope separated one of the nerve fibers, which have no myelin sheath at this level. The microelectrode placed on the fiber was connected by means of amplifiers with a suitable recording system. When the retina was stimulated with white light, after a short latent period, a series of spikes of uniform amplitude appeared.

By stimulating limited areas of the retina, using a fine ray of light, it was possible to determine that each fiber is distributed over an area of approximately 1 sq. mm., which has hundreds of photoreceptors. There are three groups of fibers. When the stimulus is applied, one of the groups responds to light with a rapid discharge of spikes, which gradually declines to a steady state ("on" type of receptors). Another group responds to the cessation of light ("off" type), and a third group discharges at the beginning and end of stimulation ("on-off" type).

The influence of intensity and duration of the stimulus. The frequency and duration of the discharge increase with the intensity of the stimulus (Fig. 439). The high initial frequency gradually declines to a steady state (adaptation). If the intensity is kept constant, an increase in the duration of the stimulus provokes a more frequent discharge. The nerve centers cannot discriminate variations in the intensity and duration of the stimulus with the data obtained by stimulation of a single fiber; probably notation of these characteristics in a stimulus results from integration of discharges that travel along several fibers.

The influence of the wavelength of light. Granit has developed a method for the registration of potentials in a single fiber of the retina of higher animals. The anterior segment of the eyeball is removed, as in Hartline's experiment, or a window is made in the sclera. A microelectrode of platinum isolated by glass is placed on the fiber, which is isolated from the rest by means of a micromanipulator. The retina is then stimulated by a thin ray of light of known wavelength. The impulses are amplified and recorded or converted into sound.

Approximately 60 per cent of the fibers respond to the same wavelengths as the normal

eye. These are known as "dominators," and in the light-adapted eye the sensibility curve of these fibers is the same as that of the whole eye. If the eye undergoes dark adaptation, both sensitivity curves undergo a similar change, and the apex of sensitiveness passes from 555 mμ to

FIG. 439. Influence of duration and intensity of stimulus on the action potential of a single retinal fiber of the optic nerve of *Limulus*. (*Hartline.*)

500 mμ. Fibers that are dominators in photopic vision are also dominators in scotopic vision. These fibers are probably connected with cones

FIG. 440. Synthetic curve of photopic luminosity in man. (*Granit.*)

and rods in the retina and conduct impulses that give rise to the sensation of brightness or luminosity.

The rest of the fibers respond only to a limited wavelength. There are three main types, which are sensitive to red-yellow, green, and blue, respectively, *i.e.*, to the three primary colors. These fibers are called "modulators"; they are probably connected with cones and give rise to the sensation of color. The summation curve of sensibility of the three types of modulators is equal to the curve of photopic dominators (Fig. 440).

Correlation of chemical and electrical phenomena. Recently Ball and his associates[1] have observed that the sensibility curve of photopic dominators coincides with the absorption curve of iodopsin, and the curve of scotopic dominators with the absorption curve of rhodopsin. The curve of modulators coincides with the absorption curves of retinene$_1$ and vitamin A_1. This remarkable connection between chemical and electrical phenomena seems to indicate that light decomposes photosensitive substances in the retina, thus stimulating the receptors and discharging impulses along the optic nerve, which on arriving at the striate cortex give rise to visual sensations.

VISUAL PATHWAYS AND CENTERS

The visual pathway extends from the retina to the area striata of the occipital cortex. It is formed by a chain of three neurons with a subcortical center interposed.

[1] BALL, S., D. COLLINS, R. A. MORTON, and A. STUBBS, Chemistry of Visual Processes, *Nature*, 161, 424, 1948.

Reticulogeniculate Pathway

The *first-order neurons* in the visual pathway are the bipolar cells in the retina, which are stimulated by the photoreceptor (cone or rod) and transmit impulses to the *second-order neurons*, *i.e.*, the ganglion cells. The axons of the ganglion cells converge to the papilla or disk, which is the optic-nerve head. The papilla is the blind spot of the visual field, because there are no photoreceptors at this point. The fibers from the nasal side of the retina converge to the papilla following a straight course, like the spokes of a wheel. Fibers from the macula also go directly to the papilla, but as no fibers pass through the fovea, those from the temporal side of the retina form two loops, one above and the other below the fovea, separated by a sharp horizontal line which goes from the fovea to the temporal margin of the retina (Fig. 441).

In the optic nerve the fibers are also distributed systematically. The nasal retinal fibers are situated on the median or internal side of the nerve, and the temporal retinal fibers on the lateral or external side, separated into an upper and lower quadrant by the large bundle of macular fibers (Fig. 442).
Fig. 441. Diagram of ganglion fibers in the retina. (*After Traquair.*)
Fig. 442. Diagram of the visual pathway. *A*, lateral geniculate body; *B*, occipital cortex. The subcortical reflex paths have been omitted.

At the optic chiasm, fibers from the temporal hemiretina pass into the optic tract of the same side; those from the nasal hemiretina decussate and pass into the optic tract of the opposite side. Macular fibers are divided at the level of the chiasm into two bundles. Those from the temporal half pass into the homolateral optic tract, and those from the nasal side into the heterolateral optic tract.

The optic tract ends in the lateral geniculate body. In this tract a functional regrouping of the fibers occurs. Visual fibers, *i.e.*, those carrying impulses that provoke visual sensations, enter the lateral geniculate body, while the afferent fibers of the pupillary light reflexes end in the pretectal region. Some of the macular fibers are bilateral.

Geniculocortical Pathway

The lateral geniculate body is made up of six layers of cells, separated by fibers. The second-order neurons end in this body and are distributed systematically, so that the retina is projected on corresponding parts of the geniculate body. Thus macular fibers end in a large sector interposed between sectors with fibers from the lower quadrant of both retinas on the lateral side and those from the upper quadrant of both retinas on the medial side. Each optic-nerve fiber divides into several branches, and each branch ends on the body of a third-order neuron which receives no other fibers. These neurons are thus stimulated through a single synapse.

Fig. 443. Diagram of projection of retinal areas on the area striata.

A lesion of the retina or section of the optic nerve is followed by degeneration in the optic tract of the cut fibers, which can thus be followed up to the geniculate-body neurons; these neurons also degenerate (see "Transneuronal degeneration," Chap. 65).

The axons of the geniculate neurons form the geniculostriate bundle, which at first takes a forward direction around the ventricle of the temporal lobe, then swings back toward the occipital lobe, opening fanlike to end in the striate area, in the depth and lower and upper lips of the calcarine fissure. In this bundle the fibers continue to be distributed systematically, those corresponding to the macula being separated from those of the upper and lower peripheral quadrants (Fig. 443).

The Visual Area of the Cortex

The visual area in man is distributed in the depth and lips of the calcarine fissure. It has a particular cytoarchitecture with a marked line of Gennari, visible to the naked eye, from whence the name "striate area," given to this region of the cortex. It corresponds to area 17 in Brodmann's numeration and is clearly separated from the neighboring areas 18 and 19.

By correlating lesions in these areas with defects observed in the visual fields, and registering the local action potentials in the striate cortex of monkeys provoked by localized stimulation of the retina, it has been possible to establish the projection of the retina on the visual cortex. Macular fibers end on a surface that is much larger than the surface of both retinas, extending backward to the pole of the occipital lobe. The upper part of the peripheral retinas (homolateral quadrants) of both eyes ends on the superior lip down to the depth of the calcarine fissure and the lower part on the lower lip.

The visual area (17) is connected with areas 18 and 19, which cover an area three times as large as the visual area. This has been demonstrated by applying strychnine locally (Dusser de Barenne's method) and following the spread of the action potentials after stimulation of the striate area.

Functions of the area striata. The visual cortex increases in importance as species rise in the zoological scale. Thus visual acuity in fishes and birds is dependent on subcortical centers and is not abolished by removal of the cortex. In mam-

mals, vision is a cortical function; subcortical centers only mediate reflexes.

Marquis has demonstrated, by means of conditioned reflexes, that a decorticate dog can still discriminate difference in light intensity, which is dependent on the functions of the rods, but not difference in color, dependent on the cones. The centers for the rods would therefore be subcortical, and those for the cones would be in the cortex. These experiments were later confirmed in rats and cats; in monkeys the results were less clear; in man the centers for rods and cones are in the cortex, and all types of vision are lost after extirpation of the occipital lobe. In the rat, shape is not discriminated after removal of the cortex, because this process is not exclusively dependent on the rods (as brightness is) but also on the cones, which have their center in the cortex in this species.

Lesions of the Visual Pathway

Localized lesions of the visual path, provoked experimentally or due to disease, owing to systematization of the fibers along the whole visual path, produce deficiencies in limited parts of the visual fields.

Section of the optic nerve is followed by total blindness in the corresponding eye. Lesions or sections in the chiasma have different results according to their site. Thus a section through the mid-line cuts fibers from the nasal quadrants of both retinas, and vision is lost in the temporal half of the visual fields of both eyes. This condition, known as "bitemporal hemianopsia," occurs in cases of hypophyseal tumor. If the lateral fibers of the chiasma are damaged, *e.g.*, by bilateral lesions in the angle formed by the optic nerve and optic tract, the temporal half of both retinas is disconnected and the nasal half of both visual fields is lost (binasal hemianopsia).

Section of the optic tract interrupts the fibers from the temporal half of the retina on the same side and the nasal half on the opposite side. Half the visual field of each eye, corresponding to the side opposite to the lesion, is suppressed. For example, if the left optic tract is destroyed the right half of the visual fields is deficient; this is known as right lateral homonymous hemianopsia.

Fig. 444. Visual cortex.

Lesions posterior to the geniculate bodies, *e.g.*, in the occipital lobes, produce blindness in the corresponding half of both retinas but spare macular vision. This greater resistance of the macular cortex is due to the fact that it receives its blood supply from the medial and posterior cerebral arteries, while the rest of the occipital cortex is supplied only by the posterior cerebral artery (Foerster). Macular vision, however, is also spared when lesions are not produced by circulatory defects but by other means, *e.g.*, surgical extirpation or traumatic destruction. The macula therefore must be represented bilaterally, or else it has a very large area of cortical representation in the striate area which in part escapes the effect of the damaging agent. The latter hypothesis seems more probable, because macular representation extends farther than peripheral representation, not only in a posterior but also in an anterior direction.

CHAPTER 79

Audition

Historical note. The scientific knowledge of hearing began in the sixteenth century with the anatomical study of the ear. The simple methods used at that time had given their maximum results by the end of the eighteenth century. Most of this pioneer work was done in Italy by Vesalius (1515–1564), Ingrassia (1510–1580), Fallopius (1523–1562), Eustachius (1510–1574), and later by Valsalva (1666–1723), Morgagni (1682–1771), Cotugno (1736–1822), and Scarpa (1747–1832). To these names, those of the English anatomist Willis (1622–1675) and the Frenchman Duverney (1648–1730) should be added. In the nineteenth century the methods of comparative anatomy and histology in the hands of Corti (1822–1876), Reissner (1824–1875), and others completed the knowledge of the structure of the ear necessary for the enunciation of the first theories on the physiology of hearing.

To Helmholtz (1821–1894) goes the credit for having correlated the phenomena of audition with those studied in the physics of sound. Many important problems were thus solved and others were stated, some of which even today remain without a satisfactory answer. The best known of his works on this subject was published in 1863. He states there his theory that resonance of the basilar membrane is the mechanism by which the component frequencies of a complex sound wave are analyzed.

No important advance was made after this until the discovery in this century of electromechanical means of producing and measuring sounds of any strength and complexity, and of amplifying and recording very small electrical potentials of very short duration. The application of these techniques to the study of hearing is marked by the work of Wever and Bray (1930), who were able to reproduce faithfully sounds picked up by the ear, by amplifying and recording the electrical potentials of the cochlear nerve. In recent years knowledge has advanced at a rapid rate, as a result of the concerted efforts of physicists, psychologists, otologists, and physiologists.

The ear is a complex organ found in reptiles and higher animals. Like other sensory organs, it develops from the ectoderm of the embryo. It is extraordinarily sensitive to sound waves. It analyzes them accurately into their components and transmits them to the brain in the form of electrical potentials traveling along the axons of the cochlear nerve. These sound waves usually reach the ear through the air as very small and rapid pressure changes, caused by the vibration of the body that emitted the sound.

The ear fulfills the two essential conditions needed in an apparatus for capturing and registering sound waves: it has good resonance and damping. It can therefore faithfully reproduce a tone and prevent its persistence for a longer time than is necessary to stimulate the receptor.

This study of hearing will be divided into three parts:[1]

1. Auditory sensations.
2. The mechanics of audition.
3. Auditory pathways and nerve centers.

Disturbances caused by sound will be considered briefly; finally a general summary will be given.

AUDITORY SENSATIONS

Hearing has considerable physiologic and psychological importance. It is one of the principal means of establishing relations with the environment, particularly with other human beings. It is necessary for learning speech and

[1] The student is advised to refresh his knowledge of acoustics; he will thus find it easier to understand what follows.

song. Words are the normal means of thought and the transmission of thought from one person to another. Education and progress are therefore ultimately dependent on hearing. Auditory sensations, especially music, have a high affective tone, which is finely graded from intense pleasure to extreme displeasure. Hearing has great importance in the formation of personality and character. Deafness has a powerful influence on the psychology of the individual who suffers it, and may cause serious mental disturbance.

The Sensitiveness of the Ear. Audiometry

Sounds are vibrations of bodies which can evoke an auditory sensation in a normal ear. Tones are produced by vibrations as regular as the movement of a pendulum. Noises are produced by irregular vibrations.

Sound vibrations are transmitted by elastic bodies (solid, fluid, or gaseous) but not in a vacuum. The particles of the transmitting body vibrate longitudinally, *i.e.*, move forward and backward in the direction in which the sound wave is propagated, creating alternately areas of rise and fall in pressure, of compression and rarefaction.

A very small amount of energy is carried by an audible sound; moreover, it is only a small fraction of the energy necessary to cause the sounding body to vibrate. Thus, in electrical instruments producing sounds the proportion is 5 per cent, and in the best musical instruments only 1 per cent.

Two physical properties of sound, *frequency* and *intensity*, are of special interest to the physiologist because they are related to the perception of the *pitch* and *loudness* of a sound. Frequency is expressed by the number of double vibrations or cycles per second. Intensity is the force or strength of the sound and depends on the amplitude of the vibrations. It is difficult to express it in terms of the absolute pressure variations or energy of the sound wave. The intensity of a sound can, however, be easily expressed relatively to that of another sound. The sound taken for reference is a tone of 1,000 cycles/sec. (c.p.s.), near the threshold of the human ear (10^{-10} μw/ sq. cm.); the intensity of the sound to be compared is deduced from the voltage applied to the loud-speaker or microphone. The physical unit of intensity is called a *bel*, after Alexander Graham Bell, the inventor of the telephone. The decibel (db.), *i.e.*, one-tenth of a bel, is the unit commonly used. Formulas for number of bels and decibels are as follows:

$$N_{bel} = N_b = \log \frac{\text{Energy of sound described}}{\text{Energy of reference sound}} = \frac{E_1}{E_2}$$

$$N_{db} = 10 \log \frac{E_1}{E_2}$$

The human ear perceives a wide range of sounds; therefore, to avoid large numbers, a logarithmic scale is used, and the whole range lies within 120 db. Within certain limits the pitch and loudness of a sound can be distinguished and perceived separately.

Sensitiveness to pitch. Pitch is the quality of the sensation that permits a sound to be classified in the scale from high to low. Sounds of the same intensity (loudness) rise in pitch as the frequency is higher. The relation between pitch and frequency is not, however, absolute, because the amplitude of the sound wave (which determines its loudness) modifies the pitch. Thus if a tuning fork vibrating at a constant frequency is gradually brought nearer to the ear, the pitch of the sound becomes lower as its loudness increases.

The human ear can perceive sounds of frequencies between 16 and 20,000 double vibrations (or cycles) per second (c.p.s.), or 11 octaves. This is known as the pitch range. In music only tones between 25 and 4,800 vibrations (7 octaves) are used, and the human voice has a pitch range of 300 to 3,000 vibrations. The rat hears high tones better than the human ear and low tones not so well. Bats, when flying, emit sounds of very high pitch (supersonics), which cannot be perceived by man but which are reflected on solid surfaces, picked up by the bat's ear, and used to guide the animal when it is flying in the dark. Destruction of one ear causes serious disturbances in night flying. If both ears are destroyed, the animal cannot fly in the dark because it no longer has the means to avoid obstacles and constantly collides with them (Galambos). By means of conditioned reflexes, it has been possible to establish the pitch range of many animal species. Thus the dog has a much higher upper limit than man, and can hear the "silent" dog whistle, which emits sound waves at a higher frequency than can be perceived by the human ear.

Sensitiveness to loudness. Loudness is the quality that permits the classification of a sound as soft or loud; soft sounds are those of small intensity, loud ones those of large intensity. The relation between intensity and loudness is not, however, absolute, because the frequency (pitch) of a sound modifies its loudness. Thus if a subject

is asked to match the loudness of a sound of given frequency with that of a reference sound of 1,000 c.p.s. of given intensity, it will be seen that the intensities of the two sounds are not the same, although they are perceived by the subject as having the same loudness.

Fig. 445. Normal human auditory range. (*After Fletcher.*)

The minimum or threshold intensity of sound capable of being perceived by the human ear varies for each frequency within the pitch range. The lowest threshold (highest sensitiveness) is for tones of 2,000 to 5,000 c.p.s.; maximum audibility corresponds to tones of approximately 2,700 c.p.s. The threshold increases sharply for tones above and below these frequencies and reaches high intensities at the extreme limits of the pitch range. If the intensity is increased above the threshold, when it is sufficiently great a sensation of vibratory pressure will be perceived, accompanied by dizziness with tones of low frequency and pain with tones of high frequency. This threshold of feeling is highest for frequencies between 250 and 1,000 c.p.s., and decreases gradually for tones of lower or higher frequencies. If the auditory and sensory thresholds are plotted on a chart (Fig. 445), the former is represented by a curve convex to the abscissa and the latter by a curve concave to the abscissa; the area between both curves is the auditory range. There is a difference of 120 db. between the lowest auditory threshold and the highest tolerable intensity; the latter is a million million times the intensity of the former (Fig. 446). The auditory range is gradually reduced with age; after thirty years of age the threshold for tones of higher pitch than 1,000 c.p.s. increases.

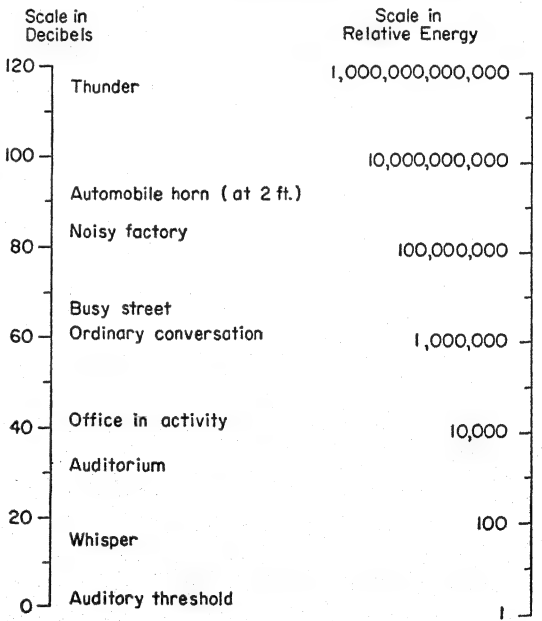
Timbre. This is the characteristic quality of a sound which allows the ear to distinguish it from others of the same pitch and loudness. Thus the same note with the same intensity is perceived differently when played on a piano, a violin, or a trumpet. Timbre is due to the fact that most sounds are not pure single tones (as those of tuning forks) but are made up of several tones. The tone of lowest frequency and highest in-


Fig. 446. Relative intensity of common noises.

tensity is known as the *fundamental tone;* others of higher frequency and lower intensity are called *overtones.* The number, frequency, and relative intensity of the overtones give the characteristic

timbre to each note. Each one of these properties of the sound can be examined by means of analyzers, and the *spectrum* of a note or sound is thus established. The spectrum of a given note varies according to its source, *e.g.*, whether it is played on a piano, a violin, or trumpet.

Difference thresholds. The ear perceives accurately small differences in intensity or pitch, but the capacity to discriminate varies for different points of the auditory range. Maximum discrimination obtains for tones within the intensity and pitch ranges of the human voice (300 to 3,000 c.p.s.); differences of 3 cycles (*e.g.*, 1,000 and 1,003 cycles) and of 1 db. are accurately perceived in this part of the auditory range. With tones of constant intensity of medium strength, 1,500 different frequencies can be perceived between the highest and lowest audible pitches. With a tone of constant frequency near the lowest threshold, 325 different intensities can be perceived. From these two figures it is not possible to deduce the total number of different tones perceived within the auditory field, because the difference threshold changes for each frequency and intensity; but by subdividing this field into small areas and determining the number of tones perceived in each of these areas, it has been estimated that approximately 340,000 different sounds can be perceived by the normal human ear.

Analytical capacity. The analysis of a compound sound consists in the discrimination of its component simple tones. This can be done by one of three methods: (*a*) by mathematical analysis (Fourier's theorem); (*b*) by means of resonators, which vibrate selectively at the frequency of each component tone; (*c*) by transforming sound by means of microphones into electrical potentials, which are then amplified and analyzed.

The human ear is capable of distinguishing the different components of a compound sound if the intensity is not too great and there are not too many overtones. This remarkable property of the ear is known as its analytical capacity.[1] Thus the ear can pick out in an orchestra not only the sound produced by each instrument, but also notes played simultaneously. The different stimuli act at the same time on the ear, which analyzes the compound result and distinguishes each component.

Audiometry. Acuteness of hearing can be tested by several methods, but in recent years the determination of the audibility curve by means of an audiometer has been generally adopted. Audiometers transform electrical energy into pure and constant tones, having a pitch and intensity that can be regulated by the operator. They are usually calibrated so that successive frequencies vary by one octave (1:2) and the intensities by 5 db. To test the normal route of sound conduction, the sound is emitted from a loud-speaker or a telephone receiver. To test bone conduction, sound vibrations are made to act on the mastoid process of the temporal bone. A tone of highest intensity (1 volt) is sounded, and then its intensity is gradually diminished down to the auditive threshold. The result is given in negative decibels below 1 volt. The operation is repeated with sounds of other frequencies.

Results are usually charted in an audiogram; frequencies are noted on the abscissae and intensities on the ordinates (Fig. 447). *Normal hearing by air conduction* is represented by a horizontal line and taken as zero. A broken line situated below the former represents *normal hearing by bone conduction.* The *auditory threshold* is represented by a curve concave to the zero line; these two lines enclose the normal *auditory field.* The different lines have been established by testing normal persons of both sexes at different ages. The results obtained by testing the subject under observation are marked on the chart; the frequencies at which there is deficient hearing and the degree of the deficiency can be seen at a glance. Loss of hearing is expressed in decibels or in per cent of normal for each tone.

This method permits the localization of auditory deficiencies in the area of the auditory field in which they occur, and it determines the pitch of the tones that must be amplified to correct them. Amplification of sounds is obtained by audiphones, instruments that are placed on the ear and consist of (*a*) a microphone that converts sound into electrical potential; (*b*) an amplifier; (*c*) a transformer that reconverts the amplified potential into a sound louder than the original one. A small battery feeds the ap-

[1] This power of analysis may be stated in the form known as Ohm's acoustical law: "Every motion of the air which corresponds to a composite mass of musical tones can be analyzed into a sum of simple pendular vibrations; to each single vibration corresponds a simple tone, which the ear can distinguish, and which has a pitch determined by the periodic time of the corresponding vibration."

paratus. Audiphones are efficient only when they are "selective," *i.e.*, when they reinforce the intensity of the tones that are poorly heard. An audiphone that increases the intensity of all audible sounds should not be used, because it increases not only the deficient tones but also

responding to the ear at which it first arrives. If the difference is greater than 1.8 msec., a double sound will be heard. The importance of the time factor can be demonstrated by listening to a tuning fork through a stethoscope with the two earpieces joined to the
FIG. 447. Horizontal line at zero, normal hearing by air conduction. Broken line, normal hearing by bone conduction. The curve represents the auditory threshold.

all noises. Tones most needed for normal hearing are those of 1,000 to 3,000 c.p.s.; the majority of street noises are of approximately 500 c.p.s. Vacuum and crystal amplifiers are the best, because they reinforce tones of 1,000 to 7,000 c.p.s.

LOCALIZATION OF SOUND

The ear is a distance receptor, *i.e.*, it localizes sound at its source, outside the body, and can recognize the direction from which it is coming. For example, it is possible to locate the violins or a wind instrument in an orchestra and to define fairly accurately the relative position of each instrument (auditory perspective).

Sound localization is achieved by the analysis of the differences in the sound entering the two ears. Three factors concerned are of importance:

1. The difference in the time of arrival of the sound to each ear is the most important of these factors. If a sound reaches both ears simultaneously it is located as if its source were placed in the median plane of the subject. If it does not reach both ears at the same time, it will be localized on the side corresponding to the ear at which it first arrives. If the difference is greater than 1.8 msec., a double sound will be heard. The importance of the time factor can be demonstrated by listening to a tuning fork through a stethoscope with the two earpieces joined to the mouthpiece by tubes of adjustable length. When both tubes are of the same length, the sound is located in the middle plane. If one tube is shortened, so that the sound wave travels a shorter distance to arrive at one ear than at the other, the sound will appear to come from the side corresponding to the short tube (Fig. 448). The time factor is particularly important in the localization of short or intermittent sounds.
2. The different intensity of the sound as it enters the two ears is the next in importance of the three factors. The sound is referred to the side corresponding to the ear that perceives it loudest. This can be demonstrated by simultanously stimulating the ears with the same tone, but with greater intensity on one side; the sound will be referred to the side that receives the more powerful stimulus. The "listening" movements of the pinna in animals and of the head in man are such that they increase the difference in intensity of stimulation of the two ears. This factor is most effective as a means of localization with continuous sounds of 5,000 c.p.s. The sound reaches the more distant ear after it has been

partially absorbed by the "shadow" of the head; this decreases the intensity, sometimes by as much as 30 db.

3. Sound is transmitted in air by vibratory movements conveyed from one particle to another, creating a successive rise and fall in
Fig. 448. Sound localization. The sound of the tuning fork will be localized in the mid-line when the arms of the stethoscope are of the same length, and on the side corresponding to the short arm when they are of unequal length.

pressure. There are therefore phases of compression and decompression. In a complete double vibration a particle is first displaced in one direction, then returns to its initial position, then is displaced in the opposite direction, and finally again returns to its initial position. These movements are similar to those of a pendulum. When the sound wave reaches both ears in the same phase, it is localized in the median plane. When it arrives at each ear in a different phase it is localized on the side at which the crest of the wave arrives first. This factor is of importance only in the localization of continuous sounds of low pitch.

Certain conditions facilitate sound localization, while others increase its difficulty. Continuous sounds are more difficult to localize than intermittent sounds, those from above than those on one or other side of the head, pure tones (especially if they are very high or very low) than noises formed by a complex of high and low tones.

These facts have been applied for the localization of airplanes and submarines. One type of apparatus has two widely separated horns, which correspond to the two ears and which are displaced so that both perceive the sound with the same intensity.

Auditory Harmonics

When the ratio of the frequency of the overtone to that of the fundamental tone can be expressed by a simple number, the overtone is called a harmonic overtone.
Fig 449. Microphonics of the ear of a cat stimulated by a tone of 1,000 c.p.s. Similar results are obtained with tones of other frequencies. The fundamental tone is of greater intensity than the harmonics. These are not registered when the intensity of the tone is below 50 db.; their intensity increases with the intensity of the fundamental tone. Harmonics of even number (second and fourth) decline with high intensities, but those of odd number (first, third, and fifth) remain stable. (*Obtained by Stevens and Newman, 1936, and reproduced from Stevens, S., and H. Davis, "Hearing: Its Psychology and Physiology," John Wiley & Sons, Inc., New York, 1938.*)

When a pure tone (*i.e.*, free from overtones) of an intensity greater than 45 db. reaches the ear, harmonic overtones arise in the ear. If the frequency of the fundamental is 100 cycles, the overtones will have frequencies of 200, 300, 400,

etc. The fundamental is always the most intense of the tones; the intensity of the harmonics diminishes progressively as the frequency rises (Fig. 449).

When two tones reach the ear simultaneously, a "combination tone" is heard. There are two classes of combination tones: (*a*) "difference tones"; (*b*) "summation tones." If, for example, the frequencies of the two tones are 700 and 500 cycles, there will be a summation tone with a frequency of 700 + 500 = 1,200 cycles and a difference tone of 700 − 500 = 200 cycles. The difference tone is always of greater intensity than the summation tone. Each one of the combination tones (if it is sufficiently intense) can give rise to harmonics that can also produce combination tones with other harmonics arising at the same time.

This abundance of tones arising in the ear is due to the tympanic membrane; if this membrane is destroyed, all these tones are suppressed. The tympanic membrane, owing to its asymmetry, reinforces and distorts the sound waves, producing the harmonics just mentioned when the intensity is greater than 45 db.

The existence of these overtones has been demonstrated mainly by two methods: (*a*) by the analysis of the electrical potentials of the cochlea stimulated by a fundamental of known pitch and intensity; (*b*) by sending a tone of similar pitch to the harmonic that is to be analyzed and observing the appearance of "pulsation." Telephones and phonographs reproduce only tones of high pitch, above a certain frequency, the missing harmonics being supplemented by the ear. A record engraved in this way reproduces sounds that do not differ to the ear from those of a record in which all the vibrations have been engraved.

Consonance. Beats

When two tones fall simultaneously on the ear and there is a simple ratio between their frequencies (1:2:3:4), an agreeable sensation known as "harmony" or "consonance" is perceived. Maximum consonance is obtained by two tones in unison, *i.e.*, of the same frequency (1:1). The octave (1:2), the fifth (2:3), the fourth (3:4), and other consonant intervals are employed in music. Consonance is increased by the harmonics of the fundamental tone; this occurs in a well-tuned orchestra.

Fig. 450. Interference of sound waves a and b. The resultant wave c is the algebraic sum of $a + b$.

When two tones of different but similar pitch (*e.g.*, 1,000 cycles and 1,003 cycles) reach the ear at the same time, the sound perceived undergoes periodic reinforcement and weakening; the phenomenon called "pulsation" or "beats" is produced. It is due to interference between the sound waves of the two tones (Fig. 450). When both reach the ear in the same phase they reinforce each other; when they are in opposite phases they mutually weaken their effects. Pulsation is perceived at its maximum when it occurs with a frequency of 2 to 3 per second; 6 or 7 per second are perceived as variations in pulse, and a greater frequency produces a disagreeable sensation in which the beats are no longer perceived.

Masking

A tone is masked by another simultaneous tone when the latter raises the threshold of the former (Fig. 451). An example is given by the difficulty in following a conversation in the midst of traffic noise. Masking is expressed by the number of decibels by which the threshold of one tone is increased when the other tone is simultaneously applied. The masking effect of a tone increases as its pitch is nearer the pitch of the masked tone; thus a tone of 950 cycles will have considerably more masking effect on another of 1,000 cycles than on one of 800 cycles.

It is easier to mask a tone by another falling on the same ear than by one that falls on the other ear; in this case the threshold of the masked tone must rise 40 to 60 db. There is a double

mechanism of masking: (*a*) a peripheral mechanism in the ear; (*b*) a central mechanism in the brain centers. The peripheral mechanism is the more important of the two.
FIG. 451. Masking. *A*, auditory threshold for a single tone; *A′*, threshold for the same tone when a second tone *B* is sounded at the same time. Masking of *A* by *B* is measured in decibels by the difference between *A* and *A′*.

Fatigue

The ear is being stimulated continuously, but it is remarkable how rapidly it recovers from fatigue. There are several ways of measuring fatigue; the one most commonly used consists in determining the intensity threshold of a tone before and after the tone has been heard continuously for a certain time.

Fatigue lasts for a few seconds or minutes according to the pitch of the tone. High tones produce more prolonged fatigue than low tones. For example, if a sound of 94-db. intensity of 2-min. duration has a frequency of 100 cycles, it produces fatigue lasting 20 sec.; if the frequency is 4,000 cycles, fatigue lasts 6 min. Fatigue is not strictly specific; it is maximum for the tone used as stimulus, but it also spreads to the neighboring tones on the scale.

Rawdon Smith has observed a decrease in auditory acuteness in one ear when the other ear is stimulated. There is therefore a central factor in fatigue, dependent on the response of the brain centers, which makes the estimation of fatigue in the receptor difficult.

THE MECHANICS OF AUDITION

The ear has three parts: (*a*) the external ear; (*b*) the middle ear; (*c*) the inner ear. Not only from the structural, but also from a functional, point of view, these three parts of the ear must be considered separately but in a correlated manner.

The External Ear

The external ear consists of the lobe or pinna and the external auditory meatus. Both have a cartilaginous support, completely covered by skin. The auditory meatus is a tube 2.5 cm. long and 0.7 cm. in diameter, with a capacity of about 1 cc. Its natural frequency is 430 c.p.s. It is not straight, and the inner part is enclosed in the temporal bone. The internal end is closed by the tympanic membrane.

The pinna takes up the sound waves and contributes to the localization of sound, especially in animals with a conical and movable pinna. In man it is not so important; nevertheless, many years ago Schneider showed that hearing was impaired when the irregularities in the pinna were filled up and smoothed out with wax. The meatus amplifies the sounds and directs them toward the tympanic membrane. Reinforcement has been demonstrated by registering the intensity of the sound as it travels to the tympanic membrane. The meatus protects the eardrum, preventing by its hairs and waxy secretion (cerumen) the passage of foreign bodies (dust, insects, etc.); it also warms the air. In some aquatic animals, *e.g.*, the whale, a sphincter can close the meatus and prevent water from entering it.

The Middle Ear

ANATOMY

The middle ear, or eardrum, or tympanum, is a small cavity 1 to 2 cm. in diameter situated in the petrous portion of the temporal bone. The walls of the cavity are lined with a mucous membrane, which is ciliated except on the external wall (the tympanic membrane). The median or internal wall is a bony septum which separates the eardrum from the inner ear. In the middle of this septum there is a bony salient or promontory made by the base of the spiral lamina of the cochlea. Toward the rear of the promontory there are two openings by which the eardrum communicates with the internal ear. The upper

opening is the oval window (fenestra ovalis); the oval base or footplate of the stapes (stirrup bone) is attached to the margins of this window. The other opening—the round window—is closed by a membrane.
FIG. 452. Diagram of the middle and inner ear. The thick line represents the ossicle chain and the basilar membrane at rest; the broken line, the same structures when in movement. When the tympanic membrane is pushed inward by a sound wave, the base of the stapes is pushed into the oval window; at the place where the pressure wave in the perilymph crosses from the scala vestibuli to the scala tympani the basilar membrane is deformed; finally the pressure wave pushes the membrane of the round window out into the cavity of the middle ear.

The tympanic membrane is elliptical in shape; its diameters measure 9 and 10 mm. and it is 0.1 mm. in thickness. It is placed obliquely downward and inward and is slightly funnel-shaped, with the concavity toward the meatus. Seen from the auditory canal in the living subject, it has a pearl-gray color, and the manubrium of the malleus (hammer bone) can be seen through it. The manubrium is attached to the membrane like an almost vertical ray ending at its apex. The tympanic membrane is made up of a thin layer of fibrous tissue (circular and radial elastic fibers), to which it owes its properties, and is covered externally with skin and internally with the mucous membrane of the middle ear.

The eardrum is connected with the pharynx by the eustachian tube. Its posterior and upper aspects are connected with the mastoid cells.

Within the tympanum there is a chain of ossicles which extends from the tympanic membrane to the oval window. The three bones together weigh less than 55 mg., and none is more than 10 mm. in its greatest length. The manubrium of the malleus is firmly attached to the tympanic membrane, and its head is articulated with the incus (anvil bone). The tip of the long process of the incus is articulated with the head of the stapes. The base or footplate of the stapes is oval-shaped, the horizontal diameter being the longest; its surface measures 3.2 sq. mm. It is firmly attached by the annular ligament to the margin of the oval window, which it fills completely. The stapes can rotate slightly on an axis that passes through the plane separating its posterior third from the two anterior thirds; it does not have pistonlike movements (Fig. 452).

There are two small muscles in the tympanum, the tensor tympani and the stapedius. The former arises in a bony duct above the eustachian tube and ends in a tendon which turns at right angles over the cochlear process, having its insertion on the manubrium of the malleus, near its base. The latter arises in the inner wall of the eardrum and ends on the neck of the stapes. The tensor tympani is innervated by a branch of the trigeminal (fifth) nerve, and the stapedius by a branch of the facial (seventh) nerve. The fibers of both nerves arise in the same column of nerve cells situated in the pons (seventh nerve) and medulla (fifth nerve).

PHYSIOLOGY

The main function of the middle ear is to transmit to the inner ear sound vibrations which reach it through the auditory canal or the bones of the head. It can reinforce the intensity of these vibrations or protect itself and the inner ear from the harmful effects of excessively intense sounds.

The tympanic membrane. The pressure changes caused by the sound waves make the tympanic membrane vibrate, reproducing the motion of these waves and transmitting it to the manubrium of the malleus. If the membrane is gilded or a small mirror is attached to it and a ray of light is reflected on it, the motion of the membrane can be registered photographically. It will then be seen to reproduce the oscillations of a tuning fork that is made to vibrate in the proximity of the ear. It vibrates as if it were suspended by its upper margin, but owing to its shape and attachments to the temporal bone and the manubrium of the malleolus, all its parts do not vibrate uniformly. Charts have been made of the parts vibrating most at different sound frequencies. It is noteworthy that small perforations of the tympanic membrane do not alter its efficiency. The tympanic membrane is extraor-

dinarily sensitive; sound waves are perceived that cause displacements equivalent to the diameter of a hydrogen molecule. It is also aperiodic, *i.e.*, it reproduces faithfully the vibrations of sound waves of all pitches. It is well damped, and ceases to vibrate as soon as the sound waves have ended. It distorts sound waves when their intensity is more than 45 db.; this is due to its shape and the attachment of the manubrium, which prevent it from vibrating regularly in both directions. Thus harmonic overtones, previously discussed, are formed.

Functions of the ossicles. The chain of ossicles is of primary importance in the transmission of the tympanic vibrations to the oval window. If the chain is broken or is fixed by inflammatory processes, the auditory threshold rises by approximately 60 db. The movements of the ossicles are minute and not easy to study. They have been observed by means of the stroboscope or lapse-rate cinematography after removing one of the walls of the eardrum and attaching little mirrors on the ossicles or sprinkling them with powder so that they reflect light. This has been done in the human ear.[1] The chain moves as a unit; when the manubrium of the malleus is pushed inward, there is a corresponding movement of the base-plate of the stapes and vice versa. Up to 2,400 c.p.s., vibrations are transmitted simply; higher frequencies give rise to harmonic overtones.

The ossicles not only transmit the vibrations of the tympanic membrane to the inner ear, they also reinforce them, acting as a bent lever, the axis of which passes through the neck of the malleus and the body and short process of the incus. One of the arms of the lever is the manubrium of the malleus embedded in the tympanic membrane. When this moves inward, the head of the malleus and the body of the incus move outward, and the long process of the incus and the stapes move inward, *i.e.*, in the same direction as the manubrium. The area of the tympanic membrane is approximately 20 times that of the base of the stapes, and the ratio of the length of the manubrium to that of the long process of the incus is 3:2. Therefore, after discounting loss due to friction, energy applied to the tympanic membrane is increased 10 times when it reaches the oval window (Fig. 452). The base of the stapes is pushed in and out of the oval window, rotating on an axis that passes through its posterior margin, where the annular ligament is short and thick, whereas it is long and thin on the opposite side. When loud noises fall on the ear, the stapes rotates on its transverse axis and thus protects the inner ear. In summary, the ossicles constitute a lever that follows the movements of the tympanic membrane, reinforces them, and transmits them to the inner ear through the oval window.

Functions of the muscles. The two muscles in the tympanum have opposite effects on the base of the stapes. The stapedius tends to pull the stapes outward from the oval window. The tensor tympani, on the contrary, pulls the manubrium of the malleus inward; therefore it increases the tension of the tympanic membrane and pushes the stapes into the oval window. When both muscles contract simultaneously, the ossicle chain is shortened by bringing the ossicles into closer contact, and tension of the tympanic membrane increases. Contraction of these muscles is provoked by very rapid reflexes (as fast as those that provoke blinking). The usual stimuli are stimulation of the skin of, or near, the ear, and sounds of more than 45 db. Stimulation of one ear by a sound causes contraction in the muscles on the contralateral ear (Metz). Anesthesia suppresses these reflexes.

Contraction of the middle-ear muscles, owing to the greater tension of the tympanic membrane, considerably depresses the transmission of low tones, but does not modify the transmission of high tones, and may even favor it. This depression of low tones is a protective reflex, because low tones of great intensity are harmful to the inner ear.

The function of the eustachian tube. The cavity of the middle ear communicates with the exterior by means of the eustachian tube and the pharynx. Thus the tympanic membrane supports equal pressure on both surfaces and is in optimum condition for vibrating. The eustachian tube is opened by yawning, swallowing, and Valsalva's test (forced expiration with mouth and nose closed). When the pressures on both sides of the tympanic membrane are not equal, the membrane is deformed and hearing is decreased. This happens when the tube is closed by inflammatory processes (common cold), or when there is a rapid ascent or descent in an airplane, as long as the tube does not open and the pressure is not equalized. An excessive

[1] Guelke, R., and J. A. Keen, *J. Physiol.*, **116**, 175, 1952.

pressure difference may rupture the membrane, causing intense pain, hemorrhage, and in some cases severe general disturbances. If the tube is obstructed for some time (*e.g.*, owing to a cold) there is effusion into the middle ear cavity, which can be easily evacuated by puncturing the tympanic membrane.

The transmission of sound in the middle ear. Deafness. Sound vibrations are transmitted to the ear by the air in the auditory meatus (air conduction) or by the bones of the head (bone conduction). Air conduction is the usual and most important means of transmission. The impact of sound waves on the tympanic membrane makes it vibrate. This vibration is transmitted to the ossicles, and the base of the stapes moves in and out of the oval window, causing pressure changes in the perilymph of the inner ear. These changes in pressure travel up the scala vestibuli and down the scala tympani and end on the membrane of the round window, which is the only part of the walls of the inner ear that can give way to pressure (Fig. 452). The level at which the pressure wave passes from the scala vestibuli to the scala tympani varies with the wavelength of the sound wave.

when a vibrating tuning fork is placed in contact with the head. Osseous transmission was first studied by Ingrassia in the sixteenth century. Sound waves in this case usually go directly to the inner ear, but there is also transmission through the tympanic membrane owing to vibration set up in the air of the external auditory canal.

The importance of the round window is due to the elasticity of its membrane which permits equilibration of pressure within the inner ear, which is otherwise surrounded by bony inextensible walls. Davis remarks that there are two factors to be considered in the functioning of this membrane: (*a*) if its rigidity increases there is a decrease in hearing, because this rigidity depresses the vibration of the perilymph, which is fluid and therefore incompressible; (*b*) if it is protected from the direct transmission of sound waves from the middle-ear cavity, which normally damps the effect on the basilar membrane of vibrations transmitted through the oval window, auditory sensitiveness is increased. Confusion of these opposite effects on hearing has caused much disagreement as to the functions of the round window.

Up:	Tympanic membrane →	Ossicle chain →	Oval window →	Scala vestibuli
				↓
				Ductus cochlearis
				↓
Down:			Round window ←	Scala tympanica

Path of Sound Wave

The membrane of the round window is therefore submitted to pressure on both its sides whenever a sound wave falls on the ear—the pressure transmitted through the ossicles and the perilymph of the inner ear on one side, and the pressure transmitted directly by the air in the cavity of the middle ear on the other. These pressures act on the membrane in opposite directions, and the former is by far the greatest. When the tympanic membrane and the ossicle chain are destroyed, the sound waves act directly on the round window and the pressure changes in the perilymph travel up the scala tympani and down the scala vestibuli, *i.e.*, in a direction opposite to the normal.

There is a third possibility; sound waves are transmitted by the bones of the cranium, *e.g.*,

Pathological (inflammatory reactions, effusion, pus, etc.) or experimental disturbances of the external or middle ear cause different degrees of deafness owing to detects of *transmission*. The functional loss of the ossicles diminishes hearing by 45 to 60 db. In this type of deafness perception of low tones is usually more impaired than that of high tones, and considerable improvement in hearing can be obtained by means of hearing aids. Lesions in the inner ear cause deafness due to deficiencies in *perception*. This type occurs in old people, who have difficulty in perceiving high tones, and in subjects exposed to loud noises during prolonged periods (boilershop workers, aviators, etc.). Hearing aids are uselsss in these cases. A third type of deafness is due to lesions in the auditory nerve paths and

centers. Several tests (Weber, Rinne, Schwabach) have been devised to differentiate these types. These tests are based on the changes undergone by air and bone transmission of sound vibration. For example, in transmission deafness, only the air route functions deficiently; therefore a tuning fork is not heard when placed in the air near the ear, but its vibrations are transmitted normally if it is placed on the mastoid process of the temporal bone. In perception deafness the tuning fork is not heard, whether it is placed in the air or is in direct contact with the head.

Protective action. The middle ear has a protective action, defending the inner ear from the effects of excessively intense sounds. This is obtained by two mechanisms:

1. The air within the cavity of the middle ear acts as an elastic cushion and diminishes the vibrations of the tympanic membrane and the ossicle chain. This effect disappears if the tympanic membrane is perforated, and it is offset by the communication with the exterior through the eustachian tube, which tends to equalize the pressure on both sides of the tympanic membrane.
2. Vibration of the ossicle chain is regulated by reflex contraction of the auditory muscles.

Fig. 453. Section through the cochlea, showing the organ of Corti.

The Inner Ear

The inner ear and the auditory pathway are the essential parts of the auditory apparatus. Destruction of the cochlea causes irreparable deafness on the side on which it occurs. If the cochlea alone is destroyed, there are no disturbances in the maintenance of body equilibrium; on the other hand, if the labyrinth is destroyed without damage to the cochlea, hearing is not disturbed.

ANATOMY

The labyrinth is made up of a series of cavities in the petrous portion of the temporal bone. These cavities (the osseous labyrinth) contain a series of membranes (the membranous labyrinth) and are filled with a fluid, the perilymph. There are three cavities: (*a*) the vestibule, the center cavity, which measures 5 mm. in diameter and is connected to the middle ear by the oval window; (*b*) the three semicircular canals, placed behind and above the vestibule, which have nothing to do with hearing; (*c*) the cochlea, in front of the vestibule, which is the auditory receptor.

The cochlea is a tube coiled in a spiral fashion around a bony axis, conical in shape, known as the modiolus or columella. The whole resembles the shell of a snail, whence its name. It is

approximately 5 mm. high and 9 mm. at its base. The tube has two and a half coils in man, three in the dog and cat, and four and a half in the guinea pig. Inside the tube there is a bony shelf inserted on the modiolus which does not reach the outer wall of the tube; this is the spiral lamina (Fig. 453). The free border of this lamina is joined to the wall of the tube by a stout connective-tissue membrane (the basilar membrane). The tube is thus divided into two passageways. The upper half is again divided in two by Reissner's vestibular membrane. This membrane stretches from the spiral lamina, near the insertion of the basilar membrane, to the outer wall of the tube, some distance above the insertion of the latter. The cochlear tube is thus divided into three ducts: (*a*) the upper, known as the scala vestibuli, which extends from the vestibule to the apex of the cochlea, where it communicates by means of a small orifice, the helicotrema, with the next; (*b*) the lower duct, known as the scala tympani, which ends in the round window; (*c*) between these ducts, the cochlear duct, or scala media, closed at both ends, but communicating by a minute canal (Hensen's duct) with the sacculus. The cochlear duct is separated from the scala vestibuli by the membrane of Reissner, and from the scala tympani by the basilar membrane which arises between the oval and the round window; the diameter of its first spiral turn is 6 mm., and that of the second is 4 mm. (Fig. 454). These ducts are filled with fluid, which is called endolymph in the cochlear duct and perilymph in the scalae tympani and vestibuli.

FIG. 454. The internal ear, showing the osseous and membranous labyrinth.

The mechanism for selectively capturing the sound waves and converting them into nerve impulses is found in the scala media or cochlear duct. The length of the basilar membrane is 30 mm.; its width increases gradually from 80 μ at the base to 500 μ at the apex of the cochlea. This difference in width is a sign of the localiza-

FIG. 455. Organ of Corti

tion in different parts of the membrane of the receptive mechanisms for tones of different frequency. There are fibers of many different lengths in the basilar membrane. Helmholtz was the first to consider them the receptors of sound waves.

On the inner part of the vestibular aspect of the basilar membrane there is a complex structure known as the spiral organ of Corti (Fig. 455). It is formed by highly developed epithelial cells and fibers of the acoustic nerve. There are two pillars formed by long rodlike cells (the rods of Corti), an internal and an external pillar. Separated at their base on the basilar membrane, they come together at their apex, covering a triangular tunnel (the inner tunnel of Corti). The lumen of this duct has a diameter of 50 μ at the base of the cochlea; it widens gradually up to 100 μ at the apex. On the internal aspect of the internal pillar, and on the external aspect of the external pillar, there are the inner and outer hair cells, each one of which has up to 100 hairs of different lengths, forming a tuft which touches the tectorial membrane. These cells are not placed directly on the basilar membrane, but are supported by Deiters' phalangeal cells. There are approximately 3,500 internal hair cells distributed in a single row; and some 20,000 external hair cells in three rows. The internal hair cells are 8 μ in length, and each one receives only one nerve fiber; the external hair cells are 12 μ in length and each one receives several nerve fibers.

The inner part of the organ of Corti is covered by the tectorial membrane. This structure is attached to the spiral lamina at one end and is free at the other. It is formed by a homogeneous substance in which there are fine colorless fibers. Its inferior aspect is in contact with the hairs of the hair cells. The significance of the tectorial membrane is still unknown.

PHYSIOLOGY

Sound vibrations, transmitted through the middle ear, are converted in the cochlea into nerve impulses which travel along the acoustic nerve. Pitch, loudness, and timbre have their origin in the cochlea. The intimate mechanism of cochlear function is unknown, but the discovery of cochlear microphonics and the application of new techniques have given valuable information.

The microphonic response of the cochlea. In 1930, Wever and Bray[1] reported that a telephone or loud-speaker connected by means of electrodes to the acoustic nerve of a decerebrate cat reproduced sounds and even words whispered into the animal's ear. This fact was later confirmed in several other species. At first this effect was attributed to action currents in the acoustic nerve, but later Adrian suggested, and Saul and Davis demonstrated, that it had its origin in the cochlea.

Definition. The microphonic response of the cochlea (or simply cochlear microphonics), so called because of its resemblance to the electrical phenomena provoked by sound waves in microphones, consists in electrical potentials caused by the stimulation of the cochlea by sound. These potentials reproduce the frequency and form of the sound. Their exact nature and significance are still unknown. They precede the action potentials in the acoustic nerve. The sequence, therefore, is as follows: sound waves → microphonics → acoustic-nerve potentials.

Properties. Cochlear microphonics can be amplified and registered by a cathode-ray oscillograph, or they can be reconverted into sound. They can be detected by electrodes placed on different parts of the head, because they are transmitted to the tissues surrounding the cochlea, *e.g.*, the meninges, the acoustic nerves (especially near the cochlea), the cochlea itself, and the round window. The polarity of the current varies according to the placement of the electrodes and the phase of the sound wave. Variations in polarity in the guinea pig are given in Table 110.

Source: Stevens, S., and H. Davis, "Hearing: Its Psychology and Physiology," Wiley, New York, 1938.

A remarkable characteristic of cochlear microphonics is the faithful reproduction of the

[1] Wever, E., and C. Bray, *Proc. Nat. Acad. Sc.*, **16**, 344, 1930.

original sound, except that loud sounds have added onto them the auditory harmonics arising in the middle ear. Thus an observer placed in a distant room can hear (by means of a telephone connected with an apparatus that captures and amplifies the cochlear microphonics) what is said into the ear of an animal, and can even recognize the voice of the person speaking.

Microphonics show the same sensitiveness to frequency and intensity as auditory phenomena. Sometimes differences are found because of deficiencies in the recording apparatus or the placing of the electrodes; these differences disappear when an adequate instrument is used and the electrodes are suitably placed. The voltage of microphonic potentials increases with the intensity of the sounds, but very loud ones provoke a decrease of as much as 30 per cent of the maximum voltage. This decrease persists for several days; transitory or permanent lesions of the organ of Corti have been observed at the same time.

There is a very short latent period (0.1 msec.) between the arrival of the sound and the microphonic response. Between the microphonic response and the beginning of the acoustic-nerve action potential there is a much longer interval (0.7 msec.). At the beginning and end there are three or four ample vibrations, different from the others, with a periodicity of 700 to 2,000, which is the same as the periodicity of the ear. These vibrations are due to inertia and incomplete damping of the ear.

Severe oxygen deprivation causes cochlear potentials to decrease, but there is no decline when the gas mixtures contain more than 4 per cent oxygen, equivalent to altitudes up to 40,000 ft.[1] The reduction in the amplitude of the potential seems to be a direct effect of hypoxia on the organ of Corti. Repeated periods of hypoxia are followed by complete restitution of the cochlear potentials, but the action potential of the acoustic nerve gradually disappears. This method has been used to eliminate the action potential without affecting the cochlear potential.

The microphonic effect is not suppressed by anesthesia, and it persists for several hours after death, when it diminishes gradually. It has, however, been observed even 5 hr. after the animal had died.

Site of origin. Two facts seem to have been well established: (*a*) cochlear microphonics arise in the organ of Corti; (*b*) microphonics due to high tones arise near the base of the cochlea, and those due to low tones arise near the apex. It is still a subject of discussion whether the hair cells are or are not the precise locus of origin of cochlear microphonics.[1]

Microphonics are not observed in animals with congenital deafness and lesions in the organ of Corti. This has been observed in "dancing" guinea pigs with disturbances in the labyrinth and in albino cats and dogs; it is a good proof that microphonics arise in the organ of Corti.

High and low tones stimulate the production of microphonics in the basal parts of the cochlea and in the parts near the apex, respectively. This has been demonstrated in several ways. For example, localized lesions can be produced in the organ of Corti by a sustained loud pure tone, or by injecting cocaine or concentrated NaCl into the round window, or by extirpating the apical coils of the cochlea. In each case there is deafness, and microphonics are decreased or suppressed, for a limited number of tones, the frequency of which varies with the locus of the lesion.

These experiments destroy all the elements of the organ of Corti and do not allow any conclusions to be drawn as to what part of this organ is responsible for the production of microphonics. In other experiments, fibers of the acoustic nerve have been cut near the internal meatus. This operation causes retrograde degeneration of the spiral ganglion and of the fibers that innervate the hair cells. Microphonics persist as long as the hair cells themselves do not degenerate. Davis suggests that the hair cells are comparable to quartz crystals in the production of piezoelectric effects; *i.e.*, they respond to mechanical deformation by the production of an electric current. According to this hypothesis, movements of the basilar membrane would exert pressure or tension on the hair cells and thus give rise to electrical potentials.

Significance of microphonics. Microphonic potentials are a valuable sign that sound has stimulated the organ of Corti and of the normal or abnormal response of this organ. They are therefore increasingly used in the experimental study of hearing, since they reproduce the sound

[1] WEVER, E. G., *et al.*, *Am. J. Physiol.*, **159**, 199, 1949.

[1] The lateral lines of fishes have hair cells which have a microphonic response to water currents (JELOF, R., A. SPOOR, and H. DE VRIES, *J. Physiol.*, **116**, 137, 1952).

waves with the same intensity threshold and tonal field, and moreover serve to localize the part of the cochlea at which a lesion is situated. Microphonics, nevertheless, do not give any information on the nature of auditory sensation, which depends on the central nervous system; yet section of the acoustic nerve, which produces complete deafness on the corresponding side, leaves the microphonics unaltered until the organ of Corti, especially the hair cells, degenerates.

The true significance of microphonics is still unknown. Some workers believe that they are the normal stimulus of the acoustic nerve endings, but there is no definite proof that this is so.

The human cochleogram. Microelectrodes have been placed in the round window of human subjects and microphonics recorded when the ear was stimulated by different sounds. They are similar to microphonics recorded in animals.[1]

Summating potential. Another electric potential, interpolated between the microphonics and the acoustic-nerve action potential, has been described. It appears after two or more sound vibrations have reached the cochlea; hence its name. This potential apparently arises in the hair cells, at the pole where the acoustic-nerve fibers end It seems to represent the local excitatory process that initiates the auditory-nerve impulse.[2]

Tonal localization in the basilar membrane. The problem of what part of the auditory system serves to distinguish the pitch of a tone has been the subject of much discussion for many years. Some observers have maintained that it is a function of the cochlea, others that it is a function of the central nervous system. Rutherford believed that the whole basilar membrane vibrated to sound, like the membrane of a telephone, and transmitted impulses to the nerve centers, where they were analyzed. This "telephone theory" can no longer be accepted because, among other reasons, there is no close relationship between the frequency of a sound wave and the action potentials in the acoustic nerve.

Helmholtz's "cochlear" or "resonance" theory, proposed over 85 years ago, is more in agreement with modern facts, although it must be modified to a certain extent. According to Helmholtz the cochlea, and not the nerve centers, analyzes the pitch of sound. The basilar membrane has fibers of different length which vibrate selectively to tones of different frequency, in the same way that the strings of a piano vibrate in response to a sound of the same periodicity. The nerve centers would recognize pitch by localizing the place of the basilar membrane that is stimulated.

It is now generally admitted that tones of each frequency stimulate selectively a definite place in the basilar membrane, which by vibrating stimulates the corresponding nerve endings of the acoustic nerve, and nerve impulses are transmitted to the auditory nerve centers. There is as yet no agreement as to what element (fibers or other structures) in the membrane is responsible, and still less is known about the mechanism by which the sound wave acts.

Proofs of localization. There are many proofs of localization of pitch in the different parts of the basilar membrane. Anatomical, experimental, and pathological observations give concurrent results. Thus hardness of hearing in old age is especially notable for high tones; this coincides with degenerative lesions in the basal coil of the organ of Corti, and has been reproduced experimentally by injecting cocaine or sodium chloride into the round window, thus destroying the basal coil and producing deafness to high tones. Guinea pigs that are stimulated with a pure tone of high intensity for a long time become deaf to that tone, as is demonstrated by the conditioned reflex technique and the absence of a microphonic response to the tone. This effect coincides with degenerative lesions in a definite place of the basilar membrane, which varies according to the pitch of the tone.

These methods do not allow precise localization, because the lesions extend to a relatively large part of the organ of Corti, and there is deafness to a large number of tones. The advent of microphonics has been an important aid to these studies. Culler[1] trephined the osseous cochlea in guinea pigs in 25 different places between the base and apex of the cochlea without causing damage to the membranous structure. He was therefore able to record the threshold of microphonics for tones of different pitch at each one of the 25 places. He observed that there was an optimum place for each pitch,

[1] Lempert, J., *et al.*, *Arch. Otolaryng.*, **51**, 307, 1950.
[2] Davis, H., *et al.*, *Proc. Nat. Acad. Sc.*, **36**, 580, 1950.

[1] Culler, E. A., *Ann. Otol., Rhin. & Laryng.*, **44**, 809, 1935.

and that high tones were placed near the base of the cochlea and low ones near the apex. Walzl and Bordley[1] were able to produce localized lesions in the basilar membrane of the cat, without damage to the delicate membrane of Reissner. They observed an increase in the threshold for tones of definite pitch, which varied according to the place where the lesion was made.

Results. The facts so far described are in agreement with the theory that each place on the basilar membrane is particularly susceptible to tones of a certain pitch. Maps have been constructed which show that tones of low pitch act near the apex of the cochlea, those of high pitch near the base, and intermediate ones (*e.g.*, those of 2,700 cycles) in the middle (Fig. 456). The areas for the different low tones are placed near each other; those for the high tones are more widely spaced. It is necessary to use tones of threshold intensity for the precise localization of the area for a certain pitch; stimulation by louder tones spreads to neighboring areas.

Response of basilar membrane to intensity of sound. The basilar membrane is an elastic structure which vibrates on the reception of sound waves. These vibrations have been observed directly in animals and in the human cadaver by stroboscopic observations with the microscope. The site of vibration varies with the frequency of the sound wave, and the area vibrating becomes larger as the intensity of the sounds increases. The voltage of the microphonics is related to the size of the area of basilar membrane which is being stimulated; it increases proportionally to the logarithm of the intensity of the tone used as stimulus (Weber and Fechner's law). With intensities above 50 db., harmonic overtones appear. These overtones must arise in the cochlea, not in the middle ear, because destruction of the ossicles or the whole tympanum does not suppress them.

FIG. 456. Map of human and guinea-pig cochleas, showing the localization of pitch reception on the basilar membrane. Figures represent c.p.s. of sounds received. (*Stevens, S., and H. Davis, "Hearing: Its Psychology and Physiology," Wiley, New York, 1938.*)

Electrical stimulation of the cochlea. Electrophonic effect. If one electrode is placed on an ear and another on an arm, the passage of alternating currents of 200 to 10,000 c.p.s. stimulates the ear. Sounds are heard, with a pitch directly related to the frequency of the current. Stevens showed that if a radio set is directly connected with the head, it is possible to hear the music and words, although with some distortion. If the current is too intense, *i.e.*, the equivalent of more than 20 db., the subject may present symptoms of shock.

This electrophonic effect has been interpreted as an inverted microphonic effect. In this case electrical potentials are perceived as sound, while in the case of microphonics sound gives rise to electrical potentials. The tympanic membrane modifies the electrophonic effect; the normal ear perceives the tones as one octave higher, while subjects who have lost this membrane perceive the tone with its true pitch.

The electrophonic effect has its origin in the cochlea. It does not exist in subjects in whom the cochlea is damaged and in whom the acoustic nerve is stimulated directly; they hear only noises. It is possible that these facts may be usefully applied in the treatment of middle-ear deafness.

The dynamics of the inner ear. The facts so far discussed can be used to form an idea of how the inner ear functions when a sound falls on the ear. The vibrations of the plate of the stapes provoke pressure changes in the perilymph of the inner ear. The osseous labyrinth is inextensible; therefore the pressure waves travel up the scala vestibuli and down the scala

[1] WALZL, E. M., and J. BORDLEY, *Am. J. Physiol.*, 135, 351, 1942.

tympani, and end on the membrane covering the round window. The point at which the pressure wave passes from one scala to the other varies with the pitch of the tone. If the pitch is low, the wave travels up to near the apex of the cochlea; if it is high, it passes to the scala tympani near the base. On crossing from one scala to the other, the waves cross the scala media and cause the basilar membrane and the organ of Corti to vibrate at that place and to stimulate the corresponding nerve endings of the acoustic nerve. The organ of Corti gives rise to the microphonics, perhaps owing to deformation of the hair cells (Figs. 452 and 453). A loud tone is distinguished from a soft tone because it causes vibration in a wider area of the basilar membrane.

AUDITORY PATHS AND NERVE CENTERS

Anatomy

From the cochlea to the temporal cortex, auditory impulses pass through four neurons (Fig. 457). The neurons of the first order are situated in the modiolus and form the spiral ganglion of the cochlea. They are bipolar cells, 25,000 to 29,000 in number. Each has a short peripheral process ending on the internal or external hair cells, and a long central process which forms part of the cochlear division of the eighth nerve. They pass out of the temporal bone through the internal meatus and end in the cochlear nuclei. These are two groups of cells (second-order neurons) situated in the restiform body, where the latter turns toward the cerebellum. The dorsal cochlear nucleus forms the tuberculum acusticum on the dorsal aspect of the restiform body; the ventral cochlear nucleus, or ganglion ventrale, is situated in the ventrolateral aspect of the restiform body. The ventral cochlear nucleus emits fibers which cross the mid-line, forming the trapezoid body, and then turn rostrally to form the bundle known as the lateral lemniscus, which ends in the inferior colliculus. The dorsal cochlear nucleus sends out fibers toward the mid-line, running under the floor of the fourth ventricle (striae acusticae). After these fibers decussate, they sink into the reticular formation and join the lateral lemniscus, also ending in the inferior colliculus. Part of the secondary auditory path does not decussate but ascends in the homolateral lemniscus.

Third-order neurons of the auditory path are found in the superior olivary nuclei, the nuclei of the trapezoid body, the nucleus of the lateral lemniscus, and the inferior colliculus. Their efferent fibers form the brachium of the inferior colliculus and end in the medial geniculate body. The fourth-order neurons in this body send fibers to the temporal cortex through the internal capsule. The medial geniculate body receives fibers from other sensory pathways and from the cortex. Probably it acts as a coordinating center. It is also systematized, and each point of the organ of Corti has its corresponding point in the geniculate body, but this systematization is not so precise as that of the lateral geniculate body in the visual path.

Fig. 457. Auditory path in the central nervous system. (*After Rasmussen.*)

The auditory cortex in the temporal lobe is divided into two parts:

1. Poljak's "nuclear area" (areas 41 and 42 of Brodmann) in the superior temporal gyrus, deep in the lower lip of the sylvian fissure. It measures only 8 × 4 mm., but it receives nearly all the auditory fibers. It is formed by large pyramidal cells, and

numerous fibers of which a deep layer runs parallel to the cortical surface.
2. The remainder of the temporal cortex (area 22 of Brodmann) is formed by small pyramidal cells and is not limited by a deep fibrous layer. It receives fibers from the auditory pathway and nonauditory fibers.

Physiology

Electrical potentials in the auditory nerve. When the ear is stimulated by sound, action potentials arise in the acoustic nerve, corresponding to nerve impulses sent out from the cochlea. They should be registered at some distance from the inner ear; otherwise they are covered by the cochlear microphonics. The mechanism by which they arise is not yet fully understood, but several facts of interest in this respect are fairly well known.

Variations in pressure in the perilymph and endolymph can no longer be considered as stimulating the nerve endings directly; the mechanical theory of stimulation must be discarded. Pressure changes in the endolymph caused by sound vibrations distort some element in the organ of Corti. All the evidence points to the hair cells as the receptors and indicates that microphonics represent the electrical response of these cells. A local excitatory state then arises, probably at the foot of the hair cells, where they are in contact with the auditory-nerve endings. The summating potential is the electrical manifestation of this phenomenon. After a relatively long latent period (0.7 msec.), the propagated nerve impulse is fired off.

A chemical mediator may play a part in this process. There is no evidence that acetylcholine is released when the inner ear is stimulated by sound waves. Cholinesterase, however, has been found in the endolymph and perilymph in sufficient amounts to play a physiologic role. Moreover, cholinesterase inhibitors, *e.g.*, physostigmine, prolong the latent period of the acoustic potentials.[1] More facts are needed before it can be concluded that a chemical mediator, probably acetylcholine, is a factor in the excitation of the receptor or the transmission of the excitatory state from the receptor to the nerve endings.

The action potentials of the cochlear nerve are similar to those of other sensory nerves, but they are very sensitive to anoxia and cease soon after the animal dies. They begin 0.8 msec. after the arrival of the sound wave. The first oscillation is always negative, while the first microphonic potential may be negative or positive. It lasts 1 msec., as in other myelinized fibers of similar diameter, and the refractory period is also of 1 msec. The speed of conduction is 30 m. per sec., as in the optic nerve and in tactile fibers. The threshold varies with the distance of the active fiber from the electrode.
Fig. 458. Amplitude of the action potential of the auditory nerve of the cat related to the pitch of the stimulating tone. The first drop occurs around 900 cycles, when half the fibers are stimulated alternately; the second drop occurs around 1,800 cycles, when one-third of the fibers are stimulated in rotation. (*Stevens, S., and H. Davis, "Hearing: Its Psychology and Physiology," Wiley, New York, 1938.*)

Galambos and Davis[1] have registered the action potentials of single fibers. Each fiber is stimulated by tones of a limited number of frequencies (pitch) when the sound is near the threshold intensity. As the intensity increases, the fiber responds to a larger number of frequencies.

Relation of action potential to sound. Action potentials in the auditory (cochlear) nerve are clearly related to the pitch of the stimulating tone. Stimulating with tones of increasing frequency, it has been observed that, up to 3,500 to 4,000 cycles, for each vibration there is a corresponding nerve impulse. Above this frequency the individual impulses can no longer be recognized. The maximum amplitude for each tone drops to one-half for tones of 900 to 1,800 cycles, to one-third for tones up to 2,700, to one-quarter for higher tones, after which there is no further decrease (Fig. 458). The

[1] Gisselsson, L., *Acta oto-laryng.*, Suppl. 82, 1950.

[1] Galambos, R., and H. Davis, *J. Neurophysiol.*, **6**, 39, 1943.

explanation of this fact is given by alternation and rotation in the activity of the different fibers (Fig. 459).

Up to 900 cycles, all the fibers of the nerve that transmit at this frequency conduct impulses at the same frequency as the sound waves, and the amplitude of the action potential is the sum of the axon potentials of all these fibers. The refractory period of the fibers does not permit them to respond to frequencies greater than 900 cycles. Tones of higher frequencies stimulate alternately one-half of the fibers, with the following results: (*a*) each fiber responds to half the stimuli, *e.g.*, if the frequency of the tone is 900 cycles, some fibers will respond to half these stimuli (450) and others to the other half; (*b*) at a given moment only half the fibers are active; (*c*) the action potential therefore is one-half of the maximum potential for lower frequencies. When the frequency increases to 1,800 cycles, owing to the refractory period, only one-third of the fibers responds, and excitation rotates through three sets of fibers; therefore the voltage of the action potential is reduced to one-third. With frequencies of 2,700, excitation rotates through four sets of fibers, and the voltage of the action potential is reduced to one-quarter. In summary, as the frequency (pitch) of the tones rises, owing to the refractory period of the fibers of the cochlear nerve, each sound wave provokes simultaneous nerve impulses in a smaller number of fibers, and the number of sets of fibers activated in rotation increases.

Fig. 459. Diagram of action potentials in the fibers of the auditory nerve in response to stimulation with tones of different pitch. Alternation and rotation.

The fibers of the auditory nerve are systematized; tones are transmitted by different fibers according to their pitch. Therefore by placing the electrodes on different parts of the nerve, the threshold for tones of different pitches can be varied.

If the ear is stimulated with a tone of constant pitch, as the intensity (loudness) increases a larger number of fibers are brought into activity and the action potential increases. This effect is due to the larger area of the basilar membrane which vibrates as the intensity of the sound increases.

"Masking," *i.e.*, decrease in loudness of a tone when it is perceived simultaneously with another tone, can be demonstrated by recording the action potentials of the auditory nerve. The action potential provoked by a tone diminishes when the ear is stimulated by a second tone. This effect is especially marked if the intensity of the first tone is close to the threshold. The second tone sets up impulses in the same fibers and leaves a refractory period, so the "line is busy" during certain intervals and cannot be used by the first tone. This phenomenon is not

observed in the microphonic potentials, which summate.

Hartridge and his collaborators have observed that if, while a tone is being perceived, the phase of the tone is changed by half a cycle, it appears to be interrupted for a brief interval, and is then
FIG. 460. Diagram of simultaneous records of sound waves, cochlear microphonics, and auditory-nerve action potentials. At the arrow the phase of tone is changed by half a cycle.

again heard. The same phenomenon is observed in a resonator, a fact that has been brought forward in support of Helmholtz's theory of hearing. By registering simultaneously the vibrations of the tone, the cochlear microphonics, and the action potential of the auditory nerve, it is seen that the microphonics reproduce faithfully the change of phase, but the action potentials are interrupted and then again respond rhythmically (Fig. 460). According to Davis, these observations show that the ear is an aperiodic system, and the delay is caused by the nerve; therefore the cochlea does not behave as a resonator.

Differences between action potentials and cochlear microphonics. Action potentials and cochlear microphonics are two separate phenomena, both due to the arrival of sound waves at the cochlea. Confusion between them has arisen owing to the proximity of the structures where they arise, the remarkable similarity of their thresholds, and the fact that microphonics are sufficiently intense to "cover" the action potentials if due precautions are not taken. At one time they were thought to be only one phenomenon, but later their separate individualities and significances were established. The differences between them are summarized in Table 111.

Auditory paths and centers. Action potentials in the auditory tract (Fig. 457) have been recorded by means of special electrodes. This method has shown that the impulses travel to the cortex on the same, and on the opposite, side of the ear in which they arise. The delay increases considerably at each synapse; it has therefore been used to establish the number and situation of the neurons in the path. Between the cochlea and the auditory cortex there are four neurons. In neurons of the first order, *i.e.*, those of the auditory nerve, there is perfect synchronization of the impulses and sound waves up to a frequency of 3,500 c.p.s.; in the second-order neurons, synchronization is achieved only up to 2,500 cycles; in the third-order and fourth-order neurons it exists only for tones of low frequencies (less than 500 cycles). The higher neurons are also more susceptible to anesthesia than the lower ones.

Table 111. Differences between the Action Potentials of the Auditory Nerve and Cochlear Microphonics

	Cochlear microphonics	*Action potentials*
In relation to sound		
Latent period, msec	0.1	0.8
Form of sound wave and electrical potential wave	Same	Different
Synchronization with tone	Perfect	Only up to 3,000 cycles
Masking	No	Yes
Change of phase in sound	Followed	Not followed (silent interval)
Susceptibility to anesthesia, cold, ischemia, death	Little	Much
Polarity	Variable	Negative
Place of registration	Several	Auditory nerve
Refractory period	No	Yes

There is a certain degree of systematization in the auditory nuclei related to tonal frequency. The ventral cochlear nucleus receives fibers from the base of the cochlea. The medial geniculate body is also laminated. Ades, Mettler, and Culler[1] have shown in the cat that destruction of one layer in the medial geniculate body causes deafness to tones of certain pitch. There is also systematized projection of the medial geniculate body on the homolateral auditory cortex. Localized destruction of the medial geniculate body causes localized degeneration in the cortex.

The auditory area in the temporal cortex comprises two parts with recognizable differences in structure. The following methods have been used in the study of auditory cortical functions in cats, dogs, monkeys, anthropoids, and man.

1. *Anatomoclinical observations.* Observations in patients with disturbances in hearing are correlated with lesions found at autopsy or in the course of surgical operations. Thus, in cases of tumors in the temporal lobe there is a decrease in auditory acuteness, localization of sound is deficient, and nonexistent sounds are heard (auditory hallucinations). The disturbances are present in both ears, but more marked on one side. Destructive lesions of the temporal cortex cause aphasia (see Chap. 80).
2. *Extirpation of the temporal cortex* causes disturbances which have been studied in animals by conditioned reflexes to certain tones. If the cortex is removed on one side only, there is good compensation, but the threshold rises by 2 to 5 db. If the cortex is removed on both sides, the auditory threshold rises by 75 db., but some degree of hearing remains. The bilateral distribution of the auditory pathway has been demonstrated by removing the temporal cortex on one side and destroying the cochlea on the other; in this case the threshold rises by 15 db.
3. *Electrical stimulation of the cortex* provokes "listening" movements of the ears in animals, and in man the perception of noises, but no motor response.
4. *Electrical potentials* (*action potentials*) have been registered at all levels of the auditory path and have been used for the localization of sound reception. Thus tones of a certain pitch give rise to potentials mainly in a definite part of the auditory cortex, which varies with the pitch. On the other hand, when there is localized destruction of certain places in the cochlea, electrical response to sound ceases in circumscribed areas of the auditory cortex. Maps have been drawn from data obtained by this type of experiment, giving the locus of perception of tones of different pitch in the temporal cortex of the dog and cat.[1] The results are similar in both species.

[1] Ades, H., F. A. Mettler, and E. Culler, *Am. J. Physiol.*, **125**, 15, 1939.

Summary. The auditory path arises in the cochlea. It is a four-neuron chain, ending on the temporal cortex of both sides. An outstanding feature of the auditory system is tonal systematization, evident in the cochlea, the auditory nerve, the medial geniculate body, and the temporal cortex, as if each tone provokes impulses that travel along a certain path conditioned by the pitch of the tone. Each cochlea sends impulses along the ipsilateral and contralateral paths, and action potentials can be registered on both sides when the ear on one side only is stimulated. Destruction of only one cochlea is followed by a very small loss of hearing. Unilateral destruction of the auditory area of the temporal cortex is well compensated by the remaining cortex; bilateral destruction is followed by a considerable reduction, but not the total suppression of hearing. The auditory area has no motor functions. The auditory area on the left side is necessary for the integration of the spoken word; its destruction produces a certain type of aphasia (Chap. 80).

SUMMARY OF THE MECHANISM OF AUDITION

Sounds, *i.e.*, vibrations of elastic bodies, are transmitted to the air. They cause variations in pressure in the external auditory meatus, which provoke vibrations in the tympanic membrane. This membrane reproduces sound waves and transmits them to the ossicle chain, which, acting as a lever, amplifies them and transmits them to the base of the stapes. Contraction of the muscles in the middle ear diminishes

[1] Woolsey, C., and E. Walzl, *Bull. Johns Hopkins Hosp.*, **71**, 344, 1942; Tanturi, *Am. J. Physiol.*, **141**, 397, 1944.

sensitiveness to tones of low pitch and protects the ear.

Movements of the base of the stapes are transmitted as pressure changes in the perilymph of the inner ear. These pressure changes, owing to the inextensibility of the osseous labyrinth, travel up the scala vestibuli and down the scala tympani to the membrane of the round window, which bulges out on receiving them. High tones cross from one scala to another near the base of the cochlea; low tones cross over near the helicotrema. On crossing, the pressure wave passes through the scala media and causes the basilar membrane to vibrate, at a definite place in relation to the pitch of the tone. This is the fundamental phenomenon in the recognition of pitch.

The vibration of the basilar membrane gives rise to cochlear microphonics, which reproduce the form and frequency of the sound waves. Their origin is still unknown, but they have been very useful in the study of audition.

The cochlea stimulates the auditory nerve. Tones of frequencies up to 900 cycles provoke responses in all the nerve fibers that are stimulated by tones of the pitch in question. The frequency of the impulses is the same as that of the sound waves. The ratio of tone frequency to impulse frequency is 1:1. When the frequency of the tone reaches 1,800, this ratio is 2:1; half the fibers are stimulated alternately. When the frequency of the tone reaches 2,700, the frequency of response again drops, and the ratio of sound frequency to impulse frequency is 3:1; one-third of the fibers are stimulated in rotation. When the tone frequency is 3,500 or more, there is no synchronization between sound waves and frequency of impulses.

The pitch of a sound depends on the part of the basilar membrane and the organ of Corti that vibrates and stimulates the corresponding fibers of the auditory nerve. There is localized projection of the cochlea on the medial geniculate body and the superior temporal gyrus, so that a tone of given frequency stimulates a definite place in the cochlea and is transmitted along a definite path to a definite place on the auditory cortex.

The intensity of a sound depends on the length of the basilar membrane that is set in vibration and therefore on the number of nerve fibers stimulated, although as yet a precise numerical relation between intensity of sound and number of fibers stimulated has not been established.

Masking is due to overlapping of pitches in the basilar membrane and to the competition for transmission of impulses along the same nerve fibers.

Stimulation of one ear provokes action potentials in the auditory paths and auditory cortex of both sides of the brain. Each cochlea, therefore, has bilateral cortical representation. This explains why loss of one ear, or unilateral destruction of the auditory paths or cortex, provokes little loss of hearing.

DISTURBANCES CAUSED BY SOUNDS. ULTRASONICS OR SUPERSONICS

Very loud sounds or noises, brief or prolonged, cause damage to the middle ear and cochlea, which in some cases is irreparable. This is the cause of a certain type of deafness in boiler workers, aviators (who always have faulty bone transmission after 3,000 hr. of flight), tank drivers, subjects exposed to explosions, etc.[1] In all these cases protective measures are taken in order to prevent deafness, *e.g.*, covering the ear or the external meatus, etc. Moreover, noise causes general disturbances even in normal subjects. There is difficulty in concentrating and sustaining attention, loss of sleep, increase in oxygen consumption (up to 25 per cent), increase in the work of the heart and respiratory organs, etc. Noise may cause a loss of efficiency up to 50 or even 60 per cent in factory workers. Convulsions and coma have been produced in rats by very loud sounds and by supersonics.

Supersonics are frequencies above 20,000 cycles; this is a conventional figure, because many subjects, especially old people, cannot hear sounds of more than 16,000 c.p.s., or even 12,000 c.p.s. Moreover, some animals hear supersonic vibrations inaudible to man. Subsonics are vibrations below 25 c.p.s., *i.e.*, below the minimum audible frequency.

Electrical energy can be converted into sound vibrations of very short wavelength, corresponding to frequencies between 20,000 and 500,000,000 c.p.s. In one kind of apparatus an iron bar or tube is placed in a magnetic field so that it

[1] Armstrong, H., and J. Heim, *J. A. M. A.*, **109**, 417, 1937.

lengthens and shortens very rapidly; powerful supersonic vibrations are emitted from both ends. Piezoelectric crystals are also used and can give very high sound vibrations.

Supersonic vibrations transport energy. They travel in a straight line, but they can be reflected and therefore directed along a given path. By measuring the time taken by supersonic waves to travel to and from a surface on which they are reflected, it is possible to calculate the distance to the reflecting object. In clinical medicine this has been used for the location of brain tumors, gallstones, etc.[1]

The results of the experimental application of supersonics to animals vary with the animal species and with the duration and frequency of the vibration. The energy transmitted increases with the frequency. Many bacteria and other unicellular organisms are not disturbed by these very short sound waves, because they ride on them; other cells, such as erythrocytes, may be severely damaged and explode. Fishes, frogs, and other animals have been killed by supersonics. Supersonics have been applied in human therapeutics, but even in "therapeutic" doses, they have been shown to produce lesions in the bones, liver, and nerve centers of experimental animals.[2]

The mechanism by which the damage is caused varies. The most important is "cavitation," *i.e.*, the production of submicroscopic bubbles in tissue fluids (owing to the changes in pressure), which disorganize tissue structure. The process is instantaneous; *e.g.*, eggs of *Arbacia* are destroyed in 1/1200 sec., as can be demonstrated by photographic registration. Supersonics also have chemical activity, which is evident, for example, in the depolymerization of starch, gelatin, etc. Physical effects are produced, *e.g.*, sulfathiazol crystals are reduced to microscopic dimensions. They have thermal effects, causing a rise in temperature in solutions and emulsions, in tissues and in the whole animal, *e.g.*, they can raise the body temperature of mice to 45°C. They have other physical and chemical effects, such as the formation of microcrystals (sulfathiazol, etc.); mixtures of nonmixable fluids, *e.g.*, oil and water; depolymerization of starch and gelatine; etc.

[1] This method is used for measuring the depth of the sea and for locating submarines, shoals of fish, etc.

CHAPTER 80

Voice and Speech

Language is the means by which animals and man communicate and express feeling and thought.

There are two kinds of language: (*a*) spontaneous, natural, or primitive language; (*b*) conventional language, in which certain signs are given a definite meaning. The latter must be learned in order to be understood and used.

Natural or primitive language. This type of language is used by all the higher animals, including man; it becomes more developed as the inteligence of the animal increases. States of mind are expressed in many ways, which can be classified into three groups: (*a*) attitudes, which indicate feeling or mood, such as the extended limbs, arched back, erect fur, and lashing tail of an angry cat; (*b*) gestures, such as the pricking of the ears and movements of the head in the act of listening; (*c*) emission of sounds. In vertebrates, sounds are produced in the larynx and modified by changes in the shape of accessory structures (throat, mouth, and nasal cavities), thus forming the voice. Each animal species has its own voice, which changes in the expression of different emotional states; *e.g.*, it is easy to recognize the differences in the clucking of a hen calling her chicks, her cackling after she has laid an egg, or the screeches she emits when frightened.

Conventional language. This type of language is used exclusively by man, who reinforces its meaning by the simultaneous use of primitive language. There are two forms of conventional language, the spoken and the written. In the former the voice is emitted in a series of articulate elementary sounds or phones, known as vowels and consonants, which are combined into words. Words are symbols for ideas, and they form the basis of speech. In written language, graphic symbols represent ideas (ideographic writing) or sounds (phonetic writing). In the latter the symbols for the different vowels or consonants are combined into words as in spoken language.

Speech, *i.e.*, the expression of thought by articulate sounds, is the most highly developed form of language. A series of complicated mechanisms is necessary for speech. In the formation of the spoken word, by means of the auditory apparatus (ear and nerve centers), certain articulate sounds are perceived, distinguished from others, and endowed with meaning, *i.e.*, associated with certain visual, tactile, or other sensations, and recognized as symbols for these. These sounds are reproduced by adequate movements of the respiratory muscles, the larynx, and the resonating apparatus, coordinated by special nerve centers. Hearing exerts a predominant influence on speech, not only in childhood when speech is learned but throughout life, as is evident by the serious disturbances in speech caused by deafness. Deprivation or serious deficiency of hearing in early childhood causes mutism (deaf-mutism).

In the following paragraphs the different physiological aspects of speech will be considered: (*a*) voice production and the characteristics of the human voice; (*b*) the acoustics of speech; (*c*) the nervous mechanism of speech; (*d*) deaf-mutism.

VOICE PRODUCTION

There is great similarity between the apparatus for the production of the voice and musical instruments. In both there are (*a*) a force that puts a vibrating mechanism into action; (*b*) the vibrating mechanism itself; (*c*) a resonator that reinforces certain vibrations. In the piano these are respectively the hands of the pianist, the strings, and the sounding board of

the instrument. In a wind instrument they are the blast emitted by the player's lungs (the bellows in the organ), the reed (*e.g.*, in the clarinet) or the player's lips (*e.g.*, in the trumpet), and the tube of the instrument. In the instrument that produces the human voice, the force is given by the blast sent through the trachea by the lungs, which act as a bellows; the true vocal cords form the vibrating mechanism; and the resonator is made up of all the supraglottic cavities, *i.e.*, the upper part of the larynx, the pharynx, the mouth, and the nose.

The Respiratory Bellows

The voice is produced by the blast passing through the glottis. Immediately before speaking, the glottis is closed by the approximation of the vocal cords. The abdominal and thoracic muscles compress the lungs, increasing the pressure in the respiratory tract. When the pressure has reached a certain level, the glottis opens and the voice is emitted. The primary importance of the rise in pressure is demonstrated as follows: (*a*) if the trachea is opened, there is no rise in pressure and no voice; (*b*) if intratracheal pressure is measured in a tracheotomized subject (an experiment performed by Cagniard de Latour for the first time), it will be seen to rise to 16 cm. H_2O in ordinary conversation, to 30 cm. when the subject plays the clarinet, and to 94 cm. when he emits shrill cries.

Thoracic and abdominal muscles contribute to this increase in pressure in both sexes. This can be demonstrated by recording the action potentials of the different muscles. Thoracic muscles play the most important part in men and women, especially in the latter, and their activity increases in rapid talking.

The *intensity* or *loudness* of a voice is proportional to the amplitude of the vibrations of the vocal cords, which increase with the force of the expiratory blast. This can be demonstrated on an isolated larynx, varying the pressure of the air which is blown through it. Loudness of voice is measured in decibels. There is a difference of approximately 100 db. between the softest whisper and the loudest cry. In ordinary conversation, loudness of voice varies between 40 and 50 db.

The Vibrating Mechanism. The Larynx

The larynx is a short tube situated between the trachea and the pharynx. It can be considered as the modified upper part of the trachea.

ANATOMY

The larynx is formed by a framework of four cartilages, joined by fibrous tissue and ligaments, and several small muscles, which play a part in the production of voice. The lumen of the larynx is narrowed in three places; the lowest one, formed by the true vocal cords, is an essential part of the mechanism of voice production. The larynx is lined by a ciliated epithelium, except over the inner margin of the true vocal cords, which is covered by a stratified epithelium. A man's larynx is about one-third larger than a woman's, which is about one-third larger than that of a child at birth. The larynx grows rapidly up to the age of three years; at puberty there is another period of rapid growth, especially in boys.
Fig. 461. Muscles of the human larynx. *a*, front view; *b*, back view.

Cartilages. The cricoid cartilage is the lowest. It is a modified tracheal ring shaped like a

signet ring, with the seal plate in the posterior aspect. The upper margin of this plate articulates with the base of the two pyramid-shaped arytenoid cartilages. These cartilages can rotate on their base around a vertical axis, and the whole cartilages can slide outward or inward so that their inner margins draw apart or come together. The cartilages have two processes: a median, or vocal, process on which the true vocal cord is inserted, and a lateral, or muscular, process on which several muscles are inserted (Fig. 461).
FIG. 462. Transverse section of human larynx. The upper surface of the true vocal cords is flat; their inner margin is sharp and the lower surface is concave toward the mid-line (*conus elasticus*). Both vocal cords form an arch at the summit of the trachea, which resists the expiratory blast when the glottis is closed.

The thyroid cartilage forms the anterior and lateral walls of the larynx. It is placed under the skin of the neck, forming the protuberance known as "Adam's apple" in the male. It consists of two vertical plates joined in the mid-line by fibrous tissue. The plates form an angle with its vertex directed forward. The anterior extremities of the true vocal cords are inserted on this cartilage. Ligaments and fibrous membranes join the thyroid cartilage to the hyoid bone above and the cricoid cartilage below.

The true vocal cords. The glottis. The true vocal cords are inserted in the angle formed by the thyroid cartilage. They are directed horizontally and backward, ending by insertion on the median or vocal process of the arytenoid cartilage. In a frontal section they appear as triangular structures with an upper horizontal surface and a lower median concave surface; the inner margin is formed by the union of these two surfaces, and in certain cases comes into contact with the inner margin of the vocal cord on the opposite side (Fig. 462). They are formed by the inner fibers of the thyroarytenoid muscle and by a fibrous ligament. The mucosa covering the vocal cords is made up of cylindrical ciliated cells, with mucous glands, except over the inner margin, where there is a stratified epithelium. These glands continuously secrete mucus, which lubricates the vocal cords. There are always a few drops of mucus on the inner margin of the cords. Between the inner margins of the two vocal cords there is an angular space, with the vertex directed forward, which is continuous with the interarytenoid space. Seen from above, this space has the shape of a lance head. The anterior part between the vocal cords is known as the vocal glottis. Its length is approximately 18 mm. in men and 13 mm. in women; the posterior part is the cartilaginous glottis, which is 7 to 8 mm. in length.

Above and parallel to the vocal cords are two mucous ridges known as the false vocal cords. On each side, between the false vocal cords and the lateral wall of the larynx, there is a recess called the ventricle of Morgagni. The mucosa at this level covers loose adenoid tissue, which can be easily infiltrated by fluid, becoming edematous. This edema causes a serious obstacle to respiration, and may even cause death by asphyxia.

The *air sacs* are rudimentary in man, merely a depression in the ventricle of Morgagni. In certain animals they are large sacs full of air. They open into the mouth in frogs, the larynx in the anthropoids, the trachea in ducks, the lungs in chickens. They act as air reservoirs, used in a struggle when the breath is held (they swell out in anthropoids when angered), or to keep up the air blast during singing in birds. In pathologic cases in man, they can be abnormally large (laryngocele).

Muscles and movements of the vocal cords. All the muscles of the larynx except the arytenoid muscles are paired and symmetrical. All of them act on the vocal cords, by approximating them, separating them, or changing their tension.

FIG. 463. Diagram of horizontal section of the larynx at the level of the arytenoid cartilages. I, contraction of the posterior cricoarytenoid muscle, rotation of the arytenoid cartilages in the direction of the arrows, and opening of the glottis; II, contraction of the lateral cricoarytenoid muscles, rotation of the arytenoid cartilages in the direction of the arrows, and first stage in closure of the glottis; III, contraction of the arytenoid muscles and approximation of arytenoid cartilages; IV, contraction of the thyroarytenoid muscles, shortening and complete closure of the glottis.
FIG. 464. Contraction of the cricothyroid muscles. The vocal cords are stretched and drawn together, closing the glottis, when the posterior part of the thyroid cartilage is pulled down. (*After Pressman.*)

1. The vocal cords are separated and the glottis is dilated by the posterior cricoarytenoid muscles, which rotate the arytenoid cartilages (Fig. 463, I).
2. The vocal cords are approximated and the glottis is constricted by three groups of muscles: the lateral cricoarytenoid muscles, which rotate the arytenoid cartilages around a vertical axis in the opposite direction to the rotation produced by the posterior cricoarytenoid muscles; the arytenoid muscles, which draw the arytenoid cartilages together; and the lateral fibers of the thyroarytenoid muscles, inserted on the muscular process of the arytenoid cartilage, which rotate these cartilages and draw them forward, completing the closure of the glottis (Fig. 463, II, III, and IV).
3. The tension of the vocal cords is increased by two pairs of muscles: the cricothyroid muscles cause the anterior angle of the thyroid cartilage to move upward and forward, thus stretching the vocal cords by separating their anterior and posterior insertions (Fig. 464); and the inner fibers of the thyroarytenoid muscle, which forms the musculus vocalis in the vocal cord. The fibers of this muscle are inserted on the thyroid or arytenoid cartilages by one end and on the vocal cord by the other. They contract in separate bundles; they sharpen the margin of the vocal cords, diminish their surface of contact, and modify the contour of the glottis. They are fast fibers, which respond very rapidly to stimulation.

Nerves. The upper and lower laryngeal nerves are branches of the vagus nerve. The upper laryngeal nerve sends a lateral branch to the cricothyroid muscle and has an inner branch which gives out sensory fibers to the whole larynx. There are also vasomotor and secretory fibers to the mucous glands. Section of this nerve anesthetizes the larynx and suppresses reflex coughing when a foreign body drops into the larynx. It also causes paralysis of the cricothyroid muscle, and the voice becomes hoarse because of the lower tension of the vocal cord.

The recurrent laryngeal nerves send out motor fibers to all the muscles of the larynx except the cricothyroid muscles. Section of one lower laryngeal paralyzes the homolateral vocal cord, which then approximates the mid-line. The voice becomes bitonal, and the vocal cord is not separated on inspiration. Bilateral section of the recurrent laryngeals suppresses phonation (aphonia) and causes serious disturbances in respiration; the glottis is not dilated in inspiration, and it may even be closed by further approximation of the vocal cords (*e.g.*, during muscular exercise). In young animals death by asphyxia may occur because the cartilaginous glottis may also be closed by approximation of the arytenoid cartilages; in the adult these cartilages are hardened, and the posterior part of the glottis remains open. In normal conditions the dilators of the glottis predominate over the constrictors, and the glottis has a width of 12 to 14 mm. After section of the four laryngeal nerves, the width of the glottis is reduced to 4 or 5 mm.

PHYSIOLOGY

The main function of the larynx in all animals is to assure that only air passes into the lungs. In man and other species a sound is produced by the vibrations of the vocal cords, which is modified in the supraglottic resonators and converted into the voice. The laryngeal sound can be emitted with different loudness and pitch, because it can be modified by the following factors: (*a*) the strength of the blast coming from the lungs; (*b*) the size and shape of the glottis; (*c*) the tension of the vocal cords.

Functions of the larynx in voice production. The laryngoscope. Müller in 1839 showed that a vocal sound was produced by the isolated larynx when a blast was sent into it from a bellows through the trachea. He also demonstrated the changes in loudness and pitch produced by varying the strength of the blast and the tension of the vocal cords, which were stretched more or less by weights pulling on the thyroid cartilage.

Magendie pointed out that the vocal tone is produced at the level of the true vocal cords. He separated the larynx of dogs by a transverse section below the hyoid bone and saw that when the animal barked the glottis was constricted. Extirpation of the vocal cords in animals leaves them voiceless. Models of the larynx can be made which show how the voice sound changes when the tension of the vocal cords is modified.
FIG. 465. Observation of the larynx by means of the laryngoscope.

Manuel Garcia, a tenor and singing teacher, in 1855 invented the laryngoscope, which is still used by laryngologists. It consists of two mirrors. One is a large concave mirror with a central aperture placed in front of the observer's eye. It reflects a beam of light onto a second small mirror fixed at an angle on a handle so that it can be placed close to the soft palate of the patient, who holds his mouth wide open. The observer can thus see the image of the larynx reflected in the small mirror (Fig. 465).

Periscopes introduced into the mouth or through the nose have also been used to visualize the larynx. The photographic method was first used by French in 1886. A series of pictures (plain or colored) are taken on fast films and projected with the slow-motion camera or by means of a stroboscope.[1] The images are associated with the production of vocal tones. No two larynges are exactly alike, but they all have certain common characteristics which make it

[1] An instrument for showing a series of pictures rapidly, so that an illusion of motion is produced.

possible to give a general description of laryngeal movements in voice production.

When the larynx passes from the resting position to that necessary for emission of sound, the first movement is the approximation of the vocal cords until they come into contact with each other; this is known as the phonation position of the cords. The glottis is thus closed, and air pressure in the trachea increases. Approximation and tension of the vocal cords are brought about by contraction of the laryngeal muscles as described above. The countertension mechanism formed by the internal fibers of the thyroarytenoid muscle then enters into activity; the cords are separated, in part owing to retraction of their internal margin; and the contour of the glottis changes. Finally, as the voice is emitted the internal margins of the cords enter into fine vibratory movements; there is periodic expansion and narrowing of the glottis.

THE PHYSICAL MECHANISM OF VOICE PRODUCTION

The laryngeal sound is produced by the passage of air under pressure through the narrow glottis. Vibrations of the vocal cords interrupt the passage of air, which becomes intermittent. Thus eddies are formed in the supraglottic cavities.

There is still some discussion as to whether the blasts of air that pass through the glottis act directly on the air in the supraglottic cavities, causing it to vibrate and making the vocal cords vibrate in response, or whether the cords are set in vibration by the blast of air passing through the glottis, as wind causes vibration in stretched wires. If the cords were set in vibration directly by the blast of air passing through them, they would be submitted to very high tension in the emission of certain tones, higher than they could resist. The other hypothesis, in which the larynx has been compared to several wind instruments with or without vibrating reeds, is the more probable. So far, however, no fully satisfactory explanation of the mechanism that sets the cords in vibration has been given.

FIG. 466. Tonal changes in the human voice from birth to puberty. Solid line, boys; broken line, girls. (*According to data given by Paulsen and by Gutzmann.*)

Pitch. The "highness" or "lowness" of a sound depends on the cycles per second of its vibrations. The number of tones which can be emitted by the human voice and their position in the musical scale vary with age and sex.

The frequency range of the newborn is limited to approximately three semitones. As the child grows the frequency range increases mainly by the addition of higher tones, but also of a few low tones (Fig. 466). The highest frequency is attained usually around the eleventh year; at this age girls can emit very high sounds, seldom reached by sopranos in later years. At the age of puberty there is little difference between the voices of boys and girls, except that the latter can usually reach a few notes higher.

Structural modifications in the larynx which occur at puberty cause the voice to change suddenly. The pitch is lowered one octave[1] in boys and only two notes in girls. Thus the voices of boys change from soprano to tenor and from contralto to bass.

as has been shown by observations in laryngectomized subjects and by observations with the laryngoscope.

Effects of laryngectomy. Laryngectomized subjects can recover speech by learning how to swallow air, how to retain it in the esophagus by constriction of the pharyngoesophageal sphincter, and then how to control its passage into the pharynx and mouth. Words can be formed, but there are no tonal variations and it is not possible to sing.
Fig. 467. Ranges of human voice in the musical scale compared with the keyboard of a piano.
Fig. 468. Shape of the glottis during the emission of the voice.

The voices of adult men and women differ in their position in the musical scale. Three voices are distinguished in each sex: bass, baritone, and tenor in men; contralto, mezzo-soprano, and soprano in women (Fig. 467). The pitch of the voice is often lowered with age; thus a tenor may change into a baritone and a soprano into a mezzo-soprano. The pitch range in ordinary conversation is usually not more than half an octave. It increases in recitation and goes up to two octaves in singing. The whole range of human voices covers four octaves; two and one-fifth octaves for each sex, with an overlap of one-fifth octave in the middle of the scale.

The voice does not change at puberty in eunuchs. It retains its infantile characteristics, but pitch range and intensity increase. In the past, famous choirs were made up of eunuch voices.

Changes in pitch. Voice registers. Tonal changes in the voice are produced in the larynx,

[1] The frequencies of vibration of two notes separated by one octave are as 1:2.

Observation of the larynx during voice production. According to the pitch of the sound emitted, the larynx moves up or down; the vocal cords change in length, position, and tension, and the shape of the glottis varies (Figs. 468 and 469). The force of the blast also varies.

In the production of *low tones* the larynx rises a little, the cords lengthen and relax, they come into contact with each other, and the whole cord vibrates. The glottis is open, especially in its posterior part, but not so much as during breathing.

During the emission of *high tones* the larynx rises considerably, the cords shorten and become tense, their margin sharpens and is the only part that vibrates. The glottis is reduced to a narrow slit. In the production of very high tones, such as those of the head register or falsetto, a special

damping mechanism comes into play. This mechanism has been compared by Pressman to the effect produced on the string of a violin by pressure exerted with a finger; the string is divided into two parts, only one of which vibrates. The vocal cords are brought together and touch, except on a small length of their anterior end; the smaller the length of this free vibrating part, the higher the tone emitted (Table 112).

Table 112. Position of the True Vocal Cords and Shape of Glottis and Supraglottic Space in the Emission of Low and High Sounds

	Sound		
	Low	*High*	*Very high (falsetto)*
Vocal cords			
Length	Short	Long	Long
Tension	Low	High	High
Vibrations	Total	Inner margin	Inner margin of anterior part
Glottis			
Position	Low	High	High
Shape	Racket, handle backward	Lineal	Lineal, posterior part closed
Supraglottic space	Lengthened	Shortened	Much shortened
Subjective vibrations	Chest	Head	Head

In whispering the arytenoid cartilages and the vocal cords are widely separated. The cords vibrate irregularly. The resonators modify the sound thus produced, and it becomes articulated into words but remains toneless.

The effect of the expiratory blast. Pitch rises simultaneously with loudness, as the force of the blast increases. This phenomenon can be easily demonstrated in an isolated larynx, and it explains the difficulty in singing softly tones of high pitch.

In *summary*, the pitch of the voice depends on the length and tension of the vocal cords, the shape of the glottis, and the force of the blast. If the vocal cords are suppressed, the voice is toneless.

Registers. The capacity to emit sounds of different pitch is outstanding in man. In other species it is much more restricted; thus cattle emit only low tones, and monkeys high tones. Singers pass smoothly from high to low tones and vice versa. In music, voice range is usually divided into registers. The low or chest register comprises low tones rich in harmonic overtones; it is given this name because vibrations are objectively and subjectively located in the chest. The head register comprises high tones, with few harmonic overtones; the vibrations are subjectively located in the head; hence its name.
Fig. 469. Shape of air tube in the emission of low and high tones.

The false vocal cords. These structures are not necessary for the production of voice, and in some animals (*e.g.*, the cat) they do not exist. In very good singers they are separated and placed against the wall of the larynx, giving a free passage to the sound waves; in others they are brought near the mid-line and give a harsh quality to the voice. Their main effect is the production of overtones by entering into vibration in response to the vibrations of the glottis. When the true vocal cords are extirpated, the false ones may replace them to a certain extent, giving a harsh sound of low intensity and little tonal variation.

The Resonating Mechanism

All the space through which the expired air passes, *i.e.*, the lung, trachea, larynx, pharynx, mouth, and nasal cavities, are called the resonators, because of the part they play in voice production.

The resonators are not static, but dynamic; their shape changes, adapting itself to the pronunciation of vowels and consonants needed in the articulation of words. The resonators consist of static parts, such as the bony palate, the nasal canal, etc., and movable parts such as the soft palate and uvula, the tongue, lips, cheeks,

etc. Malformations of the resonators cause considerable disturbances in the quality of the voice. The effects of a harelip or cleft palate, the absence or incorrect implantation of teeth, and the presence of adenoids in the pharynx are well-known causes of defects in speech. Facial paralysis, or paralysis of the soft palate or the tongue, also causes speech disturbances.

The resonators increase the volume of the weak laryngeal sound, and they reinforce some of the overtones, giving the voice its individual timbre, which permits the recognition of each person's voice. Thus also is it possible to distinguish the voice of a tenor from that of a baritone even when both sing the same note. More important still is the part played by the resonators in forming the vowels and consonants which make up words.

Changes that take place in the resonators in the course of speech have been recorded photographically, by x-rays taken after making the different parts opaque with barium, and by cinema films. It has thus been seen that there are considerable individual variations in the position of the tongue on pronouncing the same voice sounds.

Mechanics of vowel formation. Vowels are formed by a continuous sound, easy to recognize, produced by the arrival of the laryngeal sound at the mouth and the reinforcement of some of its overtones. Helmholtz showed that each one is formed by special tones, and he was able to reproduce the vowel sounds by a system of tuning forks, each one giving a single pure tone. The laryngeal sound is not indispensable, since it can be replaced. For example, a vowel sound can be produced by placing the mouth in the adequate position for its pronunciation and percussing the cheek with a finger. It can also be produced by whispering, and laryngectomized persons can pronounce vowels correctly.

The resonators adopt a particular position for the pronunciation of each vowel sound. There are three typical or extreme vowel sounds: *ä* (as in "far"), *ē* (as in "eve"), and *ōō* (as in "tool"). Other vowel sounds derived from these vary from one language to another. The *ä* sound is considered as the fundamental vowel; it is pronounced with the tube open to a maximum, and it is easy to sing. For the pronunciation of *ē* and *ōō* the tube is narrowed, and these sounds are not so easy to sing. Changes in the resonating tube in the pronunciation of fundamental vowel sounds are summarized in Table 113.

Table 113. Pronunciation of Fundamental Vowel Sounds

	ä	*e*	*ōō*
Position of larynx	Intermediate	Very high	Very high
Opening of mouth	Wide open	Narrowed by tongue and palate	Narrowed by lips
Position of tongue	Retracted down	Close to palate	Tip down, root high
Number of paces at which vowel sounds can be heard	360	300	280

Mechanics of consonant formation. Consonants are sounds or noises produced in the mouth by suddenly placing an obstacle to the passage of the expiratory air blast. They are interrupted vowel sounds. The site where this obstacle is placed is known as the area of articulation. The laryngeal sound is not indispensable.

According to the place of formation, consonants are classified into

1. Labials or lip consonants, which are bilabial (*b, p, m*) when formed between the two lips, or labiodental (*v, f*) when formed between the lower lip and upper teeth, and labiogutturals (*wh* in when.)
2. Dentals, formed by the tip of the tongue extended between the edges of the front teeth (*th* in "then"), or by the tip of the tongue touching the back of the upper front teeth or gums (*d, t*), or by forming a narrow passage between the back of the tongue and the upper front teeth (*s, z*). In some cases the tip of the tongue is raised (*sh* in "shoe").
3. Palatals, in which the tongue is raised up against the palate (*y* in "yell," *r* in "round").
4. Gutturals, formed by raising the root of the tongue toward the soft palate (*g* in "go").

According to the manner of formation, the consonants are called (*a*) stopped consonants,

when the blast of expired air is completely stopped at some point in the air passage (*b*, *p*, *t*); (*b*) nasal consonants, when the mouth passage is completely stopped but the soft palate does not close the passage into the nasal cavities (*m*, *n*); (*c*) open consonants, when the blast is not stopped but is forced through a narrow passage (*s*, *z*, *th*, *ch*).

Summary

Speech is produced as follows:

1. Words are always formed during expiration. If the subject is inspiring, the movement is interrupted and replaced by expiration. At the same time the vocal cords adopt the phonation position, becoming tense and closing the glottis, by contraction of the appropriate laryngeal muscles. Intratracheal pressure rises owing to the contraction of expiratory muscles in the thorax and abdomen.
2. The glottis is partially opened. The internal fibers of the thyroarytenoid muscle (musculus vocalis) contract to give the glottis the shape adequate for the tone to be emitted. Pitch is due to the tension and length of the vocal cords, to the shape of the glottis, and to a certain extent to the force of the blast, which conditions the loudness of the voice.
3. The air escapes through the glottis under pressure. The vocal cords are separated and vibrate. The air passing in blasts into the supraglottic space also vibrates.
4. The laryngeal sound (vocal tone) thus produced is modified in the resonators, which change in shape so that some of the overtones are reinforced and the passage of the expiratory blast is checked. Thus vowels and consonants are formed, which are combined into words, and the voice acquires its characteristic quality or timbre.

THE ACOUSTICS OF SPEECH

The physical analysis of speech was begun a century ago. Helmholtz and König were among the first to make important contributions to this subject, but progress was relatively slow until the advent of electromechanical devices for recording, producing, and reproducing sound. Advancement along these lines has proceeded simultaneously with the development of the phonograph, telephone, radio, etc.

Methods. The majority of the methods that have been used are not sufficiently sensitive. Resonators of different size and periodicity were first used to determine the components of a sound. König added to the resonators a "sound flame," which oscillates with the vibrations of the resonator and can be photographed so as to obtain a permanent record. Sensitive membranes, which vibrate on the impact of the voice, have also been used. Phonographic registration of the voice and analysis of the records have recently been considerably developed. More sensitive and accurate methods are based on the conversion of sound waves into electric potentials; these electroacoustic methods are now commonly used in the registration of the sounds and noises of speech and give records that are easy to analyze. The oscillograph registers on a fluoroscope, or on paper, wave sounds which have been taken up by a microphone, converted into an electric current, and amplified. The wave recorded is composite, made up by the different tones which constitute the sound registered, so it must be submitted to a rather laborious analysis. In the spectrographic method the sound is first recorded on a gramophone record, then reproduced, and by using adequate sound filters each tone is recorded. This mechanism is similar to that of the inner ear. Vowel sounds thus analyzed have been resynthesized.

Physical Properties of Fundamental Voice Sounds (Phones)

According to Gemelli and Pastori, a phone is "a speech sound or noise which cannot be divided into simpler elements of speech, but only into simple oscillatory phenomena." Phones are therefore phonetic units, *i.e.*, vowels and consonants.

Vowels. Vowel sounds have been analyzed as they are pronounced within a word (real vowels) or separately (vowel types). A vowel type gives a curve with an initial phase, a central or uniform phase, and a final phase. In real vowels (pronounced within a word) the first and last phases are transitional between the preceding and following sound. Whispering and singing give very clear curves.

Each vowel has a typical curve that can be easily recognized. This constant element has a variable part added which depends on the tone of voice, the type of pronunciation, etc., *i.e.*, the individual characteristics of the phonetic appa-

ratus of the subject, and regional peculiarities in pronunciation. The fundamental nature of the curve can nevertheless always be recognized.

Analysis of the components of the curve of each vowel sound, by Fourier's mathematical analysis or Dietsch's photoelectric method, has shown that all the vowels are formed by algebraic summation of two or more simple tones of different rhythm and form. These tones are typical for each of the vowel sounds, some of which (*e.g.*, ŏ and o͞o) can be reproduced by summation of the simple components. The most complex curve is the one corresponding to ä, which is the most highly developed vowel sound; ē and o͞o are very simple (Fig. 470). Other vowel sounds are of intermediate complexity.

Fig. 470. Oscillographic registration of sound waves corresponding to pure vowels (upper curve). Below, the different components of the complex wave obtained by Fourier's analysis. The ä sound corresponds to a male voice; it has a fundamental frequency of 235 c.p.s. The o͞o and ē sounds correspond to a female voice; their frequencies are 430 and 586 respectively. (*After Gemelli and Pastori.*)

Consonants. Consonants also have typical, recognizable curves. These curves have been analyzed into their components, and some of the consonant sounds have been reproduced by synthesis, but the results have not been as perfect as with vowel sounds.

Some of the consonants are sounds, *i.e.*, they are produced by regular cycles; others are due to irregular oscillations, *i.e.*, they are noises. The former are called voiced consonants, or sonants, or semivowels (*l*, *n*, *m*, *v*); the latter are true consonants, or voiceless breath consonants.

Words. Oscillographic and spectrographic methods have been applied to the study of words and sentences. The spectrogram[1] shows, on the fluoroscope or on paper, simultaneously all the different frequencies and their changes so that a complete analysis of the word can be made. This method which makes words "visible" has been used in the instruction of deaf-mutes and in voice training. Reading of the records must, of course, be learned first.

Some applications of acoustics. The physical analysis of speech is of great practical importance in the construction of auditoriums with good "acoustics" and in improving audibility in telephonic communication or faithfulness in the reproduction of sound by phonographs and radio sets. For example, a vowel sound must last a minimum time of 7.7 msec. (*i.e.*, 2 cycles); if it is below this minimum, it will not be heard over the telephone or the radio. The optimum time for perception of a phone is 0.1 to 0.033 sec.; if it lasts more than 0.5 sec. it is not heard well. In an auditorium sounds are heard by direct transmission from the source, but mainly (90 per cent) indirectly after they have been

[1] Potter, R. K., Sensory Devices. Sound Portrayal, in O. Glasser's "Medical Physics," Vol. 2, Year Book Publishers, Chicago, 1950, p. 979.

echoed from the walls and other surfaces. The ear receives these reflected waves with a delay that increases with the distance of the reflected surface (Fig. 471). Reverberation (as this phenomenon is called) should not prolong the duration of the sound for more than 0.5 sec.
FIG. 471. Reverberation. The sound of the bell reaches the observer directly (thick arrow) and indirectly (thin arrows) after reflection on the walls and objects (dotted arrows), with a delay proportional to the length of the path traveled by the reflected sound waves. The stimulus is thus prolonged and the sound continues to be heard after the bell has ceased ringing.

The intensity of the sound is conditioned by the fundamental tone; the overtones condition the possibility of understanding its significance. Crandall eliminated by adequate filtration all waves of frequencies below 500 c.p.s. from certain speech sounds; the intensity diminished 60 per cent, but audibility diminished only 2 per cent. Therefore the high tones in the voice, *i.e.*, those of 1,000 to 2,000 c.p.s., which carry the overtones, are the important ones for audibility and are those which should be reinforced in order to improve hearing.

THE NERVOUS MECHANISM OF SPEECH

The clinical observations of Broca (1861) and Wernicke (1874) awakened interest in the study of the nervous mechanism of speech. A diagrammatic conception of speech formation was built up by artificially separating elementary components of speech and assigning to each a cortical center. In the first quarter of this century, further clinical observations led to the critical revision of this diagrammatic interpretation of the neural mechanism of speech, and new concepts were gradually developed (Pierre Marie, 1906; Head, 1917; Goldstein, 1927).

The learning of speech requires the development of two closely associated processes, reception and understanding on the one hand and expression on the other. The first process consists of two parts: (*a*) stimulation of the auditory receptors and centers; (*b*) the passage of impulses from these centers to mechanisms of association, where they acquire the attributes of symbols and are "stored" in memory. For example, the word "bell" awakens the idea of the object it represents, but if the equivalent word of an unknown language is heard it will have significance only as a sound, without any associated idea to give it the particular meaning of bell. The process of verbal expression also consists of two parts: (*a*) impulses are first coordinated in higher association centers; (*b*) they are then transmitted to the centers that control the respiratory, laryngeal, and other muscles that play a part in the emission of speech. In written language there is a similar process, but visual receptors and centers take the part played by the auditory mechanism in spoken language, and the nerve centers and muscles of the arm and hand replace the respiratory and laryngeal nerves and muscles. The mechanism of speech is summarized in the diagram below.

Between the merely sensory and motor activities are placed the complex mechanisms of association, which endow sounds or written characters with the meaning of symbols and coordinate the complex movements needed for the emission of speech.

Sensory and motor centers occupy well-

Auditory or visual receptors, paths, and centers	→	Cortical mechanisms of association for understanding and expressing spoken or written language	→	Nerve centers, paths, and muscles of respiration, larynx, eyes, hands, etc.

Sensory or receptive mechanisms (Auditory or visual receptors, paths, and centers → Cortical mechanisms of association) | Motor or expressive mechanisms (Cortical mechanisms of association → Nerve centers, paths, and muscles)

defined areas in the cortex. Thus the auditory center is situated in the temporal lobe, the visual center in the occipital lobe, and the motor centers in the precentral gyrus. Association centers for the understanding of words or written symbols and for verbal expression are not clearly localized, but are widely spread in the cortex of the left hemisphere. They are closely correlated with intellectual capacity. Localized lesions in this widespread area produce little or no disturbance in cortical functions localized in the damaged area but may cause serious disturbances in the mechanisms of association. Lesions in the speech area, therefore, disturb the whole process of speech formation, but the disturbance is predominantly sensory or receptive when the posterior part of the area is involved and predominantly motor or expressive when the anterior part is damaged.

The speech areas are situated in the cortex of the left hemisphere in right-handed persons. They extend from the posterior part of the third, or inferior, frontal convolution through the temporosphenoidal lobe and the island of Reil to the posterior part of the parietal lobe (Brodmann's areas 4, 6*aα*, 44, 43, 41, 42, 22, 39).

Aphasia

Aphasia is a disturbance in speech due to damage in the cerebral mechanisms of verbal understanding and expression, but without mental disturbances. The lesions which cause aphasia are situated in the left cerebral hemisphere, in a large area supplied by the sylvian artery. When the lesions are situated in the posterior part of the area, defects in understanding predominate; when they are in the anterior part, defects in expression are predominant. Head maintains that all the components of speech are disturbed in aphasia, although in different cases some are more affected than others. He classified aphasia into four clinical types: verbal, nominal, syntactic, and semantic.

Verbal aphasia. Word formation is defective; there is difficulty in evoking and pronouncing words, and it is almost impossible to express ideas. Writing is difficult. This type corresponds approximately to motor aphasia (inability to speak articulately) and agraphia (inability to write).

Nominal aphasia. Words and phrases are enunciated, but there is difficulty in finding the correct words to express an idea or name an object. Reading and the mental process of arithmetic are also impaired.

Syntactical aphasia. Isolated words are sometimes formed correctly, but sentences are not properly constructed. The patient talks volubly in an unintelligible jargon without realizing that he has spoken incorrectly. Such patients are often considered insane.

Semantic aphasia. Words and short sentences are correctly understood and formed, but conversation cannot be kept up because its general significance is lost.

Déjerine's[1] classification of aphasia, derived from Charcot's theories on the subject, gives a good idea of the classical concept of disturbances in speech. Aphasia was divided into motor, sensory, and total aphasia.

Motor, or Expressive, Aphasia

Motor aphasia or Broca's aphasia. Disturbances in the formation of the spoken or written word predominate; there are few disturbances on the receptive side of the speech mechanism. Mental speech is impaired. There is no paralysis. There are lesions in the posterior part of the third or inferior frontal convolution, on the left side (Broca's center) in front of the cortical motor centers of muscles taking part in voice formation.

Pure motor aphasia. Words cannot be articulated, although mental speech is not disturbed and there is no paralysis. It is an attenuated form of Broca's aphasia.

Sensory, or Receptive, Aphasia

Sensory, or receptive, or Wernicke's aphasia. The subject does not understand the spoken word (verbal deafness) or the written word (verbal blindness), although he can hear and see. He is in the situation of a person hearing an unknown language. There is also slight impairment in the formation of words, and printed type cannot be copied into writing. Lesions of the convolutions around the posterior part of the sylvian fissure cause this type of aphasia.

In pure verbal deafness and pure verbal blindness, the patient does not understand the spoken or the written word, but there is no other defect in speech. Pure agraphia, *i.e.*, the loss of the ability to write, without paralysis or any other defect in speech, was not admitted by Déjerine.

[1] Déjerine, J., "Séméiologie des affections du système nerveux," Masson et Cie, Paris, 1914.

TOTAL APHASIA

In this type there are sensory and motor disturbances in speech. Pierre Marie[1] made a critical study of Déjerine's concepts and classification of aphasia. He concluded that only Wernicke's aphasia, due to intellectual deficiency, could be accepted as a separate entity. Pure verbal deafness and pure motor aphasia caused by lesions in the third frontal convolutions were also discarded as entities, because cases of Broca's aphasia could occur without any damage to this area, and lesions in Broca's center did not necessarily provoke aphasia. On the other hand, Marie defined a new entity, called "aphemia," due to subcortical lesions under the island of Reil. Déjerine's and Marie's classifications of aphasia are compared in Table 114.

Table 114. Déjerine's and Marie's Classifications of Aphasia

Déjerine	*Marie*
Motor aphasia	
Broca's aphasia (pure motor aphasia + verbal blindness)	Broca's aphasia (aphemia + attenuated Wernicke's aphasia)
Pure motor aphasia	
Sensory aphasia	
Wernicke's aphasia (verbal deafness + verbal blindness)	Wernicke's aphasia
Pure verbal deafness	
Pure verbal blindness	Alexia
Total aphasia	
Broca's + Wernicke's aphasia	

Aphasia is now usually considered as a severe disturbance in cortical function, which involves the whole mechanism of acquired speech, but the symptoms vary according to whether the lesions are situated mainly in the motor, auditory, or visual areas.

DEAF-MUTISM

This term is used for cases of congenital or acquired deafness in which speech has not developed. Mutism without deafness occurs very rarely. Deaf-mutes can be taught to speak, in which case they are simply deaf persons.

Historical note. Spartan law prescribed that deaf-mutes should be killed by being cast from Mount Taiget. According to Aristotle, "those born deaf then become mute," and the general idea was that these persons could not learn to speak. Following Fr. P. Ponce de Leon (1510–1584), deaf-mutes were taught to speak by several teachers in the course of the fifteenth and sixteenth centuries. Organized treatment of deaf-mutes was first started in France by Charles Michel de l'Epée (1712–1789) who taught them to express themselves by hand signs (deaf-and-dumb alphabet). Shortly afterward Samuel Heinecke (1729–1790) initiated the oral method of education in Germany, and it was soon universally adopted. Alexander Graham Bell (1847–1922), a Boston teacher of deaf persons, made many contributions to the relief of the deaf. His most outstanding achievement is, of course, the telephone. The sums he was awarded as prizes for his discoveries were dedicated to founding institutions for the benefit of the deaf and deaf-mutes.

Congenital deafness. Anomalies in development of the ear or auditory paths and centers and fetal diseases cause congenital deafness. Individuals with such deafness are mute.

Acquired deafness. Disease and trauma of the ear or auditory paths and centers occurring after birth but before the age of three years have the same effect on speech as congenital deafness. If the damage occurs at a later age, the defect in speech is not so severe, and after the age of seven or eight years there are only defects in enunciation and modulation of the voice. Deafness does not involve intellectual deficiency.

The number of the deaf-mutes is considerable, especially in certain districts (*e.g.*, areas of endemic goiter). In civilized countries there are approximately 8 deaf-mute children for every 10,000 (Hartmann). Deafness is a serious problem in public welfare. In 30 per cent of the cases there is some degree of hearing, which is of great value in learning speech, especially if it is improved by modern hearing aids.

Problems created by deafness and their treatment. The physician plays an important part in the prevention and cure of diseases causing deafness and in directing the education of the deaf. Where proper measures are taken, the number of the deaf is reduced and their disability is diminished.

Congenital deafness or deafness acquired in early childhood creates the serious problem of mutism, which isolates the patients from the community and deprives them of educational opportunities. Several methods have been invented to endow them with a conventional

[1] MARIE, P., Révision de la question de l'aphasie, *Sem. med.*, p. 241, 1906.

language. The manual method invented by de l'Epée and the oral method of Heinecke have been greatly developed and are widely used in the education of the deaf.

1. The manual method uses a special alphabet consisting of signs made by one or both hands. Words are formed, as if these signs were letters. It is therefore a kind of written language. The drawback of this type of language is that it cannot be understood by the general population but only by those who have learned it.
2. The oral method teaches the deaf-mute to form phones and words with his voice. He is taught to correlate respiratory movements, movements of the lips, and speech vibrations in the thorax and larynx with the emission of vocal sounds. He thus learns how to speak, graduating the rhythm, pitch, and volume of his voice, and how to understand the spoken word by lip-reading. Training should be commenced at an early age to avoid mental and educational backwardness; usually special schools admit children from two to six years old. Persons who have become deaf in adult life also derive benefit from this type of training.

Deafness creates not only medical and educational problems but also psychological and social ones. It undoubtedly restricts the activity of the disabled person, but it does not close many useful manual and intellectual pursuits, and has its compensation in the development of greater acuity in other senses and in freedom from noise. Edison considered his deafness an advantage because it permitted a greater degree of mental concentration. Education of deaf children and adults is of great importance if the consequences of isolation, which often lead to social maladjustments, are to be avoided.

CHAPTER 81

The Regulation of Posture

THE DIFFERENT PARTS of the body are disposed in relation to each other, and the whole body in relation to the environment, in a manner typical for each species; *e.g.*, the upright posture in man. There are also individual differences in posture, which may be as characteristic as the facial features, height, or any other anatomic trait.

In many invertebrates, posture is passive; *i.e.*, it depends on the form of the organism and the effects of external forces, such as gravity, tropisms, and the resistance of the environment. Posture is actively adopted in vertebrates; *i.e.*, it is produced, maintained, and restored by a series of coordinated reflexes. Postural reflexes are usually unconscious, unaccompanied by pleasurable or painful sensations, and they can be maintained for a long time without fatigue. In lower animals postural reactions are not greatly disturbed by removal of the cortex; a "thalamic animal," *i.e.*, an animal in which the brain stem has been cut just below the thalamus so that the midbrain centers remain intact, maintains and can reacquire a normal posture. Certain postural reactions (*e.g.*, the so-called "placing" reactions) are integrated in the cortex, and as encephalization increases, the importance of cortical integration also increases. The extensors of the limbs and the vertebral muscles play a preponderant part in the performance of postural reflexes, but many other muscles also concur.

Stimulation of proprioceptive receptors is the main source of postural reflexes—in the first place, impulses from proprioceptive receptors in muscles. Thus if the dorsal spinal roots corresponding to a limb are cut (deafferentation), the limb loses its tonus and becomes flaccid. The labyrinth and the receptors in the ligaments of the upper cervical joints play a special part in postural reflexes. Photoreceptors and tactile receptors also may give rise to postural reactions, but they are less important and are usually supplementary to proprioceptive reflexes.

MUSCLE TONUS

Posture is built on muscle tonus, which is a muscular contraction maintained by asynchronous impulses of low frequency, discharged by the spinal motor neurons. Sherrington's myotatic (μῦς, muscle, and τατος, extended), or stretch, reflex is the primary tonic reflex

THE MYOTATIC, OR STRETCH, REFLEX

"If the tendon of a healthy muscle is drawn upon by an antagonistic muscle or by the manipulations of the investigator or by the movement of a joint in response to gravity, the muscle actively resists the extending force. A muscle which has been paralysed by section of its motor-nerve or of the ventral or dorsal roots supplying it, does not actively resist and behaves like a piece of non-contractile tissue. . . . The resistance . . . is a reflex contraction, the stretch reflex" (Sherrington). The full response can be obtained after the skin of the limb has been removed or the nerves to all the muscles except the one stretched have been cut. The reflex, therefore, arises in the receptors of the stretched muscle.

The reflex nature of the response is confirmed by the fact that it can be inhibited. Thus centripetal stimulation of a cutaneous nerve of a limb suppresses contraction provoked by stretching in the quadriceps femoris or any other extensor. Inhibition can be obtained by exerting tension on the tendon of an antagonist, *e.g.*, the

biceps femoris in the case of the quadriceps (Fig. 472). Contraction of the muscle itself also inhibits the stretch reflex (autogenous inhibition).

There are two components in the stretch reflex, a "phasic reaction" or stretch movement, in which tension increases, and a "static reaction" or stretch posture, in which tension is maintained, usually declining slightly after the peak has been reached. The phasic reaction is observed when a tendon is stretched suddenly by a tap, *e.g.*, on the patellar tendon or Achilles tendon. The stretch receptors in the tendon discharge an almost synchronous volley of centripetal impulses, which builds up a central excitatory state and excites a number of motor neurons. A brief contraction follows, *i.e.*, a tendon jerk, such as the knee jerk.

FIG. 472. Myotatic reflex. Rectus femoris is stretched 8 mm. by lowering the table. The dotted line *T* indicates table fall; *M*, reaction of uninhibited muscle; *I*, reaction of muscle inhibited by stretching the tendons of the antagonistic flexors; *P*, reaction of muscle paralyzed by nerve section (broken line). Ordinate, tension in kilograms; abscissa, time in seconds. (*Creed et al., "Reflex Activity of the Spinal Cord," Oxford, New York, 1942, p. 50.*)

The nerve impulses of the stretch reflex are transmitted along large axons at high speed, in both the afferent and efferent limbs of the reflex arc. Afferent fibers of muscles are distributed in three groups, named groups I, II, and III in order of descending caliber, with diameters about 16 μ, 8 μ, and 4 μ respectively.[1] Muscle spindles and Golgi tendon organs are innervated by group I fibers, which have the highest velocity of conduction. Stimulation of these fibers evokes monosynaptic reflex discharges with the same latency as the reflex discharges evoked by stretching the muscle. Moreover, these monosynaptic discharges are evoked only in the motor neurons corresponding to the muscle innervated by the afferent fibers which have been stimulated, *i.e.*, they have the same characteristics as those producing the stretch reflex. The myotatic reflex is therefore a monosynaptic reflex.[1]

A record of the electrical activity of the muscle shows that when it is completely relaxed there are no action currents. If the muscle is stretched slightly, action currents are recorded, beginning at a low rate of about 7 per second; the rate of firing increases as greater tension is exerted on the tendon. This effect is due to an increase in the rate of discharge in the motor units engaged, a fact that can be demonstrated by cutting down the ventral roots so that only one or a few motor units can respond. On increasing the tension, the frequency of the impulses rises from 7 to about 20. If the tension is increased even more, units hitherto at rest are "recruited" and become active, but the different motor units discharge asynchronously; therefore the apparent frequency may rise to 200 or 250 per second, although the actual frequency of discharge of any one neuron is only 30 or 40 per second. If the tension exerted on the tendon is decreased, the units are "disbanded," *i.e.*, they gradually fall out of activity and the strength of the contraction diminishes.

In spite of the low frequency of discharge, the muscle as a whole contracts smoothly. Oscillations are not apparent, owing to three factors: (*a*) the muscle fibers of a motor unit are not bunched together, but are distributed throughout the length of the muscle, so that the tension developed by the different fibers is also distributed throughout the whole muscle; (*b*) asynchronous activation of the different units contributes to damp the oscillatory effect of the subtetanic contraction of each unit; (*c*) muscle fibers taking part in sustained myotatic reflexes are mostly of the "slow" type, *i.e.*, they have a long contraction time (100 to 200 msec.); therefore complete tetanus is provoked by discharges of lower frequency than those necessary to provoke it in faster fibers.

The threshold of the stretch reflex and the strength of the contraction vary in different muscles. They are more highly developed in muscles that counteract the effect of gravity than in others, *e.g.*, the extensors of the limbs. These are

[1] REXED, B., and P. O. THERMAN, *J. Neurophysiol.*, **11**, 133, 1948; LLOYD, D. P. C., and H. T. CHANG, *J. Neurophysiol.*, **11**, 199, 1948.

[1] LLOYD, D. P. C., *J. Neurophysiol.*, **6**, 293 and 317, 1943.

"red," "slow" muscles, with abundant sarcoplasm and long contraction time.

In "fast" muscles, *e.g.*, the flexors, the phasic reaction is well in evidence, but the static reaction is not. When the tendon is stretched the muscle contracts, but soon it relaxes. Tendon jerks or "pluck" reflexes are elicited, but sustained tension (stretch posture) is not observed.

An outstanding feature of stretch reflexes is the restriction of the response to the muscle, or the part of the muscle, on which tension is exerted.

Stimulation of group I afferent fibers not only evokes discharges from the motor neurons corresponding to the muscle, or part of the muscle to which they supply afferent innervation, but also impinges directly on the immediate synergists and antagonists, producing monosynaptic facilitation in the former and inhibition in the latter. The greatest facilitatory effect is obtained when the conditioning and test volleys coincide in time; facilitation decays exponentially, falling to half in about 4 msec. The direct inhibitory effect on the antagonists, after a brief rising phase, also decays exponentially.[1] Lloyd refers to this group of muscles bound to each other into mutual dependence by monosynaptic interconnections, together with the monosynaptic links that bind them, as a "myotatic unit."[2]

Stimulation of fibers in groups II and III, which have a higher threshold and a lower velocity of conduction than group I fibers, evokes flexor responses; also facilitation or inhibition of monosynaptic reflexes by intercalated interneurons.

Lengthening and shortening reactions. Two aspects of the stretch reflex, *i.e.*, the lengthening and shortening reactions, are prominent in the decerebrate preparation. If an attempt is made to bend the knee of an animal in decerebrate rigidity, the extensor muscles resist up to a point, after which they suddenly give way and the limb can be flexed; there is a "clasp-knife" effect. This is caused by inhibition of the stretch reflex (autogenic inhibition), due to excessive tension, and is known as the lengthening reaction. If on the contrary the flexed limb of a decerebrate preparation is extended, the extensors relax for a moment and then shorten so as to hold the limb in the new position. This is the shortening reaction. Both these reactions endow the decerebrate animal with the capacity to hold a given position.

The stretch reflex is fundamentally a spinal reaction. It is observed in spinal animals, but it is modified by facilitatory and inhibitory impulses from higher centers, which are of great importance in the regulation of tonus and postural reactions. The spinal animal will be considered first, and then other preparations such as the decerebrate animal, in which the midbrain centers also remain intact.

The Spinal Animal

Spinal shock. Immediately after a transverse section of the spinal cord has been performed, the following effects are observed in the segments below the level of the section: (*a*) complete anesthesia;[1] (*b*) paralysis; (*c*) flaccidity of the muscles (loss of tonus); (*d*) suppression of somatic and visceral reflexes. Paralysis and the loss of sensation are permanent disabilities due to section of the ascending (spinothalamic) and descending (pyramidal) tracts, the fibers of which do not regenerate.

Depression of reflexes is the outstanding sign of spinal shock, but it is not permanent. It is more marked and lasts longer as encephalization increases. In amphibians it lasts a very short time, and a few minutes after spinal-cord section, reflex responses of normal strength can be elicited. In the cat the depression lasts longer, and in the dog it is even more prolonged; in primates, shock may last for several days, which lengthen into weeks in the anthropoids and man.

The first reflex to reappear after transection of the spinal cord is the flexion reflex. At first there is only a limited response to strong stimulation of the distal end of the limb. Later it increases in strength and amplitude, and eventually hyporeflexia is replaced by hyperreflexia. The knee jerk is the first extensor reflex to reappear; in the cat sometimes it is not completely suppressed, but only depressed. The phasic reaction of myotatic reflexes is recovered fairly soon, but the static reaction remains depressed for weeks, even in the cat and dog. Flaccidity, typical of spinal shock, is due to this depression of the

[1] *Ibid.*, **9**, 421, 1946.

[2] Lloyd, D. P. C., *Research Publ., A. Nerv. & Ment. Dis.*, **30**, 48, 1950.

[1] Some patients complain of pain (poorly localized) below the level of the injury. This pain is probably due to pain afferent fibers in the sympathetic which enter the cord at a higher level.

stretch reflex. The crossed-extension reflex reappears when there is already a well-developed flexion reflex. Cutaneous reflexes, such as the scratch reflex, which involve several spinal segments, are recovered later. In this sequence the early recovery of defense reflexes in response to nocuous stimuli is conspicuous. Reflexes arising in proprioceptors, with the exception of tendon jerks, reappear much later. The predominance of flexion over extension is demonstrated very vividly by transection of the spinal cord in a decerebrate animal with fully developed rigidity due to hyperactivity of the stretch reflexes. Rigidity is rapidly replaced by flaccidity and the threshold of extensor reflexes rises as the threshold for flexor reflexes diminishes.

Visceral reflexes are also depressed in spinal shock. The blood pressure falls owing to loss of vasomotor tonus, and pressor reflexes cannot be elicited. After a few days (in the dog) the blood pressure may be higher, but pressor reflexes are not recovered even after a long period of time. Sweat secretion is abolished, and the skin is dry; owing to vasodilatation, it is pink and warm.

Reflex evacuation of the bladder and rectum are not performed. Immediately after transection, the sphincters of the bladder are strongly contracted and there is retention of urine, which has to be evacuated by catheterization. After about three weeks in man, bladder reflexes are partially restored, but the sphincters tend to become incompetent. The bladder, however, is not evacuated completely. Microorganisms grow in the residual urine, which may cause inflammation of the bladder (cystitis). Reflex evacuation of the rectum is recovered after 3 or 4 weeks.

Other visceral functions are also recovered, including those of sex. Ovulation, impregnation, pregnancy, and parturition have been observed in bitches after complete spinal transection at the level of the lower cervical or upper thoracic segments.

Spinal shock is particularly severe in man.[1] All reflexes are completely suppressed for several weeks in most cases, but in some individuals reflexes from the perineum and genital area are never lost, and in others superficial reflexes reappear within 24 hr. after the cord has been cut.[2] After 2 or 3 weeks the flexion reflex reappears in response to strong stimulation of the plantar surface. At first there is only slight withdrawal, which gradually becomes more vigorous. A peculiar aspect of this response is the extension of the toes, especially of the big toe; this is known as "Babinski's sign" and is always accompanied by contraction of the hamstrings.[1] Babinski's sign is evidence of pyramidal-tract injury and is observed when this tract is damaged, even if the rest of the nervous system is uninjured. The knee jerk reappears later, and the crossed-extension reflex is not restored until 6 or 7 weeks have passed.

[1] Head, H., and G. Riddoch, *Brain*, **40**, 188, 1917.

[2] Kuhn, R. A., *J. Nerv. & Ment. Dis.*, **113**, 301, 1951.

The flexion reflex gradually becomes exaggerated, and after several months cutaneous stimuli provoke a widespread response, with complete withdrawal of the limb, profuse sweating, and evacuation of the bladder and rectum. This is known as the "mass reflex." Many months after spinal-cord transection, a slight degree of postural extension may be observed, but spasticity occurs only in cases of incomplete transection. Reflex rigidity can be provoked several months after the cord has been cut by pressure against the popliteal region. All the muscles innervated by the distal segment of the cord contract and form a rigid framework, so that the patient can stand up without support. Later the muscles relax simultaneously, and the patient collapses if not supported.

Section of the cord above the emergence of the phrenic nerves causes death by asphyxia because respiration ceases. If the section falls below the fourth cervical segment, there is quadriplegia (paralysis of the four limbs) but the respiratory movements of the diaphragm are not disturbed. The effects of shock in the lower limbs are less marked in cases of transection at a high level than when the injury involves the lower segments of the cord; frequently there is priapism (persistent erection of the penis).

The nervous mechanism of spinal shock. Spinal shock is due to the sudden suppression of impulses descending from the upper centers to the motor neurons in the spinal cord. It is not due to trauma or irritation at the level of injury, because its severity is the same whether a clean section is made or several segments are crushed. Moreover if a second section is made below a previous transection, after the animal has re-

[1] Fulton, J. F., and A. D. Keller, "The Sign of Babinski. A Study of the Evolution of Cortical Dominance," Charles C Thomas, Springfield, Ill., 1932.

covered from the effects of the first operation, spinal shock does not occur again.

In the cat, the dorsal two-thirds of the cord can be cut without provoking shock, but section of the ventral columns is followed by shock. Impulses that protect the animal from shock descend in the vestibulospinal tract and in fibers of the reticulospinal tract.[1] Shock is not provoked if the section is made above the level of the vestibular nuclei; on the other hand, destruction of these nuclei produces shock.

In primates, corticospinal impulses are of greater, and vestibulospinal impulses of lesser, importance. Only slight reflex depression follows destruction of the vestibular nuclei, while destruction of the motor cortex causes marked signs of shock.

In lower animals (*e.g.*, amphibians) spinal reflexes are carried out with little or no interference from the higher centers, but as these centers become more developed, their importance in all nervous activity increases. In primates encephalization is at its highest, and even spinal activity cannot be normally carried out without the involvement of supraspinal centers. Impulses from these centers either facilitate or inhibit spinal mechanisms, which can be depressed owing to the absence of facilitatory impulses, or enhanced owing to release from inhibition.

The spinal animal at first shows the effects of the absence of facilitating impulses descending

FIG. 473. Brown-Séquard syndrome. Effects following section of left half of the cord.

[1] FULTON, J. F., E. G. T. LIDDELL, and D. McK. RIOCH, *Brain*, *53*, 311 and 327, 1930.

from the higher centers, and spinal reflexes are depressed. Later a more primitive, purely spinal, equilibrium is established; spinal mechanism alone can integrate simple reactions such as defensive and visceral reflexes. Later still the phenomena of release, *i.e.*, absence of inhibition, become prominent and the mass reflex is observed because the central excitatory state spreads, without order or inhibitory control, to a large number of spinal reflex centers.
a
b
c

FIG. 474. Complete section of spinal cord at upper lumbar segments. *a*, the animal lying quietly; note extension of forelimbs; *b*, the animal's attention is awakened; note flexion of forelimbs; *c*, the animal walks dragging its hindquarters and leaving a trail of urine because of incontinence of the bladder.

Incomplete transection of the spinal cord. Brown-Séquard syndrome. In 1855 the French-American scientist Brown-Séquard described the effects of lateral semisection of the spinal cord (Fig. 473). The following effects are observed in the segments below, and on the same side as, the lesion: (*a*) paralysis, *i.e.*, loss of voluntary movements, due to section of the pyramidal tract; (*b*) loss of proprioceptive sensibility due to section of the dorsal column (cuneate and gracile fasciculi); (*c*) transitory cutaneous hyperesthesia; (*d*) at first, depression of spinal reflexes owing to the absence of facilitatory impulses mediated by the vestibulospinal and pyramidal tracts, and later release phenomena (hyperreflexia); (*e*) at the level of the lesion, if several segments have been involved, an area of complete anesthesia owing to destruction of the dorsal roots, and above it an area of hyperesthesia corresponding to the incompletely denervated dermatome; (*f*) transitory increase in skin temperature due to cutaneous vasodilatation.

On the side opposite the lesion there is cutaneous anesthesia due to section of the spinothalamic tract. Temperature sensations and pain are more severely involved, while tactile sensations are not disturbed, except in a few segments immediately below the lesion. Proprioceptive sensibility and voluntary and reflex movements are normal.

Hemisection of the dorsal quadrants of the spinal cord causes the loss of proprioceptive sensations (section of the dorsal columns) and paralysis (section of the pyramidal tract), usually accompanied by spasticity. The limbs are extended, not flexed as occurs after the signs of shock have receded in cases of complete transection. Extensor spasms can be provoked only if the vestibulospinal tract and the corticospinal paths have not been completely severed.

Lesions that involve only one ventral quadrant produce cutaneous anesthesia (mainly the suppression of thermal sensations and pain) on the side opposite to the injury. This is due to section of lateral spinothalamic pathways. There is also a tendency to paresia and flaccidity due to section of the vestibulospinal and part of the corticospinal tracts.

Schiff-Sherrington phenomenon. A dog or a cat, after complete transection of the cord at

the level of the thoracic segments, shows signs of disturbed function not only below the lesion, but also in the segments above it. There is usually an increase in extensor tonus in the forelimbs; the animals lie with their hind limbs flaccid and the forelimbs spastically extended (Fig. 474). This phenomenon is partly due to release from inhibitory impulses arising in the hind limbs and integrated in the cerebellum. The following facts are evidence of this assertion:[1] (*a*) hind-limb deafferentation in decerebrate animals converts into rigidity the flaccidity of a deafferented forelimb; (*b*) transection of the spinal cord at the thoracic level, or extirpation of the anterior lobe of the cerebellum, has the same effect; (*c*) ipsilateral labyrinthectomy immediately suppresses this rigidity. Tonic impulses from the labyrinth to the forelimb are, therefore, inhibited by impulses from the cerebellum which arise in the receptors of the hind limb. The Schiff-Sherrington phenomenon is not, however, exclusively due to release from cerebellar inhibition, because rigidity in the deafferented forelimb has been observed after extirpation of the cerebellum. Moreover, if the cord is cut at the level of the thoracic segment and later a second transection is made between the lumbar and sacra segments, the knee jerk and postural tonus of the quadriceps (integrated at the fourth and fifth lumbar segments) are increased. There is therefore a spinal component in this phenomenon. Impulses from the hind-limb receptors are not the only source of inhibitory impulses, because extension of the forelimbs is also observed if the cord is cut after lumbosacral deafferentation.[2]

Decerebrate Rigidity

If the brain stem of a cat or a dog is cut between the superior and inferior colliculi, marked rigidity develops (decerebrate rigidity). In whatever position the animal is placed, its four limbs are kept rigidly extended. The head, the spinal column (opisthotonus), and the tail are also extended. The jaws are firmly clamped. The animal cannot stand up, since it has lost the righting reflexes, but if it is placed on its feet, it stands on its toes.

Deafferentation of a muscle (section of the corresponding dorsal roots) suppresses rigidity in that muscle, but not in others. Rigidity therefore arises in the muscle receptors (muscle spindles) and is simply an exaggeration of the myotatic reflexes, especially developed in those muscles which counteract the effects of gravity. The deafferented muscles can, however, respond reflexly to impulses arising in other receptors, *e.g.*, they can take part in the crossed-extension reflex and in labyrinthine reactions.

Rigidity can be suppressed by inhibition. Thus stimulation of the motor nerve of an antagonistic muscle, *e.g.*, the biceps femoris, causes the quadriceps to become flaccid. The same effect is observed after stimulation of a cutaneous nerve, which provokes a flexion reflex.

Rigidity is more marked in muscles that counteract the effects of gravity, but it is also evident in the flexors, which respond to a pull on the tendon with clonic (repeated) contractions, not simply by a "pluck" reflex. The threshold of flexor reflexes is, however, high, while that of extensor reflexes is low, in the decerebrate preparation—a condition opposite to that observed in the spinal animal.[1]

The nervous mechanism of decerebrate rigidity. Rigidity is due to exaggerated stretch reflexes owing to suppression of inhibitory impulses and predominance of facilitatory impulses descending from centers above the spinal level. Thus transection of the ascending tracts in the dorsal columns of the spinal cord does not modify rigidity. Transection of the anteroventral column suppresses it on the same side in the segments below the section. Magnus endeavored to localize the centers responsible for rigidity in the cat by transecting the brain stem at different levels. Rigidity developed when the section was made between the anterior and posterior colliculi; sections at higher levels did not provoke it. Sections at lower levels did not modify rigidity until the vestibular nuclei were excluded, in which case it was abolished, the preparation becoming flaccid.

Transection between the colliculi excludes the red nucleus, and rigidity may be observed when only the parvicellular portion of the red nucleus has been excluded. Complete destruction of the red nuclei or their descending projections by

[1] Stella, G., *Boll. Soc. ital. biol. sper.*, **22**, 78 and 81, 1946.

[2] Ruch, T. C., *Am. J. Physiol.*, **114**, 457, 1935.

[1] The postural significance of decerebrate rigidity is evident in the three-toed sloth. This animal normally counteracts the effects of gravity with its flexor muscles. Decerebration causes rigidity to develop in these muscles and exaggerated flexion is observed (Richter, C. P., and L. H. Bartemeier, *Brain*, **49**, 207, 1926).

means of restricted lesions does not, however, provoke rigidity in the cat. The animals show signs of disturbance in cerebellar function (see Chap. 83), and a mild degree of extensor hypertonus in certain conditions, but "decerebrate rigidity" is not provoked by this operation.[1] The red nucleus alone, therefore, cannot be responsible for the inhibitory impulses that prevent the development of rigidity.

Magoun[2] and his associates have demonstrated the importance of inhibitory influences from the bulbar reticular formation. In an anesthetized animal with a background of motor activity, stimulation of the reticular formation at the bulbar level, especially in the ventromedial area, produces complete cessation of movements. Two-neuron stretch reflexes, multineuron flexor movements, and movements originated in the cortex are inhibited. This suppressor effect has a low threshold, and the impulses are conducted at a high velocity. The descending path is found in the anterolateral column of the spinal cord, and it ends in the lateral portion of the intermediate interneuron pool.[3] This path is for the most part ipsilateral, but there is some crossing over at the spinal level. Facilitation can also be obtained by stimulation of the reticular formation, at the bulbar level laterally to the inhibitory areas,[4] but more especially above the bulbar level up to the diencephalon (mid-line and intralaminar nuclei of the thalamus, subthalamus, and hypothalamus). Facilitation affects all types of movement; it has a low threshold, and the impulses are conducted in fast fibers. The descending path has several relays; in the spinal cord it overlaps the inhibitory pathway. Direct endings on the spinal motor neurons give only minor facilitation, but the descending fibers give out many large collaterals to interneurons with short fibers, which activate many motor neurons and moreover recruit other interneurons, thus facilitating and synchronizing discharges from a large number of motor neurons.

Extirpation of the frontal cortex is followed by rigidity, especially marked in primates. Re-

[4] RHINES R., and H. W. MAGOUN, *J. Neurophysiol.*, **9**, 219, 1946.

moval of the premotor cortex alone has the same effect. Inhibitory impulses travel in fibers of the pyramidal tract, because stimulation of this tract suppresses rigidity provoked by transection of the midbrain below Forel's decussation; stimulation of the contralateral frontal cortex in these circumstances inhibits rigidity.[1] Inhibitory fibers have been traced descending from area 4*s* (see Chap. 82) in the internal capsule, down to the lower level of the pons where partial decussation takes place; these fibers end in the bulboreticular formation, where impulses that inhibit not only the myotatic reflex but also movements of cortical origin[2] are relayed to the motor centers of the spinal cord. Similar inhibitory impulses originated in areas 19*s* and 24*s* travel to the suppressor areas of the bulbar reticular formation.[3] Facilitatory impulses from area 6 in the frontal lobe are relayed in the midbrain tegmentum.[4] Depression of the electrical activity of the brain by intravenous injection of sodium cyanide is followed by a transient period of decerebrate rigidity, during which the electrical activity of the suppressor reticular formation is reduced, while the facilitatory reticular formation remains active. This effect is due to failure of inhibitory impulses from the cortex and persistence of facilitatory impulses from the tegmentum of the pons. If the pontile tegmentum has been previously damaged, cyanide injection does not provoke rigidity.[5]

Extirpation of the cerebellum or section of the superior cerebellar peduncles increases rigidity. An inhibitory pathway has been traced from the Purkinje cells in the anterior lobe and paramedium lobule of the cerebellar cortex to the fastigial nucleus, and thence to the bulboreticular formation.[6] Inhibitory impulses are not discharged from the fastigial nucleus after the cerebellar cortex has been removed. Spasticity can be produced by suppression of a single one of the inhibitory cortical areas, but the effects

[1] The pyramidal tract decussates at a lower level and is not cut by the section.

are transient. More pronounced and permanent effects are obtained by combined removal of cerebral and cerebellar inhibitory areas.[1]

In primates, including man, two types of rigidity have been described: (*a*) transection at a low mesencephalic level causes rigidity with the four limbs and the head extended (decerebrate rigidity); (*b*) transection at a higher level, or removal of the frontal lobe, causes rigidity with the upper limbs flexed and the lower limbs extended (decorticate rigidity) (Fig. 475).

Fig. 475. Magnus and de Kleijn reflexes in subject with "high" decerebration. On rotation of the head, the limbs on the cranial side are flexed, and those on the mandibular or facial side are extended. With the head in the "normal" position, *i.e.*, facing forward, the upper limbs are flexed and the lower limbs are extended.

Decerebrate rigidity is a classic example of a "release phenomenon." During the last century Jackson postulated that the "positive" symptoms of hemiplegia due to hemorrhage in the internal capsule (*i.e.*, hyperreflexia and spasticdity) were not caused by irritation of nerve paths, because they were permanent disabilities, but were caused by "release" of the lower centers from inhibitory impulses normally descending from the higher centers. This inhibitory effect is mediated mainly by the pontobulbar reticular formation. Spasticity caused by the destruction of the corticobulboreticular suppressor system is due to the unbalanced effect of the facilitatory system. The midbrain tegmentum is the main facilitatory center, because lesions above this level do not modify spasticity, but injury of the tegmentum reduces it considerably. Destruction of the vestibular nuclei does not modify spasticity when the midbrain reticular formation is active, but abolishes it when combined with removal of the latter.[1]

The diencephalic-midbrain facilitatory and suppressor systems also regulate the level of general cortical activity (see Chaps. 87 and 88).

Regulation of Muscle Tonus

Muscle tonus is fundamentally a reflex arising in the muscle itself, *i.e.*, the stretch reflex, which is more prominent in muscles counteracting the effect of gravity. The stretch reflex is facilitated by impulses descending from the motor cortex (area 4) the tegmentum and the vestibular nuclei. It is inhibited by impulses descending from the premotor cortex (4*s*) and the cerebellum, mainly through the reticular formation to the spinal motor centers. Suppression of facilitatory impulses causes depression of tonus for a certain time (*e.g.*, in spinal shock). Later a new equilibrium, in which flexor responses are predominant, is

[1] Lindsley, D. B., L. H. Schreiner, and H. W. Magoun, *J. Neurophysiol.*, **12**, 197, 1949.

[1] Schreiner, L. H., D. B. Lindsley, and H. W. Magoun, *J. Neurophysiol.*, **12**, 207, 1949.

established in the spinal cord. Suppression of inhibitory impulses is followed by an increase in tonus if the facilitatory impulses are active; there is rigidity, especially in muscles that counteract the effects of gravity, and extensor reflexes predominate.

The different centers that regulate tonus act not individually but coordinately, and their impulses are summated when they have similar effects. Spinal centers, vestibular nuclei, the tegmentum, and the motor cortex have a positive influence on tonus. Mesencephalic centers, the cerebellum, and the premotor cortex have a negative (inhibitory) influence. Muscle tonus is regulated by the interplay of the two mechanisms.

POSTURAL REFLEXES

Magnus classified postural reflexes into (*a*) static reactions and (*b*) statokinetic reactions. Static reactions come into play when the body is resting; they are responsible for the establishment and maintenance of posture. They may be limited to a single limb (local static reactions) or may involve the whole segment (segmental static reactions). More complex responses are carried out by more than one spinal segment (intersegmental reactions) or they may also involve supraspinal centers (general static reactions). Statokinetic reactions are observed when the body is moving, *e.g.*, walking or running.

Local static reactions. "A movable limb is at times used as an instrument for very different purposes (such as scraping, scratching, fighting, etc.) and moves freely in all joints, whereas at other times it is transformed into a stiff and strong pillar, which gives the impression of being one solid column, able to carry the weight of the body."[1] The coordinated reflex responses that fix the joints into a column constitute Magnus's "positive supporting reaction." The column is broken down, and the limb set free so that it can be moved, by another series of reflexes known as the "negative supporting reaction." The stretch reflex plays a fundamental, but not exclusive, part in the formation of the column; there is also synergical contraction of extensors and flexors, abductors and adductors, which in this reaction do not act as antagonists as they do in phasic reactions.

The positive supporting reaction is initiated in two kinds of receptors; (*a*) proprioceptors in the small muscles of the foot, *i.e.*, stretch receptors in the interosseus muscles stimulated by separation of the toes, and in plantar flexors stretched by dorsal flexion of the foot; (*b*) exteroceptors, *i.e.*, tactile receptors in the skin of the plantar surface. In the decerebellate dog, Magnus saw that a light tactile stimulus on the plantar surface of the toe pads provoked extension, so that the foot seemed to be attracted by the observer's stimulating finger as by a magnet ("magnet reaction"). This reaction is reduced to the extensor thrust provoked by pressure exerted on the plantar surface, in the spinal preparation. When the animal stands on its feet, both types of receptor are stimulated and the effects are summated. An increase in the load on the supporting column increases the strength of stimulation and provokes a more vigorous reflex response, which reinforces the column.

The negative supporting reaction that releases the limb is initiated by (*a*) suppression of stimuli for the positive supporting reaction, *e.g.*, taking the load off the limb; (*b*) inhibition of the positive reaction by plantar flexion or by the application of a stimulus that provokes a preponderant phasic reflex, *e.g.*, defensive withdrawal of the limb.

Segmental static reactions. The crossed-extension reflex is one example of a postural reaction that involves both sides of a segment. Another is reflex extension, produced by stretching the adductors of the opposite limb. This occurs when the weight of the body is supported on one foot and the subject leans to the opposite side; the adductors are stretched and the opposite limb is extended, thus preventing the body from falling.

Intersegmental static reactions. The effects on the limbs of flexion or extension of the trunk are good examples of postural reactions carried out by several spinal segments. Flexion of the trunk increases extensor tonus in the hind limb and diminishes it in the forelimb; extension of the trunk has the opposite effect.

General static reactions. The position of the head is a predominant factor in reflex stance. Reflexes are initiated in (*a*) the proprioceptors in the neck; (*b*) the labyrinth. Both types of receptors are stimulated by changes in the position of the head, and they produce effects that reinforce each other. Labyrinthine reactions can be suppressed by destroying the labyrinth, or the neck reflexes can be suppressed by immobi-

[1] Magnus, R., *Lancet*, **2**, 531 and 585, 1926.

lizing the neck in a plaster cast. In order to avoid the effects of the righting reactions, decerebrate animals are used in the analysis of these phenomena.

Tonic neck reflexes. These reflexes can be examined in the decerebrate preparation after bilateral labyrinthectomy. The following effects are observed:

1. Rotation of the head produces an increase in extensor tonus in the forelimb and hind limb on the side toward which the face is turned and a decrease in extensor tonus (flexion) on the opposite side.
2. Inclination of the head toward one side increases extensor tonus on that side and decreases it on the opposite side.
3. Extension of the head by bending the neck backward increases extensor tonus in the forelimb and diminishes it in the hind limb.
4. Flexion of the head increases extensor tonus in the hind limb and diminishes it in the forelimb.
5. Pressure exerted on the spinous process of the last cervical vertebra diminishes extensor tonus (*i.e.*, produces flexion) in the four limbs.

Section of the three upper cervical dorsal roots suppresses these reflexes. Tonic neck reflexes do not arise in the neck muscles, because they can be evoked after bilateral section of all the muscular and cutaneous branches of the first three cervical nerves and denervation of all the muscles in the neck. They arise in the ligaments of the upper cervical joints, especially the occipitoatlantal, and atlantoaxial joints.[1]

Tonic labyrinthine reflexes. These reflexes can be observed without the complicating effects of neck and other reflexes in decerebrate animals with the neck fixed in a plaster cast, or after the three upper cervical dorsal roots have been cut. The following are the main reactions:

1. Lateral inclination of the head increases extensor tonus in both limbs on the side toward which the head is bent and diminishes it on the opposite side.
2. When the animal is placed on its back, the extensor tonus of the four limbs increases; maximal effects are observed when the mouth cleft is inclined upward at 45° to the horizontal.
3. When the animal is placed on its belly, extensor tonus decreases in the four limbs; maximal effects are observed when the mouth cleft is inclined downward 45° to the horizontal, *i.e.*, the animal has rotated on a transverse axis 180° from the position it occupied when extensor tonus was at a maximum.
4. Rotation on a vertical (longitudinal) axis does not provoke static labyrinthine reactions, because the receptors (otolith organs) are not stimulated by changes in position that take place in a horizontal plane.

[1] McCouch, G. P., *et al.*, *J. Neurophysiol.*, **14**, 191, 1951.

Labyrinthine reflexes have a direct effect on muscle tonus and an indirect effect produced by stimulation of the receptors in the neck when the head changes its position. In the intact animal, the effects of labyrinth and neck reflexes are summated when the head is inclined sideways. When the head is flexed or extended, the effects are summated in the forelimbs, but are of opposite sign in the hind limbs. The total effect will therefore be greater on the forelimbs than on the hind limbs.

Static labyrinthine reflexes are due to the position and not to movements of the head; bilateral destruction of the labyrinth suppresses them.

Cases of brain tumors have been observed in man in which the connections of the cortex with the lower centers are interrupted. Such patients are the equivalent of decorticate or thalamic animals. Tonic neck and labyrinth reflexes are prominent features in these subjects (Fig. 475).

Righting reactions. Normal animals acquire and maintain posture by a series of reactions initiated in several types of receptor. These reflexes can best be analyzed in the decorticate or thalamic animal, *i.e.*, after all cortical impulses have been suppressed. The different receptors are then inactivated except for the one that is under observation. The animal is in the "zero condition" when all stimuli capable of provoking postural reflexes have been eliminated. This condition is achieved when the animal has its neck fixed in a plaster cast or the upper cervical roots cut, has both labyrinths destroyed, and is held in the air taking care to exert pressure symmetrically on the body. If the cortex is intact, cats, dogs, and primates must be blindfolded, because in these animals visual stimuli are im-

portant factors in righting reactions. The following are the righting reflexes:

Labyrinthine righting reflexes. If an animal is held in the air the head tends to regain the normal position. After bilateral labyrinthectomy or section of the vestibular branch of the eighth nerve, the head hangs loosely under the action of gravity.

Body righting reflexes. If pressure is exerted on one side of the body of a labyrinthectomized animal, the head tends to assume the normal position. If the pressure is exerted symmetrically on both sides, the head hangs loosely.

Neck righting reflexes. When the head is turned to the normal position, the proprioceptors in the neck are stimulated and reflexes righting the thorax and pelvis are initiated.

Reflexes from the trunk acting on the body. If an animal in which labyrinthine and neck reflexes have been suppressed is placed lying on one side, the head and body are righted. The body is righted even if the head is fixed and prevented from returning to the normal position. This is due to pressure exerted on the undersurface of the body, as can be demonstrated by placing a board on the upper side of the animal and exerting a pressure equivalent to its weight; in this case the animal does not right itself.

Visual righting reflexes. In primates, and in cats and dogs, visual stimuli are of considerable importance in righting reactions, and the normal position can be restored in these animals even if all other stimuli for postural reflexes are suppressed. These reflexes are not observed after the occipital cortex has been removed, therefore they are not seen in thalamic animals.

Placing reactions. The feet are placed in a position suitable for normal standing by means of the so-called "placing reactions,"[1] which are initiated by visual, cutaneous, and proprioceptive stimuli. For example, when an animal is moved downward toward a supporting surface the limbs are stretched so as to support the body. This reaction is due mainly to visual stimuli (visual placing), but a blindfolded animal will also present it if it is moved downward at a speed sufficient to stimulate the labyrinth (vestibular placing). If the visual and vestibular placing reactions are suppressed, the animal "places" its foot as soon as the slightest contact is established between the limb and the edge of the table (contact placing). Extirpation of the cortex suppresses placing reactions on the opposite side of the body. In the cat and monkey the cortical centers are found in the motor cortex. In the monkey placing reactions persist after extensive cortical extirpation if the motor area (4) remains intact; destruction of this area abolishes placing reactions (Bard).

Hopping reactions. If an animal having its body supported by a single limb is displaced in a horizontal plane, the leg hops in the direction of the displacement so that it is kept below the body and can continue to support the animal. The reaction is initiated by stretching of the adductor muscles, and it is temporarily depressed by removal of the cortex.

Compensatory eye movements. When the position of the head is altered, the eyes move so as to keep the eye fields approximately unchanged. The reactions consist of two phases: (*a*) the eyes are first placed in the new position by contraction and relaxation of the corresponding muscles; (*b*) the eyes are then tonically fixed in the final position. Stimulation of the semicircular canals initiates the statokinetic phase, and stimulation of the utricle is responsible for the tonic or static phase. Impulses from proprioceptors in the muscles of the neck have the same effect as, and summate with, the labyrinthine reflexes.

The following are the principal reactions: (*a*) flexion of the head provokes contraction of the superior rectus and inhibition of the inferior rectus; (*b*) extension of the head has the opposite effects; (*c*) rotation of the head provokes contraction of the medial rectus of the eye on the side toward which the head is turned and of the lateral rectus of the other eye; the corresponding lateral and medial rectus muscles are relaxed. The utricle does not play any part in the latter reaction, because it is not stimulated by changes in the position of the head which take place in the horizontal plane.

Statokinetic reactions. These reactions are produced by movement, *i.e.*, positive or negative acceleration (increase or decrease in speed). They are observed when an animal moves in a horizontal plane or rotates around an axis. Thus when an animal is lifted up from a supporting surface it flexes its limbs and flexes the head; when it is moved downward, or dropped, the head and limbs are extended. When it is rotated, a series of compensatory movements take place in the eyes, head, and trunk which are

[1] Bard, P., *Harvey Lect.*, 33, 143, 1937–1938.

known as nystagmus. When the head rotates, the eyes move slowly in the direction opposite to that of rotation, tending to keep the eye fields unchanged, then by a quick movement the eyes are brought back to the normal position, *i.e.*, looking straight forward.[1]

Nystagmus may be horizontal, vertical, or rotatory according to whether its movements take place in the horizontal, sagittal, or frontal plane.

When the body rotates, the head turns slowly in a direction opposite to that of rotation and is then brought rapidly to the normal position; thus a "head nystagmus" results, with the rapid component in the same direction as that of rotation. The trunk also performs compensatory movements that tend to keep it in the normal position.

If rotation is kept up for a sufficient time, nystagmus ceases, because it is due to acceleration, not to movement in itself. When rotation ceases, nystagmus is again observed (postrotatory nystagmus) but in the opposite direction to that which occurred during rotation. The subject experiences a sensation of falling, and unnecessary compensatory movements are performed, which cause him to fall (see page 1032).

Changes in posture stimulate certain exteroceptive and proprioceptive receptors, and thus initiate compensatory static and statokinetic reactions. At the same time stimulation of other receptors ceases, and the postural reflexes that maintained the previously existing pose are suppressed. There are therefore positive (excitatory) and negative (inhibitory) postural reactions. The result of all these reactions is a posture that keeps the body in equilibrium under many different circumstances.

Centers that coordinate postural reactions. The "thalamic" animal can perform nearly all postural reflexes. It can therefore not only maintain a posture, but also right itself if placed in an abnormal position. (Lesions that reproduce in man the condition of the thalamic animal do, however, disturb postural reflexes, and the erect posture cannot be maintained.) Transection of the brain above the emergence of the third nerve does not disturb postural reflexes; transection below this point abolishes them. The cerebellum and the dorsal part of the midbrain can be removed without causing more than transitory disturbances in posture. Lesions in the ventral part of the midbrain cause severe alterations in postural reactions. The substantia nigra and the red nuclei can be destroyed without causing serious disturbances in postural reactions; the animal remains capable of righting itself and walking, even when it is blindfolded. Centers in the reticular formation have been shown to be of importance in the integration of postural reactions.

The cortex also plays a part in the integration of posture; thus optic impulses that give rise to postural reflexes are integrated in the occipital cortex, and the placing and hopping reactions are suppressed by extirpation of the motor cortex.[1] Ablation of the parietal cortex causes only a transitory depression of these reactions. Centripetal stimulation of the dorsal roots provokes electrical activity in the postcentral convolution which is not of tactile origin.[2] Stimulation of proprioceptors in cats and monkeys by means of passive movements or stimulation of a motor nerve provoked electrical activity in the cortex. In the cat the sensory motor area on the opposite side (sometimes on both sides) was activated; the temporal, parietal, and occipital lobes showed no changes. In the monkey areas 4 and 6 became active.[3]

FUNCTIONS OF THE LABYRINTH

The labyrinth consists of two parts: (*a*) the utricle and saccule; (*b*) the semicircular canals.

The maculae in the saccule and utricle are receptor organs innervated by the vestibular nerve. The hair cells of the maculae are covered by a mucous or gelatinous substance which contains calcareous bodies known as otoliths. When the head is in the normal position, the macula of the utricle is in an approximately horizontal position, with the otoliths lying on the hair cells. The macula of the saccule is placed on the lateral wall almost vertically, but slightly inclined so that the planes of the maculae of both sides are not parallel but form an angle opening downward and backward. When the head is in

[1] Usually the direction of nystagmus is given as that of the rapid component; *e.g.*, when the head rotates from left to right, the eyes first move slowly toward the left, then quickly to the right; this is known as nystagmus toward the right.

[1] BARD, *loc. cit.*

[2] WOOLSEY, C. N., H. T. CHANG, and P. BARD, *Federation Proc.*, **6**, 230, 1947.

[3] GAY, N. R., and E. GELLHORN, *Proc. Soc. Exper. Biol. & Med.*, **70**, 711, 1949.

the normal position, the otoliths are placed laterally on the hair cells, embedded in the mucous substance that covers them.

When the head is flexed or extended, the position of the otoliths in relation to the hair cells changes in the utricle. Lateral inclination of the head has the same effect on the otoliths of the saccule. Displacement of the body in a horizontal plane does not change the relative position of the otoliths in the utricle or the saccule. According to Magnus the otoliths stimulate the hair cells by pulling on them.

There are three semicircular canals in each labyrinth (Fig. 476). The external or horizontal canal has its convexity directed laterally and the ampulla forward; it is slightly inclined downward and backward, so that it forms an angle of 30° with the horizontal plane when the head is in the normal position. The anterior canals are placed vertically and in the same plane as the posterior canals on the opposite side; these planes form an angle of 45° with the mesial plane of the body (Fig. 477). The anterior canals have the ampulla forward and the posterior canal backward. The anterior end of the posterior canal is joined to the posterior end of the anterior canal, and both have a common opening in the utricle. The crista acustica lying within the ampulla is the receptor organ innervated by branches of the vestibular nerve. The crista is formed by cells with long cilia or hairs and supporting cells. The hairs are embedded in a gelatinous substance covering the crista, known as the cupula, which occupies the whole width of the canal. The lumen of the canal is filled with fluid called endolymph.
FIG. 476. Diagram of labyrinthine membranous structures and nerves. (*De Burlet, H. M., Anat. Anz., vol. 58, p. 26, 1924.*)

The functions of the labyrinth have been analyzed by observation of the effects of removing one or both labyrinths or of suppressing their activity by cocainization, and by stimulation of the different parts of the organ.

Unilateral labyrinthectomy. Destruction of one labyrinth is followed by asymmetrical reactions due to (*a*) the absence of impulses that

arise normally in the destroyed organ; (*b*) irritation of the vestibular nerve by operative trauma; (*c*) predominance of reflexes initiated in the intact labyrinth.

Ocular symptoms. The eye on the side of the lesion is deviated downward and outward; the eye on the opposite side is deviated upward and outward. There is nystagmus, with the fast component toward the normal side; this is due to irritation of the vestibular nerve and is abolished by cocainization.

Position of the head. The head is rotated so that the face is directed upward and toward the normal side. In some cases there is "head nystagmus."

Extensor tonus. Both limbs on the side corresponding to the lesion are flexed, owing to a decrease in extensor tonus. On the normal side, tonus is increased and the limbs are extended.

Abnormal motility. The animal falls toward the side corresponding to the lesion, owing to the lower extensor tonus. In an effort to compensate this and achieve the normal position, it rolls like a barrel. Ataxia (labyrinthine ataxia) is observed when the animal walks.

The effects are fairly rapidly compensated, and subsequent destruction of the other labyrinth causes reactions similar to those observed after the first operation, but on the opposite side, if the vestibular nuclei are intact on both sides.

Bilateral labyrinthectomy. A double labyrinthine syndrome is observed. The deviation of the eyes and head varies according to which side is more damaged or irritated. Extensor tonus is decreased on both sides, and there is complete loss of postural labyrinthine reflexes. The subject adopts a peculiar stance with widely separated legs, and locomotor ataxia is marked.

Eye and head reactions after unilateral labyrinthectomy are due directly to suppression of one labyrinth with predominance of the other. The effects in the trunk and limbs are caused in part by the abnormal position of the head, and they diminish when the head is rotated back to the normal position. Labyrinthectomy in fishes, birds, and certain mammals (*e.g.*, the rabbit) is followed by severe disturbances; in cats and dogs these disturbances are less severe, and their importance diminishes as encephalization progresses. In primates, especially in anthropoids and man, labyrinthectomy provokes milder and less durable symptoms than in lower animals. Section of the eighth nerve in man is followed by only slight and transitory labyrinthine symptoms.

Symptoms due to irritation of the vestibular nerve soon disappear. On the other hand, labyrinthine reactions are permanently lost after labyrinthectomy, a fact that can be demonstrated by means of several tests. Nevertheless disturbances due to the absence of these reactions are adequately compensated by visual, proprioceptive, and tactile reflexes.

ANTERIOR

POSTERIOR
Fig. 477. Diagram of position of semicircular canals.

Functional localization in the labyrinth. The functions of different parts of the labyrinth can be analyzed by destroying or stimulating one or another of them. Thus each one or all of the semicircular canals can be destroyed (Flourens) or stimulated (Ewald). Centrifugation at 1,000 to 2,000 rev./min. detaches the otoliths from the maculae of the saccule and utricle but does not damage the semicircular canals in guinea pigs.

Static labyrinthine reactions arise in the utricle, statokinetic reactions in the semicircular canals. Destruction of the utricle therefore does not disturb statokinetic reactions in response to acceleration, but suppresses almost completely static reactions in response to changes in the position of the head. Destruction of one utricle in the frog[1] is followed by loss of extensor tonus on the side of the lesion; the head and body are bent toward that side and the contralateral limbs are extended. If the animal is stimulated, it progresses in a circle toward the damaged side. Bilateral destruction of the utricle is followed by loss of extensor tonus and severe disturbances in postural reflexes; some of the righting reactions can, however, still be performed. The

[1] Tait, J., and W. J. McNally, *Am. J. Physiol.*, **75**, 155, 1925; *Quart. J. Exper. Physiol.*, **23**, 147, 1933.

utricle therefore plays an important, though not exclusive, part in static labyrinthine reflexes.

The saccule can be destroyed on both sides without disturbing labyrinthine reflexes, even in the rabbit, an animal in which these reflexes are highly developed.[1] The functions of the saccule are not well known; apparently it can be stimulated by vibrations of low frequency.

Functions of the semicircular canals. The semicircular canals can be denervated without provoking disturbances in posture, or abnormal movements, but their destruction is followed by the loss of statokinetic reactions such as the compensatory movements that otherwise occur during rotation.

Ewald stimulated each canal separately by increasing or decreasing the pressure of the endolymph in the following way: A small metal cylinder was cemented over a hole made in the wall of the canal. The narrow end of the canal was plugged, so that changes in pressure, brought about by moving a piston fitted into the cylinder, were exerted on the ampulla. An increase in pressure in the horizontal canals caused the head and eyes to move toward the opposite side; decompression caused a weaker movement in the reverse direction. Compression and decompression of the vertical canals cause similar effects (*i.e.*, deviation of the head and eyes) in the plane of the stimulated canal, but decompression is a more potent stimulus than an increase in pressure. The slow component of nystagmus is of vestibular origin; the rapid component is a compensatory reaction.

The effects of rotation can be easily understood in the light of Ewald's experiments. When the head is rotated with sufficient speed, the endolymph, owing to inertia, is at first displaced at a lower rate than the bony structures, so that it exerts pressure on one end of the canal while the opposite end is decompressed. For example, if the head is rotated in the horizontal plane, from left to right, the endolymph exerts pressure on the ampulla of the right horizontal canal, and the ampulla of the left horizontal canal is decompressed. The eyes move slowly toward the left and are then rapidly brought back toward the right (nystagmus). If rotation continues at a constant rate, the endolymph moves at the same speed as the bony structures; there are no longer differences in the pressure on the ampullas, and nystagmus ceases. When rotation stops, nystagmus commences again (postrotatory nystagmus), but in the opposite direction. The endolymph, owing to inertia, now exerts pressure on the ampulla of the left horizontal semicircular canal, and the ampulla of the right horizontal canal is decompressed.

The movements of the endolymph bend the cupula in the direction in which pressure is exerted, and the "hairs" of the receptor cells are pulled. Dohlman[1] visualized the movements of the cupula by introducing a drop of oil into the canal. He was thus able to see that the cupula bends during the phase of acceleration in rotatory movements and coincides with nystagmus. When the constant phase is established, the cupula returns to the "resting" position and nystagmus ceases. When rotation stops, the same coincidence can be observed between the beginning and ending of postrotatory nystagmus and the bending and straightening of the cupula.

After rotation ceases, there is a sensation of dizziness. The subject feels that rotation still continues, and he sees the objects in the environment rotating in the same direction in which rotation has been taking place. For example, after rotation from left to right, the objects appear to be moving from left to right, *i.e.*, in the same direction as the slow component of the postrotatory nystagmus. Unnecessary compensatory reactions for this apparent movement are performed, and the subject may fall down.

Stimulation of the semicircular canals provokes nystagmus in the plane of that canal (Flourens's law). Therefore to provoke vertical nystagmus the head must rotate in the sagittal plane. This can be performed by bending the head sideways at an angle of 90° and rotating the body in the horizontal plane. Rotatory nystagmus is provoked by flexing or extending the head 90° and rotating in the horizontal plane. Postrotatory vertigo, nystagmus, and compensatory reactions are also observed, and the body falls sideways, forward, or backward according to the position at which the head was held during rotation. For example, if the head is inclined toward the right and the body is rotated from left to right, there is a vertical postrotatory nystagmus with the rapid component downward. The subject feels he is falling forward and performs compensatory reactions

[1] DEKLEIJN, A., and C. J. R. VERSTEEGH, *Pflüger's Arch. f. d. ges. Physiol.*, **232**, 454, 1933.

[1] DOHLMAN, G., *Proc. Roy. Soc. Med.*, **28**, 1371, 1935.

which make him fall backward. If the head is inclined toward the left when rotating, postrotatory nystagmus has the rapid component upward, the subject feels he is falling backward and falls forward.

In the frog the semicircular canals are stimulated by rapidly inclining the supporting surface in the plane of the canal.

Sharp inclination forward and to the left causes movements in the endolymph of the left anterior and right posterior vertical canals. The ampulla of the former is decompressed, pressure is exerted on the ampulla of the latter, and there is extension of the left forelimb. By varying the direction in which the supporting surface is moved, extension of each one of the four limbs can be provoked.

Caloric labyrinthine reactions. On irrigating the external auditory meatus with cold or warm water, convection currents are provoked in the endolymph of the semicircular canals and changes in the pressure on the ampulla result, causing the cupula to bend. The canals are stimulated, and vertigo and nystagmus are observed. The direction of the reactions depends on the temperature of the water, the side stimulated, and the position of the head. If the head is extended 60°, the horizontal canal is placed in an approximately vertical plane. Irrigation of the left ear with warm water (40°C.) or of the right ear with cold water (20°C.) produces horizontal nystagmus to the right (rapid component). Heat produces convection currents toward the ampulla, and cold in the reverse direction; therefore an increase in pressure on the right ampulla will cause slow deviation of the head and eyes toward the left, with a rapid return movement to the right. If the semicircular canals are damaged, these reactions are abolished.

Fig. 478. Vestibular centers and paths.

Galvanic labyrinthine reactions. If an electrode is placed on one of the mastoids, with another electrode on a distant part of the body or on the other mastoid, and a galvanic current (2 to 5 milliamperes)

is passed through the body, the eyes are turned toward the anode and a horizontal or rotatory nystagmus, with the rapid component toward the cathode, is observed. The subject feels dizzy, and objects in the environment seem to be moving from the cathode to the anode. The head and body fall toward the anode. The three semicircular canals are stimulated in this experiment. If the canals are damaged, the same results are obtained by stimulation of the vestibular nerve, but a stronger current (10 to 12 milliamperes) must be used.

Barany's test. A normal subject can place a finger on a given spot even when blindfolded. After rotation he can still do so if his eyes are open, because visual sensations guide the finger to the right place; but if he closes his eyes the finger cannot be accurately placed. For example, after rotating toward the right with the head in the normal position, there is postrotatory nystagmus to the left and the finger deviates or past-points to the left. The subject has the sensation that objects are moving from right to left, and in an effort to "catch up" with the apparently moving object, he passes it and places his finger "ahead" of the object. This is not a vestibular reflex, but a compensatory reaction integrated in the cortex.

Vestibular paths and centers. (Fig. 478.) The maculae of the utricle and saccule and the cristae of the semicircular canals are innervated by fibers of the vestibular nerve, *i.e.*, by axons of cells in the vestibular ganglion (of Scarpa). The central processes of these neurons enter the pons between the inferior cerebellar peduncle and the spinal root of the trigeminal nerve. They then divide into a short ascending branch and a long descending branch, which ends in the vestibular nuclei.

There are four vestibular nuclei: (*a*) the medial (dorsal or principal) nucleus; (*b*) the spinal, or descending, nucleus; (*c*) the superior nucleus of Bechterew; (*d*) the lateral nucleus of Deiters.

The secondary vestibular paths are the following:

1. Fibers from Bechterew's nucleus, together with a few fibers from Deiter's nucleus and others coming directly from the vestibular nerve, form the vestibulocerebellar tract, which enters the cerebellum through the inferior cerebellar peduncle (restiform body) and ends in the cortex of the flocculonodular lobe (see Chap. 83).
2. Fibers from the medial, spinal, and superior nuclei form the medial longitudinal fasciculus, the fibers of which end in the nuclei of the oculomotor nerves (third, fourth, and sixth cranial nerves) of the same and opposite sides. Descending fibers end in the motor nuclei of the cervical segments of the spinal cord. Impulses traveling along this bundle are concerned with the reflex control of movements of the head and eyes.
3. Fibers from the lateral vestibular nucleus descend in the anterior funiculus of the medulla and spinal cord, and end on the spinal motor neurons. Impulses conveyed by this tract facilitate myotatic reflexes.
4. Vestibular paths ending in the thalamus have not been satisfactorily demonstrated, although there are reports of vestibular tracts ending in the lateral part of the ventral and in the medial nuclei of the thalamus. There is suggestive but inconclusive evidence of localization of vestibular function in the temporal lobe.[1] Extirpation of the temporal cortex, however, is not followed by signs of vestibular disturbance or alterations in labyrinthine reactions.

CHAPTER 82

Cortical Integration of Movement. The Pyramidal and Extrapyramidal Motor Systems

THE ACTIVITY OF the nervous system consists in the integration of functional patterns. The two-neuron arc reflex is the simplest integration and takes place in the spinal cord. The complexity of integration increases by the interpolation of internuncial neurons in the reflex arc, as occurs in segmental reflexes (*e.g.*, flexion and crossed-extension reflexes) and in the more complex intersegmental, or "long," spinal reflexes (*e.g.*, the scratch reflex). In the intact animal the spinal level of integration is under the control of higher centers, and even relatively simple spinal synergies may be modified by positive or negative impulses from a higher level, *i.e.*, these impulses may facilitate or inhibit spinal reactions. Outstanding cases of this supraspinal control are the conditions of spinal shock, where facilitation is absent, and decerebrate rigidity, where inhibition is lacking. Beside this effect on spinal reflexes, supraspinal centers integrate patterns of greater complexity than those integrated in the spinal cord. Perfect integration of the whole body requires the activity of the cerebral cortex, *i.e.*, a cortical level of integration, but after the cortex has been removed, even relatively complex synergies are integrated at subcortical levels of function, *e.g.*, the postural reflexes in the somatic sphere and the regulation of blood pressure in the visceral sphere. When the subcortical centers have been destroyed, isolated parts of these synergies can still be carried out, but their complete and harmonious accomplishment is no longer possible.

Effects of total extirpation of the cortex. Cortical integration increases in importance with the development of the nervous system and the process of encephalization. This fact can be demonstrated by experimental removal of the whole cortex, an operation that results in more marked disturbances the higher the position of the subject in the vertebrate scale. In fishes and amphibians, ablation of the cortex does not disturb reflex and automatic movements. The following are the most outstanding deficiencies: (*a*) there are no spontaneous movements, but posture and swimming are normal; (*b*) the animal does not search for food, although food placed in the mouth is swallowed and digested normally.

Decortication produces more marked effects in birds, which can fly for only a very short stretch in a well-lit environment and remain motionless in the dark.

Goltz, in 1881, showed that dogs can live for a long time (18 months) after the removal of the whole cerebral cortex. Phasic and postural reflexes are apparently normal, and the animals can acquire and maintain different postures (see "Centers that coordinate postural reactions," Chap. 81). Automatic movements such as walking are also normally performed. The animals remain quiet unless stimulated to move, but once in motion they continue to move incessantly and appear to be restless. Anticipatory reactions usually initiated in the distance receptors are not observed; harmful agents do not evoke defense reflexes until actual damage has occurred, and then an exaggerated emotional

response may be seen (pseudoaffective state, sham rage; see "The hypothalamus," Chap. 84). The animals appear irritable, and weak stimuli provoke unusually strong reactions. They do not search for food, but when given it is swallowed and digested; there are no outstanding changes in visceral functions. Objects and persons are not recognized; memory is lost, and new happenings are not stored in the mind. All "learned" reactions are forgotten, and the capacity to learn has been lost.

Primates do not survive for long after total decortication. With great care, however, decorticate children have been kept alive for a relatively long time. Even removal of only part of the cortex produces more marked effects than those observed in the cat and dog after removal of the whole cortex.

The following methods have been used in the study of cortical functions: (*a*) stimulation; (*b*) observation of the effects of destruction of limited parts on innate and acquired movements, such as conditioned reflexes and trained movements, and on general behavior; (*c*) the registration of electrical potentials; (*d*) strychninization of limited areas. The correct interpretation of the results obtained by these methods requires the knowledge of cortical structure and of the afferent and efferent pathways.

Fritsch and Hitzig (1870) were the first to demonstrate that stimulation of the frontal cortex produces movements in the limbs of the opposite side. Shortly before, Jackson had seen cases of epilepsy in which convulsions began in a discrete group of muscles, *e.g.*, in the thumb muscles, and from there spread to the neighboring regions and then to the rest of the body, following a typical and constant "march." He deduced that in the cerebral cortex there were centers that controlled isolated movements. In cases where a pathologic cause irritates one of these centers, there is first a focal seizure, and on persistence of the stimulus, excitation spreads to the rest of the cortex. Fritsch and Hitzig's cortical excitation experiments and those of Ferrier on the results of localized extirpation of the cerebral cortex in monkeys gave a solid experimental basis to Jackson's conception, which has since received ample proof.

FIG. 479. Pyramidal and extrapyramidal cortical areas. Lateral view of cerebral hemispheres with principal cytoarchitectural areas. (*After Foerster.*)

The motor cortex is considerably more developed in primates, particularly in the anthropoids and man, than in other species. It is situated in the precentral convolution (area 4). This is the only part of the cortex from which discrete, well-localized movements can be obtained by stimulation, but movements can also be observed when other parts are stimulated. Thus stimulation of the frontal lobe, rostrally to the motor cortex on the premotor area 6, and area 8 (frontal eye field), parietal lobe (areas 3-1-2, 5, and 7), temporal lobe (area 22), occipital lobe (area 19), and parts of the rhinencephalon provokes movements. Some of these movements are suppressed when area 4, or its connections with the cortical center under stimulation, are destroyed. Area 4 sends out the pyramidal tract; for this reason it is known, together with its projection fibers, as the pyramidal motor system. The rest of the excitable cortex and its projection fibers are called the extrapyramidal motor system (Fig. 479).

THE PYRAMIDAL MOTOR SYSTEM

Anatomic description. The motor cortex (area 4) extends from the depth of the sulcus centralis, up its anterior wall, to the lateral aspect of the prefrontal convolution, having a breadth of about 1 cm. on the upper part and tapering down as the sylvian fissure is approached; it also extends along the median surface of the hemisphere down to the sulcus cinguli. Rostrally it is separated from area 6 by Marion Hines's "strip" region (4*s*). The large pyramids of Betz are found in this area; section of the pyramidal tract produces chromatolysis in these cells. The Betz cells are not the only neurons that send out axons to make up the pyramidal tract, since in man there are only 25,000 to 30,000 of them on each side, and approximately 1,000,000 pyramidal fibers, 61 per cent of which are myelinated.[1] Other neurons therefore contribute the majority of the pyramidal fibers. All the myelinated fibers in the pyramidal tract have a cortical origin, as is shown by the fact that hemidecortication in monkeys is followed by the total disappearance of fibers stained by the Weigert technique.[2] The origin of the unmyelinated fibers in the pyramidal tract has not yet been demonstrated.
FIG. 480. Pyramidal tract.

Antidromic stimulation of the pyramids in the medulla[3] has shown that the cortical origin of the pyramidal tract is widely spread. The electrical response is maximal in area 4, but almost as great in the postcentral convolution (area 3-1-2), and it extends to area 6 in the frontal lobe and to areas 5 and 7 in the parietal lobe.

The pyramidal tract (Fig. 480) descends along the anterior two-thirds of the posterior limb of the internal capsule, where it is sometimes destroyed owing to vascular lesions. Farther down it occupies the middle three-fifths of the basis pedunculi and then forms the pyramids of the pons and medulla. In the lower part of the medulla the tracts cross to the opposite side (decussation of the pyramids).

There is a certain degree of systematization all along the corticospinal tract. The fibers arising in the median aspect of the cerebral hemisphere and the upper part of the precentral gyrus (area 4*a*) descend along the posterior part of the internal capsule and the lateral part of the pedunculi, pons, medulla, and spinal cord (Fig. 400); they end in the lumbar and sacral segments. Medial to these fibers are those arising in area 4*b*, which end in the lower cervical and thoracic segments. The fibers in the genu of the internal capsule occupy the median part of the tract in the pedunculi. They come from the lower part of the precentral gyrus (area 4*c*) and end in the nuclei of the cranial motor nerves and the upper cervical segments.

The pyramidal fibers in the spinal cord can be divided into three groups: (*a*) the lateral or crossed corticospinal tract, which includes 70 to 85 per cent of all pyramidal fibers in man; (*b*) the ventral or direct

corticospinal tract, which is not prominent, is seldom found below the cervical segments, and is made up of fibers coming principally from area 4*c*; (*c*) direct fibers which do not take part in the decussation of the pyramids, but descend in the ipsilateral corticospinal tract; they are 10 per cent of all the pyramidal fibers in the chimpanzee. Almost all the fibers (80 to 90 per cent) end on internuncial neurons and not on spinal motor neurons (Fig. 481).[1] Part of the corticospinal projection (20 to 25 per cent) is therefore not crossed, but ends on ipsilateral internuncial or motor neurons (Fig. 480).
Fig. 481. Ending of pyramidal tract in spinal cord.

Brodal and Walberg[2] have observed ascending degeneration after section of the ventral or lateral corticospinal tracts in cats. These degenerating fibers may be seen when the section is as low as the fifth lumbar segment of the cord, but the majority arise in the cervical cord. They have been traced up to the pyramids and the cerebral peduncles; in the pontine gray matter, terminal degeneration was seen, and some fibers end in the motor cortex and a larger number in the sensory cortex. These ascending fibers in the corticospinal tracts form about 4 per cent of the total number of fibers. Kaada[3] has recorded ascending impulses by means of electrodes implanted in the pyramids when the skin of the limbs was stimulated (especially the contralateral forelimb). The significance of these fibers is not yet known.

Stimulation of the motor cortex (area 4). Stimulation of area 4 produces discrete movements, which can be analyzed by means of electromyographic records. In cats and monkeys a very weak stimulus applied to the cortex produces relaxation in muscles tonically contracted. A slightly stronger stimulus provokes movements similar to those observed in phasic reflexes; there is contraction of the protagonists and relaxation of the antagonists according to the principle of reciprocal innervation. A still stronger stimulus is followed by simultaneous contraction of the protagonists and antagonists of phasic movements (*e.g.*, flexors and extensors) and the limb is fixed.[1]

If the cortex is stimulated in conditions opposing intracortical conduction so that excitation does not spread, the response obtained may be limited to a single muscle or part of a group of muscles. A neuron pool, surrounded by a fringe that overlaps the fringes of neighboring pools, corresponds to each muscle or group of muscles.[2]

The optimum intensity of stimulation varies for different centers, but the duration of the stimulus is always relatively long. Thus the chronaxie for the center from which movements of the fingers are provoked is 1 msec.; for flexion of the hip it is 2 msec.[3] The optimum frequency for repeated stimulation also varies in different centers. Using alternating current, for area 4 it is usually below 25 c.p.s. Thus different cranial motor nuclei are excited when the face area of the cortex is stimulated at different frequencies.[4]

Further evidence of this fact has been obtained by stimulation of the bulbar pyramids in cats and monkeys. Motor neurons respond only to repetitive bombardment of internuncial neurons, and the duration of the threshold pyramidal volley varies for each muscle. Large, fast-conducting, low-threshold (short-duration) fibers end on motor neurons corresponding to the face, or fingers; smaller, slower fibers with a higher threshold (long duration) activate motor neurons of proximal limb muscles.[5]

The excitability of the cortex, as well as that of other parts of the nervous system, is modified by several factors. Following the application of an effective stimulus there is a period of depres-

sion, called "extinction,"[1] which reaches its maximum in 14 sec. and disappears in 30 to 40 sec. This phase of hypoexcitability is similar to that observed in the spinal cord and peripheral nerves, and it also coincides with a positive potential. Alkalosis, such as is produced by forced breathing, increases cortical excitability. Acidosis has mainly a depressing effect.

The different parts of the body are focally represented in the precentral convolution (Fig. 405). There is the same general distribution in all vertebrates. The parts innervated by the caudal spinal segments are represented in the cortex near the mid-line, and the more rostral segments more laterally. Thus the sacral segments (tail, perineum) have their representation in the median aspect of the hemisphere and the upper part of the precentral gyrus, and the hind limb in the adjacent parts of the gyrus, lateral to the former. Next to these are the foci corresponding to the trunk. The forelimb is represented in area 4*b*. The head and face are represented in the most lateral part of the convolution (area 4*c*), with the peculiarity that the foci pertaining to the face are lateral to those of the head, an inversion of the general order similar to that observed in the sensory centers of the postcentral convolution. This representation is principally, but not exclusively, contralateral. The extent of the cortical representation is in direct relation to the complexity and fineness of movement. Thus movements of the thumb and of the tongue and lips occupy a large surface, while those of the forehead and scalp occupy only a small one (Fig. 482). In man stimulation of area 4*c* provokes grunts and cries.

The following facts show that the movements produced by stimulation of the motor cortex are originated in the Betz cells of layer V:

1. In the newborn human infant and the monkey under one month old, area 4 is not excitable, because the cortex is not yet completely developed and the axons of the Betz cells are not myelinated.
2. The different layers of the cortex can be progressively destroyed by coagulation provoked by the application of heat at a suitable temperature (70 or 80°C.) for a limited time (3 to 5 sec). Area 4 continues to respond after the outer layers have been destroyed, but ceases to respond when layer V is destroyed. The α rhythm of the electroencephalogram also remains undisturbed as long as layer V is intact.
3. Section of the pyramidal tract produces chromatolysis in the Betz cells and suppresses the localized response to excitation of area 4. Movements provoked by cortical stimulation are of the extrapyramidal pattern (see pages 1041–1042).

a

b

c
Fig. 482 Homunculus illustrating position and extent of cortical representation in motor cortex. Part *c* shows the throat. (*Penfield, W. G., and E. Boldrey, Brain, vol. 60, p. 389, 1937.*)

If a particular center is persistently stimulated, first a localized response is provoked, then excitation spreads to the adjacent foci and can extend to the whole motor area, following a "march" in the same order as in jacksonian epilepsy. Convulsions last for 3 to 4 min., alternating with periods lasting 5 to 6 min. during which there is no response in spite of the persistent stimulation. With a sufficiently strong stimulus, the ipsilateral limbs also enter into convulsions, probably because of the uncrossed fibers of the pyramidal tracts. Stimulation of

the motor cortex after contralateral semisection of the spinal cord is followed by isolated movements on the ipsilateral side; the impulses travel along the 25 per cent uncrossed contingent of the corticospinal tract.

Facilitation and inhibition take place in the motor cortex, as in other nerve centers. Repeated subliminal stimuli provoke a response, but leave a subsequent period of depression. Stimulation of other parts of the cortex, such as area 3-1-2 in the parietal lobe and the premotor area 6, facilitates stimulation of area 4. If the connections between these areas and the motor cortex are cut, this effect is suppressed. There are also areas of the cortex from which inhibition of area 4 can be obtained. The first of these inhibitory areas to be described was the "strip" (area 4) discovered by Hines[1] in the monkey; it is situated immediately rostral to area 4, between this area and area 6. Other inhibitory areas were described later in the frontal lobe (area 8*s*), in the parietal lobe (area 2*s*), and in the occipital lobe (area 19*s*). Stimulation of the inhibitory areas suppresses movements originated in area 4, prevents facilitation, and prolongs the positive after-potentials.[2] Localized strychninization of the inhibitory areas enhances their negative influence on the motor cortex.

Facilitation and inhibition of cortical movements can also be obtained by stimulation of subcortical centers. Thus stimulation of the hypothalamus facilitates movements originated in the motor cortex. These centers do not act on the cortex but on the spinal centers, because facilitation of movement is also observed after the cortex has been removed. There are a series of facilitatory centers extending backward from the diencephalon to the bulboreticular substance.[3]

Cortical inhibition induced by subcortical centers is a prominent feature of cortical function which will be discussed later in connection with the basal ganglia.

The second somatic effector area.[4] A second somatic motor area has been found lying in front of, and in part overlapping, the second somatic receptor area (see Chap. 74). It is situated in the wall of the frontoparietal operculum and the posterior part of the insula. The different parts of the body are represented in an order opposite to the one in which they are represented in area 4; the face area is anterosuperior and the leg area posteroinferior to the arm area, which is the largest and is placed between the other two. Stimulation provokes movements in the other side of the body, especially in the distal parts of the limbs. These movements can be elicited even after area 4 has been removed. Extirpation of the second somatic effector area is not followed by lasting disturbances in motor functions.

Extirpation of the motor cortex. Ablation of the motor cortex (area 4) is followed by flaccid paralysis on the opposite side; *e.g.*, if area 4*b* on the right side is destroyed, the left forelimb is paralyzed. Immediately after the operation the limb remains motionless and flaccid, but after a time there is a partial recovery of movement. The effects are more marked and lasting, and the final deficit is greater, as encephalization is more pronounced and a larger area is removed. The final deficit is greater if area 3-1-2 of the postcentral lobe is also removed. After 1 to 3 days in monkeys and anthropoids (chimpanzee), movements of the proximal part of the limb (shoulder, hip) can be observed. Motility increases gradually, and after 3 to 4 weeks in the monkey and 8 to 12 weeks in the chimpanzee, some of the movements of the hand have been recovered. In the upper limb, flexor muscles show greater recovery, and in the lower limb, extensor muscles. Recovery, however, is never complete; the limb is clumsy, and fine movements and those acquired by learning are lost. This deficiency is not due to loss of memory but to the motor deficit of the limb; the animal knows the complicated movements it had learned, but cannot carry them out and tries to compensate for the defect with its teeth or another limb. It can learn new movements, but its performance is limited by paralysis. In man the final deficit is even more considerable. Certain drugs, such as doryl, strychnine, and thiamine, have a beneficial effect on recovery after ablation of areas 4 and 6 in the monkey; others, *e.g.*, phenobarbital, retard recovery.[1]

Reflexes are at first depressed; flaccidity is

[1] HINES, MARION, *Am. J. Physiol.*, **116**, 76, 1936.

complete, owing to the absence of the myotatic reflex. After a time reflexes recover their normal strength, and some of them may be increased; there is transitory spasticity of the fingers. Postural tonus and reflexes also improve, but recovery is not complete. If the lesion encroaches on Hines's "strip" area (4*s*), there is a certain degree of spasticity, which is considerably greater if area 6 is also destroyed. Man and the anthropoids have a positive Babinski sign, which appears whenever the pyramidal tract is damaged. This consists in disturbance of the flexion reflex of the lower limb. Normally the toes are flexed when the plantar surface is stimulated, but if there is a lesion in the pyramidal tract there is extension, especially of the great toe, and in some cases there is "fanning" of the toes, which is a sign of extrapyramidal encroachment.

After a time there is some muscular atrophy. There are also signs of autonomic disturbance, especially in vasomotor reactions (see "Cortical integration of visceral functions," Chap. 84).

Section of the pyramids in the medulla is also followed by a flaccid paralysis, without any signs of spasticity. If the corresponding area 4 is subsequently destroyed, paralysis increases and a certain degree of spasticity develops; this is especially noticeable in the resistance offered to passive movements. If, on the contrary, area 4 is stimulated after section of the pyramids, an inhibitory effect is observed, which is transmitted along extrapyramidal paths.

The functions of the pyramidal system can be considered from two points of view, according to Tower:[1]

1. The localization of function, which refers to its spatial organization. There are centers of representation of discrete, isolated movements, which are more developed for the more complicated and delicate movements. These centers are distributed in a roughly segmental pattern, and are predominantly contralateral. The impulses travel along the corticospinal tract, which also has a certain systematization.
2. The pyramidal tract functions in two phases. There is a continuous discharge of impulses, which facilitates spinal reflexes and keeps their threshold low. When these impulses are lacking there is flaccidity. Spinal shock in primates is due principally to the suppression of this corticospinal bombardment of the spinal internuncial and motor neurons. The "tonic" influence of the cortex extends to somatic and visceral reflexes. It varies from time to time; it is at its lowest during sleep and increases on awakening. Besides these continuous diffuse discharges, there are others limited to groups of neurons which produce isolated, well-defined movements and are necessary to perform delicate and complicated movement patterns. There are also inhibitory neurons in area 4, the impulses of which are not transmitted along the pyramidal tract, but along extrapyramidal paths.

[1] Tower, S., *Brain*, **63**, 36, 1940.

The pyramidal system is usually considered as the path of voluntary movements. This is so in respect to isolated movements, but even after destruction of the motor cortex some voluntary patterns can still be performed. Therefore it is not the only system carrying voluntary nervous impulses.

THE EXTRAPYRAMIDAL MOTOR SYSTEM

The cortical centers of the extrapyramidal motor system receive fibers from the thalamus and send out fibers to the nuclei of the diencephalon and, through these, to the pontobulbar and spinal motor centers. Its pathways are all short; none is as long as the spinothalamic and pyramidal tracts. There are two main paths: (*a*) the corticostriatomesencephalic projection, which integrates posture and automatic movements; (*b*) the corticopontocerebellar projection, which integrates voluntary movements. Both these projections act on the efferent side of the great reflex arc that goes from the receptors to the cerebral cortex and from the cortex to the effectors.

Stimulation of the extrapyramidal cortex. Stimulation of several parts of the cortex outside area 4 provokes movements. Some of these movements are mediated through the motor cortex, and they are suppressed by ablation of area 4, or by cutting the connections with this area. Others are not dependent on the integrity of the pyramidal system; they are mediated through extrapyramidal paths. The threshold of the extrapyramidal cortex is considerably higher than that of the motor cortex.

Stimulation of area 6 (premotor cortex) produces two types of movement:

1. Discrete circumscribed movements, not so finely limited as those produced by stimulation of area 4. They are suppressed by severing the connections between areas 4 and 6 or by ablation of area 4.
2. Complex movement patterns involving the whole limb (sometimes several limbs), which are carried out slowly. They are not dependent on the integrity of the pyramidal system.

Well-localized, discrete movements are obtained on stimulation of the caudal parts ($6a\alpha$), seldom from the more rostral regions ($6a\beta$). "Adversive" movements (turning of the head and eyes toward the opposite side) are provoked by stimulating area $6a\beta$. Stimulation of the more lateral part of the premotor cortex (area *6b*) situated rostrally to area *4c*, produces movements of the tongue and lips, chewing and swallowing, and in man grunts and cries. These movements are not mediated by the motor cortex, and they are inhibited by stimulation of area 8γ. Stimulation of the lateral part of the premotor cortex spreads to the orbital surface of the frontal lobe, and produces the same effects as stimulation of area 13, *i.e.*, inhibition of respiratory movements and of gastrointestinal motility.

In the posterior part of the second frontal convolution, rostral to $6a\alpha$ and lateral to $6a\beta$, there is an area ($8\alpha\beta\delta$) known as the frontal eye field. Stimulation of this region provokes conjugate movements of the eyes to the opposite side, opening of the eyelids, and sometimes dilatation of the pupil. Closure of the eyes can be obtained by stimulating a point situated more laterally.

Stimulation of the postcentral convolution (area 3-1-2) with a strong stimulus occasionally provokes discrete movements, such as are represented in the neighboring focus of the precentral convolution. Subliminal stimulation of area 4 facilitates this effect, and stimulation of the postcentral gyrus facilitates response to stimulation of the motor cortex. All these effects are suppressed if the connections between the precentral and postcentral convolutions are cut.

Stimulation of areas 17 and 18 in the occipital lobe, and of area 19, provokes movements of the eyes, downward when the upper part, and upward when the lower part, of the occipital lobe is stimulated (occipital eye fields). Electrical stimulation of the rostral part of the cingular gyrus in the monkey (area 24) provokes complex somatic and autonomic responses. There is vocalization (cries, grunts), facial and other movements related to the expression of emotion, opening of the eyelids, dilatation of the pupil, erection of hairs, depressed respiratory rhythm (with occasionally apnea of short duration), and cardiovascular reactions.[1]

Inhibitory areas. Inhibition of area 4, and of the whole cortex, can be obtained by stimulating several "inhibitory" strips. Besides the strip region between areas 4 and 6, there are those already mentioned in areas 8, 2, and 19. Strychninization of these strips diminishes the electrical activity of the whole cortex. Strychninization of area 6, on the contrary, increases electrical activity over almost the whole cortex.

There is a powerful inhibitory area in the rostral end of the cingular gyrus.[2]

Electrical stimulation of this area (Brodmann's area 24) causes cessation of spontaneous movements. The animal closes its eyes and apparently remains asleep for several minutes after stimulation has ended. Inhibitory effects following stimulation of the rhinencephalon are not limited to area 24; stimulation of the posterior orbital gyrus around the olfactory tubercle, the anterior insula, anterior hippocampal gyrus, and neighboring temporal cortex suppresses spontaneous movements in monkeys and cats. Stronger stimuli may evoke slow tonic movements, often of the adversive type. Movements evoked by stimulation of the motor cortex, and in a lesser degree spinal reflex movements, may be facilitated, or stimulation may be followed by inhibition, or inhibitory effects alone are observed; this occurs more frequently when the areas around the olfactory tubercle and the cortex near the genu of the corpus callosum are stimulated. These areas exert their effects independently of the neocortical motor areas; removal of the motor cortex and even of a large part of the neocortex does not influence the response to stimulation of the anterior rhinencephalon. Inhibition and facilitation are proba-

[1] Smith, W. K., *J. Neurophysiol.*, 8, 241, 1945.

[2] Bailey, P., G. von Bonin, E. W. Davis, H. W. Garol, W. S. McCulloch, R. Roseman, and A. Silveria, *J. Neurophysiol.*, 7, 51, 1944.

bly mediated through the diencephalic and mesencephalic reticular systems.[1]

After removal of the whole cortex (neocortex and archicortex) the animals show exaggerated emotional reactions (sham rage; see "The Hypothalamus," Chap. 85). If the neocortex is removed but the olfactory cortex is intact, the animals remain quiet and placid. Removal of the olfactory cortex is followed by exaggerated emotional reactions.[2]

The existence of circuits between these cortical inhibitory areas and the striatum has been demonstrated by the strychninization method (see "Corticostriatal connections," page 1046), but areas 4*s*, 8*s*, 2*s*, 19*s*, and 24 also discharge inhibitory impulses into the pontobulbar reticular formation, and possibly by a series of relays, down to the spinal centers.[3]

Extirpation of the extrapyramidal cortex. Unilateral ablation of the premotor area (6*a*) produces the following disturbances on the opposite side:

1. Clumsiness in movements, especially in those acquired by learning. The animals have more difficulty in the performance of complex movement patterns than in performing discrete movements. A long period of training is necessary to reacquire the lost skill.
2. Spasticity, which diminishes as time passes.
3. Increased reflex response, which is more marked if area 4 has been previously removed. There is "fanning" of the toes on plantar stimulation, and an exaggerated grasp reflex (slow and strong flexion of the fingers or toes on palmar or plantar stimulation).

Spasticity and hyperreflexia are release phenomena due to the liberation of lower centers from cortical influence. Inhibitory neurons are not restricted to area 6 but are found in many other parts of the cortex. Ablation of area 4 produces a short-lasting spasticity limited to the distal part of the extremities. If the strip area is also destroyed, spasticity of the whole limb is observed. Permanent spasticity of an even greater degree is produced if area 6 is also included in the operation. The parietal lobe has inhibitory neurons; there is no spasticity after area 3-1-2 has been destroyed, but it does occur if area 4 is removed at the same time. The inhibitory influence of the frontal lobe is demonstrated by the increase in spasticity that follows its removal subsequent to destruction of areas 4 and 6. A maximal degree of spasticity is observed on complete decortication, in which case it is similar to decerebrate rigidity but less marked; muscles that counteract the effect of gravity are those most affected.

Other features observed after removal of area 6*a*, which are due to loss of inhibition, are (*a*) groping, which consists in repeated reaching movements preparatory to grasping; (*b*) perseveration, *i.e.*, movements are repeated and postures are held long after their usefulness has passed; *e.g.*, chewing continues when there is no longer food in the mouth.

Spasticity, rigidity, and hyperreflexia are due to release of subcortical centers; groping and perseveration are due to release of cortical centers and are not observed when the appropriate cortical areas have been destroyed; *e.g.*, groping is mainly of visual origin and ceases when vision is abolished.

Unilateral removal of the frontal eye fields ($8\alpha\beta\delta$) is followed by twisting of the head toward the operated side and forced circular movements of the body in the same direction. For some time, conjugate movements of the eyes toward the opposite side cannot be performed. Bilateral ablation of these areas is followed by transient visual agnosia; light perception is retained, but the nature and significance of objects are not recognized. When the lesion is restricted to one side, there is hemiagnosia; objects are not recognized while they occupy the visual field on the opposite side but are quickly identified when they come into the visual field on the side of the lesion. The disturbance is apparently due to lack of correlation of visual impulses integrated in the occipital eye fields (areas 18 and 19) with extraocular proprioceptive impulses integrated in the frontal eye fields (area 8).

Frontal association areas (9, 10, 11, 12, 13, 45, 46, and 47). The anterior pole of the frontal lobe is considerably developed in primates, especially in the anthropoids and in man. It contains extrapyramidal inhibitory neurons, but

the main concern of the anterior pole of the frontal lobe is nonspecific intracortical association, and for this reason it is called the frontal association area. This is a "silent" area; faradic stimulation does not produce movement nor sensory phenomena, and ablation is not followed by any disturbance in reflex, postural, or voluntary movements, or any sensory defect.

Frontal lobectomy must be bilateral to produce marked effects; few results, if any, and these transient, are observed after unilateral damage. The disturbances registered are not of movement or sensation but of behavior.

Hyperactivity is one of these disturbances. After a period of depression, during which the animals remain motionless and apathetic, they commence to have fits of hyperactivity, which increase as time passes. Stereotyped, aimless movements, such as pacing back and forth in the cage, are repeated for long periods. There is not much variety in the movement patterns, and perseveration is an outstanding feature. Hyperactivity is maximal and can assume maniacal proportions when area 13 on the orbital surface is destroyed.[1] There is also increased gastrointestinal motility, accompanied by hyperphagia, and the subject eats and drinks excessively.

Distractibility is another typical disturbance; attention cannot be kept fixed on an object, because any intercurrent stimulus distracts the animal. For example, if it is given a grape, it will be carried to the mouth but dropped immediately if a second grape is given, and this one also will be dropped if a third one is offered, and so on until the animal is surrounded with fruit that it has let fall without having eaten a single one.

Immediate memory is lost, events cannot be fixed in the mind, and therefore recent experience cannot influence behavior. The animals "live in a perpetual present," without remembering what has just occurred or anticipating the immediate future. To demonstrate this deficiency, several methods have been used which consist in testing the ability to respond after a delay. For example, an animal is shown how food is placed below one of two cups, which are then hidden for a short time before the animal is allowed to take the food. Normal animals choose the right cup even after several minutes have passed. Those which have suffered bilateral ablation of the prefrontal areas choose at random, even when the cups have been hidden for the shortest time possible. The integrity of areas *9b* and 10 is necessary for the correct performance of this type of test. The interference of other stimuli, especially visual, plays an important part in this loss of memory, as the animals are able to perform this kind of test correctly if they are kept in the dark during the interval of delay. Monkeys and rats can solve correctly any problem that does not involve symbolic concepts, provided that all the factors are present at the same time. If, on the contrary, the solution requires remembrance of a recent experience, the animal fails completely, as its mental processes lack continuity.

[1] RUCH, T. A., and SHENKIN, H. A., *J. Neurophysiol.*, **6**, 349, 1943.

Emotional changes are conspicuous after frontal lobectomy. Animals with an irritable temperament become placid and good-natured. The tip of the frontal lobe and the frontal projection of the dorsal median nucleus of the thalamus apparently play an important part in the integration of emotional reactions. It has been suggested, however, that section of the uncinate fasciculus connecting the frontal and temporal lobes is of more importance in the causation of emotional changes after frontal lobectomy than the interruption of frontothalamic pathways.[1] Some evidence in favor of this hypothesis is given by the results of orbital leukotomy in man (section of the white fibers and disconnection of the cortex of the orbital aspect of the frontal lobe, *i.e.*, area 13), in which extroversion, euphoria, and increased motor activity are even more marked than after the usual operation.

Lesions of the frontal lobes produce in man disturbances similar to those observed in animals. Many cases of destruction of these lobes by pathologic processes and by trauma have been observed, and since Moniz[2] performed the first frontal lobotomy in cases of melancholia and anxiety, psychosurgery[3] has progressed considerably.

In man frontal lobectomy (extirpation of the frontal lobe) causes more extensive and permanent

alterations than lobotomy (leukotomy), an operation that consists in cutting the connections between the prefrontal areas and other parts of the brain, with minimum damage to the cortex. Immediately following the operation, during 2 to 5 days, there is a period of lethargy and disorientation. The patient is in a condition of placid indifference, but must be fed and cleaned as if he were a baby. Gradually periods of stereotyped hyperactivity appear; the movements have the typical aimlessness and perseveration observed in experimental animals. In the succeeding months personality develops and the patients "grow up." Any emotional stress that existed, such as anxiety, obsessions, compulsions, and hypochondria, disappears and is replaced by a sense of happiness and well-being (euphoria). Indolence, distractibility, tactlessness, and boastfulness are prominent in the initial stages but tend to diminish and disappear as time passes. "A patient who has satisfactorily recovered from a psychosis through psychosurgery, gives the impression of a pleasant and enthusiastic, if somewhat immature individual, whose willingness to fall in with the 'set' of the other person's attitude makes him an agreeable companion. People on whom this operation has been performed are generous, steady, fairly reliable workers, friendly and unembarrassed at being interviewed by strangers. They take things as they come."[1] These subjects also "live in a perpetual present"; they are very susceptible to external stimuli, so that their interests are not in themselves but in the outside world. There is a certain quantitative relationship between the severity of the symptoms produced by the operation and the amount of frontal lobe separated from the rest of the brain.[2] If the section is performed so that 85 per cent of the frontal connections are severed, the patient cannot properly organize his behavior; there is lack of initiative, of constructive imagination, and of self-control. Even when recovery is satisfactory, the subjects are immature and have a puerile personality.

The frontal lobes play an important part in the process of "long-circuiting,"[3] *i.e.*, of interposing chains of internuncial neurons in a nerve path, thus increasing the opportunities for association between specialized cortical areas. This process is of great significance in the integration of complex reactions. The circuits through the frontal lobe are not specialized. When they are suppressed, no specific sensory or motor deficit follows, such as occurs when area 3-1-2 or area 4 is destroyed, but the number of possible circuits for association is considerably reduced. To a certain extent long paths can be built up again with what is left of the cortex after frontal lobotomy. Cobb[1] attributes the loss of recent memory to the destruction of these frontal association pathways. "Perhaps remote memories become associated with so many cortical mechanisms that no one operation will obliterate them." Improvement in recent memory, as in other faculties, would be due to the rebuilding of the lost circuits in the available areas. The cortex in this respect has a great degree of "plasticity."

THE BASAL GANGLIA

The main basal ganglia are the caudate nucleus and the putamen (which, together with the fiber tracts they include, form the corpus striatum), and the globus pallidus; the amygdaloid nucleus and the claustrum also form part of the complex. These nuclei discharge into several brain-stem nuclei, the subthalamic nucleus of Luys, the substantia nigra, the red nucleus, and the reticular substance. The pathways are short; they connect neighboring nuclei with each other or with the cortex. The anatomic paths have not all been established, and sometimes a connection is known only through its physiologic effects.

Connections of the basal ganglia. (Fig. 483.)

Caudate nucleus. Afferent fibers: areas 4*s*, 8*s*, and 9 of the frontal lobe and 2*s* of the parietal lobe; branches from the corticospinal tract; median nuclei of the thalamus. Efferent fibers: putamen and globus pallidus.

Putamen. Afferent fibers: areas 4 and 6; branches from the corticospinal tract; median nuclei of the thalamus; caudate nucleus. Efferent fibers: globus pallidus.

Globus pallidus. Afferent fibers: frontal (6) and parietal cortex; corpus striatum; thalamus. Efferent fibers (lenticular bundle): frontal cortex (4); thalamus (n. ventralis anterior, centrum medianum); subthalamic nucleus; hypothalamus; substantia nigra; red nucleus;

[1] COBB, S., "Borderlands of Psychiatry," Harvard University Press, Cambridge, Mass., 1943.

pontobulbar reticular formation; motor nuclei of cranial nerves; globus pallidus of the opposite side (Meynert's decussation).

Subthalamic nucleus of Luys. Afferent fibers: globus pallidus. Efferent fibers: nuclei near the substantia nigra; ipsilateral and contralateral red nuclei.

Substantia nigra. Afferent fibers: areas 4 and 6; globus pallidus. Efferent fibers: red nucleus; mesencephalic motor nuclei.

Red nucleus. (*a*) Parvicellular portion (upper two-thirds). Afferent fibers: dentate nucleus; thalamus; globus pallidus; frontal lobe. Efferent fibers: ascending, lateroventral nucleus of the thalamus (connected with areas 4 and 6); descending, reticular substance. (*b*) Magnocellular portion (lower one-third). Afferent fibers: contralateral nucleus interpositus. Efferent fibers: rubrospinal and rubro-olivary tracts.

Excitability. Stimulation of the putamen and the globus pallidus in monkeys produces no motor responses. On the other hand it inhibits phasic movements and postural reflexes that should result from simultaneous stimulation of the motor cortex. The caudate nucleus must be intact to obtain this effect.

Ablation. Localized lesions of the basal ganglia are not followed by sensory or motor disturbances. Those that destroy the striatum produce transient clumsiness in movements and slight rigidity on the opposite side. Involuntary movements (choreoathetosis) have been observed in chimpanzees after destruction of the caudate nucleus.[1] Simultaneous ablation of area 6 and the striatum produces tremor and choreoathetosis in chimpanzees; also a greater degree of rigidity than if area 6 alone is removed.
Fig. 483. Diagram of interconnections between cortex and basal ganglia.

Corticostriatal connections. Localized strychninization (Dusser de Barenne) has demonstrated the close functional relation existing between the basal ganglia and certain areas of the cortex.[2] Strychninization of area 8*s* increases electrical activity in the head of the caudate nucleus; that of area 4*s* increases it in the body; and that of area 2*s* increases it in the tail of the nucleus. Area 6 projects to the putamen and globus pallidus, and area 4 to the putamen, but neither of these areas projects to the caudate nucleus. Stimulation of the inhibitory areas is transmitted to the striatum, thence to the globus pallidus, and thence through the lateroventral nuclei of the thalamus to area 4. The interruption of any part of this circuit suppresses the inhibitory effect of stimulation of areas 8*s*, 4*s*, and 2*s* on the motor cortex (Fig. 484). Cortical

inhibitory areas, however, also discharge impulses into the bulboreticular formation.

Clinical observations. Much of our knowledge on the basal ganglia has been obtained by careful observation of patients suffering from lesions in these centers. The signs of such lesions can be divided into (*a*) hyperkinesia (increased motility) due to lack of inhibition of lower centers (these are therefore "release" phenomena); (*b*) hypokinesia, or absence of movement.

Hyperkinesia consists in involuntary movements and rigidity.

Involuntary movements are stereotyped but of varying amplitude. If they are ample and performed relatively slowly, they are called "athetosis"; those of lesser excursion and quicker rhythm are called "chorea." Athetosis has been observed in cases with lesions of the striatum, the globus pallidus, and the lateroventral nuclei of the thalamus, *i.e.*, any of the links in the inhibitory corticostriatal circuit. Localized lesions of the subthalamic nucleus of Luys produce athetosis with very ample movements of the ipsilateral upper limb (hemiballismus).[1] Ablation of the cortical centers (areas 4 and 6) relieves these involuntary movements but causes a certain degree of paresis.[2]

Tremor is an outstanding symptom in Parkinson's disease, a condition in which lesions have been found in the globus pallidus, the substantia nigra, and the neighboring areas. Tremor can involve the head or the limbs; in the hand it provokes typical movements similar to those made when counting coins or rolling pills. The tremor ceases when the patient performs voluntary movements and is therefore called a resting tremor, but it is not really so, because it also disappears during sleep. Parkinsonian tremor is a postural tremor, just as cerebellar tremor is an adjunct of voluntary or phasic activity. Removal of the motor cortex also suppresses tremor; the latter is therefore due to "release" of the cortical centers from inhibitory influences.

Tremor with the characteristics of Parkinsonian tremor has been observed in monkeys after the production of lesions in the tegmentum of the upper brain stem. Tremor was abolished by extirpation of areas 4 and 6, but reappeared when motility was recovered. Interruption of corticopallidal connections did not modify the tremor.[1] A similar effect is caused by injury to the subthalamus.[2]
FIG. 484. Diagram of corticostriate inhibitory circuits. (*After Dusser de Barenne.*)

Tremor is an outstanding disturbance after Forel's fields have been damaged. Apparently these are the crossroads where cerebellar, cortical, and subcortical paths that are of importance for the control of involuntary movements meet.

Rigidity can be extremely marked in Parkinson's disease; it involves all muscles but is not accompanied by hyperreflexia. Section of the dorsal spinal roots suppresses rigidity in the deafferented segments. This fact would seem to demonstrate a myotatic-reflex component in rigidity.

Hypokinesia is most evident in the absence of "associated movements." Normal persons perform a series of involuntary (associated) movements when they perform a voluntary movement, *e.g.*, the swinging of the arms when walking and the movements of the face and hands when talking. These movements are reduced or may be completely absent in patients with Parkinson's disease. They walk with their arms hanging stiffly and their faces void of expression; they are "poker-faced." Another feature of hypokinesia is the slowness with which movements are initiated. These symptoms are due, at least in part, to rigidity. Hypokinesia has been provoked in cats by lesions in the caudal part of the hypothalamus

[1] The patients perform movements which are similar to those of an athlete throwing a weight, hence the term used.

and the neighboring tegmentum of the midbrain. The animals were somnolent and reluctant to move; they remained in any posture that was passively given them.[1] Their condition was similar to that of catalepsy. Lesions in the caudal hypothalamus and subthalamus in monkeys diminish activity and cause inertia of such a degree it is necessary to feed and care for the animals as if they were helpless.[2] Injury to the mesencephalic tegmentum has the same effect.[3] In man lesions in the rostral brain stem produced by encephalitis are followed by lethargy and by lack of spontaneous movements and of emotional expression[4] (see Chap. 88).

Summary. The extrapyramidal corticostriatomesencephalic motor system integrates involuntary (automatic) movements and posture. This integration takes place on three levels: (*a*) cortical; (*b*) striatal; (*c*) mesencephalic. Spasticity and rigidity are observed when integration at any of these levels is suppressed, but it is greater when the cortex and striatum are simultaneously destroyed and greatest when all control of the higher centers has been removed by a section below the red nucleus (decerebrate rigidity). Besides this inhibition of tonus, movements initiated in the motor cortex are also inhibited; ablation of the premotor cortex results in perseveration or persistence of movements after they have accomplished their end and in aimless hyperactivity. Interruption of the corticostriatal inhibitory circuit results in choreoathetosis, and mesencephalic lesions provoke tremor. These symptoms are due to "release" of the cortex from the inhibitory component contributed by this system. The system is to a considerable degree bilateral in function, and no specific focal areas have as yet been located.

CHAPTER 83

The Cerebellum

The cerebellum receives fibers from the vestibular division of the eighth nerve, the vestibular nuclei, and the spinocerebellar tracts. The oldest connections of the cerebellum phylogenetically are the vestibular and spinal, but with the development of the somatic musculature and the cerebral hemispheres, the cerebellum has developed and established new connections. In mammals, especially in primates, the greater number of the afferent fibers of the cerebellum come from the pontine nuclei and, through these, from the cerebral cortex (corticopontocerebellar path). The cerebellum sends impulses to the midbrain, the spinal cord, and the cerebral cortex; every cortical region which projects to the cerebellum receives a cerebellar projection. The cerebellum is, therefore, a station in the proprioceptive path, part of the postural reflex mechanism, and an important component of the mechanism for cortically induced movements.

Recent advances in the embryology and comparative anatomy of the cerebellum, registration of potentials in centers and nerve paths evoked by stimulating the cerebellar cortex and nuclei, and registration of cerebellar action potentials following excitation of afferent paths and nerve centers, have been of considerable importance in furthering the functional analysis of this part of the brain. The work of Larsell and that of Dow are of outstanding value in this respect. Before considering the functions of the cerebellum, it will be necessary to describe briefly its structure.

Structural organization. In the lamprey *Petromyzon*—a primitive fish—the cerebellum is a small bilateral organ developed from the vestibular nuclei, with a few spinal, medullary, and tectal connections. In amphibians, the body of the cerebellum develops in a median and anterior position with regard to the vestibular cerebellum, which is formed by the two lateral lobes.

In reptiles the lateral lobes (auricular lobes) are joined together, and in birds they form the flocculonodular lobe. The fissura posterolateralis separates this lobe from the body of the cerebellum. This is the first fold to appear in the course of embryonic development, and it separates two parts of different ontogenetic and phylogenetic antiquity. In the higher vertebrates this fissure, therefore, establishes a primary division of the cerebellum into two parts: (*a*) the flocculonodular lobe; (*b*) the body of the cerebellum. In reptiles at a later stage of development a second fold, the fissura prima, divides the body of the cerebellum into the anterior and posterior lobes. A third fold, the fissura prepyramidalis, divides the posterior lobe into two parts: the anterior portion is formed by the ansiform and paramedian lobes; the posterior portion is formed by the pyramis, uvula, and paraflocculus.

In the cerebellum of mammals, three parts can be distinguished which differ in their ontogenetic and phylogenetic significance, their connections with other nerve centers, and their functional importance (Fig. 485): (*a*) the archicerebellum; (*b*) the paleocerebellum; (*c*) the neocerebellum.

The archicerebellum consists of the flocculonodular lobe. It receives impulses from the labyrinth through the vestibular division of the eighth nerve and the vestibular nuclei in the medulla. Its efferent fibers end in the vestibular nuclei (Fig. 486).

The paleocerebellum (a term in which the vestibular cerebellum is sometimes included) is formed by the anterior lobe (lingula, lobulus centralis, and culmen) and the posterior part

of the posterior lobe (pyramis, uvula, and paraflocculus). Its afferent fibers come from the spinal cord (dorsal and ventral spinocerebellar tracts), the cuneate and gracile nuclei, and the nuclei of the fifth, ninth, and tenth nerves. The lingula and uvula also receive fibers from the vestibular nuclei. The anterior lobe, moreover, receives impulses arising in tactile receptors and the somesthetic cortical centers. Efferent cortical fibers are axons of the Purkinje cells; they end in the cerebellar nuclei. Those from the uvula and lingula end in the nuclei of the roof of the fourth ventricle (n. fastigii); efferent fibers from these nuclei form the fasciculus uncinatus, which crosses the mid-line and ends in the contralateral vestibular nuclei and the reticular formation of the medulla. Other efferent cortical fibers of the paleocerebellum end in the nucleus interpositus (emboliform and globose nuclei of the higher primates), situated laterally to the nuclei fastigii. The efferent fibers of the nucleus interpositus end in the large-cell portion of the red nucleus, whence the rubrospinal tract conveys cerebellar impulses to the motor cells in the anterior horn of the spinal cord. The anterior lobe also projects to the parietal cortex.

The neocerebellum, phylogenetically the last part of the cerebellum to appear, is considerably developed in primates. It comprises the lobulus simplex, declive, lobulus ansiformis, tuber, and lobulus paramedianus, *i.e.*, the anterior part of the posterior lobe between the fissura prima and the fissura prepyramidalis. The afferent fibers come from the motor and premotor cortex (areas 4 and 6 in the frontal lobe) and apparently also from the temporal cortex. These fibers end in the nuclei of the pons. Fibers emerging from these nuclei cross the mid-line and enter the cerebellum in the brachium pontis, ending in the cerebellar cortex, mainly in the hemispheres. These fibers form the corticopontocerebellar path, and they are the most numerous contingent of cerebellar afferent fibers in primates. The neocerebellar cortex also receives impulses from the auditory and visual receptors and their cortical centers. The axons of the Purkinje cells—the only efferent cells here, as in the rest of the cerebellar cortex—end in the

Fig. 485. Diagram of the cerebellum of primates showing the functional divisions of the cerebellum, *i.e.*, vestibular spinal, and neocerebellum. (*Dow, R. S., J. Neurophysiol., vol. 5, p. 121, 1942.*)

dentate nucleus, situated laterally to the nucleus interpositus. The efferent fibers of this nucleus go to the ventrolateral nucleus of the thalamus of the opposite side, and thence cerebellar impulses are carried to areas 4 and 6 in the either directly (from the cortex of the flocculus) or indirectly through the roof nuclei (from the cortex of nodulus, lingula, and uvula). This reflex arc is important in the maintenance of body equilibrium and posture.
FIG. 486. Afferent and efferent fibers of the cerebellum. 1, cuneate and gracile nuclei; 2, vestibular nuclei; 3, pontine nuclei; 4, red nucleus; 5, ventrolateral nucleus of the thalamus; 6, dentate nucleus; *P*, Purkinje cells; *DSCT*, dorsal spinocerebellar tract (Flechsig's); *VSCT*, ventral spinocerebellar tract (Gower's); *VST*, vestibulospinal tract; *RST*, rubrospinal tract; VIII *N*, vestibular division of the eighth nerve; *CPCT*, corticopontocerebellar tract.

frontal cortex, and to the visual and auditory cortex. Many fibers end in the small-cell portion of the red nucleus; perhaps these cells project to the thalamus and cortex.

From a functional point of view, also, the cerebellum can be considered as consisting of three parts, which coincide approximately with the anatomic parts already described, but with some overlapping: (*a*) the vestibular cerebellum; (*b*) the spinal cerebellum; (*c*) the neocerebellum.

The vestibular cerebellum (flocculonodular lobe, lingula, and uvula) receives impulses from the labyrinth, either directly from the vestibular division of the eighth nerve or through the vestibular nuclei. It sends fibers to these nuclei and the reticular formation of the opposite side

The spinal cerebellum (anterior lobe and posterior part of the posterior lobe) receives impulses from proprioceptive receptors through the spinocerebellar tracts, and the dorsal spinal tracts through the cuneate and gracile nuclei. The efferent impulses are relayed through the nucleus interpositus and the red nucleus, and finally end on the spinal motor cells. These impulses are of importance in the control of tonus and posture.

The neocerebellum (anterior part of the posterior lobe) is the terminal station of the corticopontocerebellar pathway. It sends impulses through the dentate nucleus and the ventrolateral nucleus of the thalamus to the motor and premotor cortex. These impulses

are necessary for the control of voluntary movements.

There is no strict separation between the three parts; on the contrary, there is a certain degree of overlapping. Thus the lingula and uvula have vestibular and spinal connections, and the anterior lobe is connected with frontal and parietal cortex and the spinal cord. Overlapping also takes place at the level of the cerebellar nuclei. Thus the roof nuclei receive and emit fibers of vestibular and spinal significance, and the median part of the dentate nucleus near the nucleus interpositus projects to the thalamus and to the red nucleus, *i.e.*, to the cortex and the spinal cord.

The vestibular and spinal parts of the cerebellum form Sherrington's "head ganglion of the proprioceptive system." The neocerebellum is part of the mechanism of cortically induced movements.

EXTIRPATION OF THE CEREBELLUM

Early in the last century, Rolando, and later Flourens, described the effects produced by extirpation of the cerebellum: tremor, ataxia, and disturbances in speech. At the end of the century Luciani distinguished three stages following the operation:

1. At first, extensor tonus is increased (rigidity), and there are periodic fits of opisthotonus (contraction of spinal muscles) and convulsions. Sherrington noted that the disturbances of decerebrate rigidity are similar to those following extirpation of the cerebellum, and that this operation, or section of the cerebellar peduncles, increases their severity. He attributed these disturbances to suppression of cerebellar inhibitory impulses, *i.e.*, they are "release" phenomena of the same nature as decerebrate rigidity.
2. A few days later, the following signs appear: (*a*) *asthenia*, *i.e.*, muscular weakness; (*b*) *atonia*, or rather *hypotonia*, *i.e.*, low muscle tonus due to depression of the myotatic reflex (in cats and dogs this does not occur unless the vestibular nuclei are also damaged; in monkeys and the higher primates, cerebellar ablation provokes considerable loss of tonus); (*c*) *astasia*, *i.e.*, faulty coordination of movements (asynergia). There is no orderly combination of excitation and inhibition of synergic and antagonistic muscles, and there are many signs of disturbed motility: *dysmetria*, or errors committed in the range of voluntary movements (the subject overreaches an object or does not attain it); *decomposition of movements*, which are halting and not performed in orderly and balanced sequence; *tremor*, involuntary oscillations beginning when voluntary movements are started (intention or kinetic tremor) and increasing as the movement progresses; *adiadochokinesia* (Babinski), *i.e.*, difficulty in performing rapidly alternate opposite movements. All these disturbances are seen in walking. The patient walks as if he were drunk (*cerebellar ataxia*). Speech is also disturbed; words are alternately dragged out or emitted explosively and split up into fragments. Faulty coordination of the resonating apparatus gives a nasal intonation to the voice.
3. As time passes the disturbances diminish as a result of gradual compensation, but they do not disappear completely.

Unilateral extirpation of the cerebellum is followed by the same disturbances as bilateral removal, but limited to the operated side. Unilateral increase in the tonus of the extensor muscles causes the trunk to be bent toward the operated side. The head is twisted, with the occiput and the eyes deviated toward the operated side. The subject appears to be looking at the lesion.

FUNCTIONAL LOCALIZATIONS IN THE CEREBELLUM

The cerebellar cortex has a uniform structure; areas with different cytoarchitecture, such as there are in the cerebral cortex, have not been described in the cerebellum. At first the predominant idea was that the cerebellum acts as a whole and that no discrete part of the cerebellum corresponds to a definite part of the body. There is now definite evidence of functional and somatotopic localization in the cerebellum, obtained from the results of (*a*) localized ablation; (*b*) stimulation of the cerebellar cortex or nuclei; and (*c*) potentials evoked in the cerebellum by stimulating cortical or other nerve centers or paths, and in cortical centers by stimulating the cerebellum. The flocculonodular lobe forms part of the vestibular apparatus, the anterior lobe takes part in the regulation of tonus and posture, and the neocerebellum integrates voluntary

movements. There is also a fairly clear-cut topographic localization of sensory and motor representations in the cerebellar cortex. There is overlapping of neighboring areas, both in functional and somatotopic localization.

Flocculonodular lobe. The anatomic connections of this lobe with the vestibular division of the eighth nerve and the vestibular nuclei indicate the existence of a functional relation with the vestibular apparatus. Moreover, stimulation of the eighth nerve provokes the appearance of large action potentials in the flocculonodular lobe, uvula, lingula, and n. fastigii, *i.e.*, in the whole vestibular cerebellum.

Experimental destruction of the nodulus and flocculus in primates[1] causes disturbances in equilibrium. The animal has difficulty in standing and adopts a broad base; its trunk and head sway from side to side, and when walking it progresses with hesitating movements and easily falls down. The syndrome is sometimes called "trunk ataxia," but this is an incorrect term, as the reflexes in the limbs, which contribute to maintain the equilibrium of the body, as well as the reflexes in the trunk, are disturbed. There is no tremor or alteration in postural reflexes, and no asynergia in voluntary movements. The destruction of the uvula alone produces slight and transitory disturbances in equilibrium, but if it is destroyed together with the flocculonodular lobe, the severity of the disturbances is increased. Ablation of the lingula, and of the part of the anterior lobe that has vestibular connections, is followed by exaggerated labyrinthine reactions and disturbances in equilibrium, which do not occur if the labyrinths have been destroyed first; there are no changes in the postural reflexes of the limbs. Removal of the pyramis, uvula, and nodulus suppresses motion sickness in dogs, without disturbing reflex vomiting produced by deteriorated food or apomorphine.[2] Symptoms produced by the extirpation of the flocculonodular lobe decrease as time passes; compensation is established fairly rapidly. Carrea[3] confirmed these observations and found that ablation of the paraflocculus increased the severity of the disturbances caused by extirpation of the vestibular cerebellum (flocculus, nodulus, lingula, and uvula), but had no effect if it was the only part removed. Extirpation of the rest of the vermis produced "trunk ataxia."

[3] Carrea, R. M. E., *Federation Proc.*, **5**, 15, 1946.

In man medulloblastomas located in the nodulus, which later invade all the vestibular cerebellum, produce the same conditions as are observed after experimental extirpation of the flocculonodular lobe.[1] The patients, who are usually children, cannot maintain their equilibrium. When lying down they move their limbs normally, but they have "trunk ataxia," *i.e.*, they stand swaying on a broad base and progress with the hesitating walk of a drunkard. There is no tremor, and there are no changes in postural tonus.

The flocculonodular syndrome is due to absence of cerebellar inhibition of the labyrinthine reflexes. There is hypermetria in vestibular reactions, this being the cause of the loss of equilibrium (Dow).

Anterior lobe. According to Connor,[2] extirpation of the whole anterior lobe is followed by serious disturbances in postural reflexes. Muscular tonus and tendon reflexes are increased. The shortening and lengthening reactions, the positive supporting reaction, and the reflexes that maintain and restore posture are exaggerated; opisthotonus is also observed. Tonic labyrinthine and neck reflexes provoke remarkable changes in posture. If the operation is performed in decerebrate animals, rigidity increases considerably. As time passes, the disturbances decrease in intensity, but a coarse intention tremor appears in the neck and forelimbs. There is also "vasomotor ataxia," *i.e.*, vascular reactions to changes in temperature are exaggerated. Other visceral reflexes, such as those that evacuate the bladder and the rectum, and the pilomotor reactions are also increased. These effects show that cerebellar inhibition acts not only on somatic reflexes but also on visceral ones. Stimulation of the anterior lobe inhibits postural tonus in the homolateral limbs. The effect is remarkable in the decerebrate preparation, in which rigidity is suppressed. After stimulation has ceased, there is considerable "rebound" and extensor tonus is greatly increased.

[2] Connor, G. J., *Proc. Soc. Exper. Biol. & Med.*, **47**, 205, 1941.

Posterior lobe. Extirpation of the posterior lobe is followed by only a few transitory disturbances in the cat and dog. In primates, the severity of the condition increases as encephalization is greater; thus it is more severe in baboons than in monkeys, and even more so in the chimpanzee. There is muscular weakness, decreased resistance to passive movements (hypotonia), disturbances in walking, and difficulty in performing movements learned by training. Bilateral extirpation produces more marked effects than unilateral, in which disturbances are observed only on the damaged side.

Somatotopic localizations. There are two sensory-effector areas in the cerebellum. One is situated rostrally in the anterior lobe and the lobus simplex; the other caudally in the paramedian lobulus, vermis, and pyramis. These areas receive impulses from the periphery, as can be shown by stimulating the receptors and recording potentials evoked in the cerebellar cortex. Thus, in cats and monkeys stimulation of tactile receptors revealed ipsilateral representation of the cutaneous surface in the anterior lobe,[1] and in monkeys also in the paramedian lobulus.

The method of evoked potentials has also served to demonstrate the close interrelation between the cerebral cortex and the cerebellum. Discrete areas of the cerebellar cortex project to, and receive impulses from, discrete areas in the cerebral cortex. Thus, in the monkey stimulation of the face, arm, and leg areas of the motor cortex evokes potentials in the face, arm, and leg areas in the contralateral lobulus simplex and anterior lobe.[1] The second somatic area, located laterally to the main sensory area in the parietal cortex and rostrally to the auditory area, is projected bilaterally on the caudal sensory-effector area of the cerebellum.[2] Stimulation of the ansiform lobe increases the spontaneous electrical activity of the contralateral motor area. The general rule is that a cortical center which projects to a definite area in the cerebellum receives impulses from that area.

Stimulation of the sensory-effector areas of the cerebellar cortex evokes localized movements and has suppressor and facilitating effects on cortically induced movements, and on postural and spinal reflexes.

There is definite, though overlapping, somatotopic localization. Sensory, cortical, and effector representation coexist in the same area. In the rostral area, the tail, hind limb, forelimb, neck, and face are represented respectively in the

FIG. 487. Diagram of the primate cerebellum. *a*, principal divisions and connections; *b*, somatotopic localizations in the cerebellar cortex. (*Dow, R. S., Biol. Rev., vol. 17, p. 179, 1942.*)

lingula, lobulus centralis, culmen, and lobulus simplex. In the caudal area, the face is represented in the upper, the forelimb in the middle, and the hind limb in the lower folia of the paramedian lobule, and the hind limb and tail in the pyramis. There are overlapping visual and auditory areas in the tuber extending into the lobulus simplex.

Electric stimulation in unanesthetized animals by means of previously implanted electrodes, or in decerebrate cats, dogs, and monkeys,[1] evokes immediate and delayed movements following the pattern of localization described above. Thus, tail movements are obtained by stimulation of the lingula, the lower folia of the paramedian lobule, and the pyramis. Hind-limb movements are produced by stimulation of the lobulus centralis, the lower folia of the paramedian lobe, and the pyramis. Forelimb movements are evoked from the culmen and the medial folia of the paramedian lobule, and neck, face, and masticatory movements from the lobulus simplex and the upper folia of the paramedian lobe. When stimulation is discontinued there is considerable rebound, *i.e.*, the opposite movements are performed. The effect is predominantly ipsilateral. Stimulation near the mid-line affects mainly the proximal muscles, and stimulation of more lateral sites affects mainly distal muscles.

Suppressor and facilitatory effects may be obtained by stimulation of the same area, the result depending on the frequency of stimulation. Stimulation of the anterior lobe in the cat at rates of 50 to 300 per second inhibits decerebrate rigidity and the myotatic reflex; reducing the frequency of stimulation to 5 to 10 per second increases spasticity.[2] In the lower mammals and birds inhibitory effects predominate. In primates facilitation of spinal reflexes and cortically induced movements are easily obtained, especially with low frequency of stimulation.[3]

Inhibitory impulses from the anterior lobe and the paramedian lobulus, which inhibit cortically induced movements and postural and spinal reflexes, are relayed by the fastigial nuclei to the reticular formation, and from there to the spinal cord. Inhibitory impulses from the cerebral cortex also converge to the reticular formation; efferent fibers from the reticular formation are therefore a final common path of cortical and cerebellar inhibition.

Facilitation of cortically induced movements evoked by stimulation of the caudal cerebellar sensory-effector areas takes place in the cortex; the impulses are conducted by fibers in the superior cerebellar peduncle.[1] Stimulation of the fastigial nuclei activates the electroencephalogram; therefore, facilitating impulses probably ascend to the cortex not only by the superior cerebellar peduncle but also along reticular relays.[2] Facilitatory impulses from the anterior lobe are mediated by the fastigial nuclei, probably to a bulbospinal system of facilitation.[3]

After a comparative study of the cerebellums of man, monkey, cat, dog, sheep, pig, rabbit, and opossum, correlated with the physiological data available, Woolsey[4] has concluded that the following homologies exist between the different parts of the human cerebellum and those of animals: The amygdala in man is the homologue of the subhuman paraflocculus. The paramedian lobule, usually homologized with the amygdala, corresponds to the lobulus biventer and lower part of the inferior semilunar lobule of man. By analogy with cat and monkey, the somatotopic localization within these paramedian homologues would be as follows: leg in the lower division, and arm in the upper division, of the lobulus biventer; face in the lower part of the inferior semilunar lobule. The latter is a part of the lobus medius. The rest of the lobulus medius is composed of the rostral part of the inferior semilunar lobule (crus II), the superior semilunar lobule (crus I), and the posterior part (lobulus simplex) of the quadrangular lobule.

Electrical activity of the cerebellar cortex.[5] The spontaneous electrical activity of the cerebellar cortex, recorded with relatively coarse electrodes, shows waves of extraordinarily high frequency, about 150

per second. There are also spike discharges of approximately the same frequency. Both spikes and waves are originated in the Purkinje- and granule-cell layers. The spike discharges are more sensitive to ischemia than the waves. Local strychninization increases the frequency of intrinsic units to 400 to 500 per second, but it produces synchronization with low frequency (10 to 30 per second) of the waves.

Summary. The vestibular cerebellum (flocculonodular lobe and parts of the paleocerebellum) integrates labyrinthine reflexes essential for the maintenance of the equilibrium of the body. The paleocerebellum (anterior lobe and parts of the posterior lobe) integrates postural reflexes and regulates muscle tonus. The neocerebellum, highly developed in primates, is in close reciprocal relation with the cerebral cortex for the integration of movements.

CHAPTER 84

Visceral Motor Innervation. The Autonomic Nervous System

THE NERVOUS SYSTEM controls and coordinates visceral functions in two ways; it exercises a continuous or tonic action, and it discharges impulses that have stimulatory or inhibitory effects in physiologic emergencies. The structural and functional architecture of visceral sensibility does not differ fundamentally from that of somatic sensibility (see Chap. 73). On the other hand, visceral motor innervation differs in several respects from somatic motor innervation. Thus the visceral motor neurons are not situated in the central nervous system, but peripherally in ganglia which in some cases are found close to or within the effector organ. Moreover visceral effectors are not so dependent on nerve impulses as somatic effectors; they continue to function after denervation,[1] although their response is slower, more prolonged, and less well adjusted than when they are innervated.[2]

Historical note. Galen[3] described seven cranial nerves. The sixth nerve, which sent fibers to the larynx and the viscera, comprised the glossopharyngeal, vagus, and accessory nerves. It also included the cervical, thoracic, and abdominal sympathetic, with three ganglia: one situated under the cranium, formed by the superior cervical of the sympathetic and that of the vagus; a second in the upper part of the thorax (the stellate ganglion); and a third in the abdomen (celiac ganglion). Galen also saw the thoracic rami communicantes.

[1] Piloerector muscles, salivary and sweat glands, the adrenal medulla, and the neurohypophysis are exceptions to this rule.

[2] Hormones play an important part in the control of visceral functions.

[3] GALEN, "De usu partium corporis humanis."

In the sixteenth century, Etienne (1545) and Eustachius (1552) differentiated the vagus nerve from the sympathetic. In the following century, Willis (1621–1675) revised the anatomy of the cranial nerves and distinguished 10, the vagus nerve being the eighth. He gave the name of "intercostal nerve" to the sympathetic and believed that it had its main origin in the cranium but also received spinal roots at each intercostal space. This nerve, together with the vagus nerve, innervated the viscera; visceral motility, however, was not under voluntary control, but directed by the "cerebellum," a term that included the pons and medulla. The thoracic origin of the "intercostal nerve" was demonstrated by Pourfour du Petit (1727), who cut the nerve in the neck and saw the effect this operation produced in the eye (later known as the Bernard-Horner syndrome). He concluded that "animal spirits" must therefore travel in the nerve from the thorax to the head and not in the opposite direction, as was generally believed. Winslow gave the name of "great sympathetic" to the "intercostal nerve," because through the viscera, it established "sympathies" or reciprocal influences between the different organs.

Different functions have been attributed to the ganglia. Willis thought they were reservoirs of "animal spirits," and according to Lancisi (1718), Morgagni believed that they acted as pumps which forced the "animal spirits" along the nerves. Johnstone (1764) maintained that they could not be pumps because they had no muscular tissue and therefore could not contract. He thought they must act as filters which retained motor impulses and sensory impressions, thus giving an explanation of the fact that the former escape voluntary control and the latter are imprecise. Meckel (1749) and Scarpa (1779)

considered that they were simply centers for the distribution of nerve fibers. Winslow, Monro (1783), and later Bichat (1801) considered the ganglia to be "small brains," with all the functions of the central nervous system. Bichat[1] classified bodily functions into two groups, those corresponding to "animal life" (now called somatic), controlled by the central nervous system, and those of "organic life" (now called visceral), controlled by the ganglionic system; these systems, although separate and independent, being connected by many fibers.

In the second half of the last century the knowledge of visceral innervation progressed considerably. Remak (1854) discovered the unmyelinated fibers and saw that the ganglia were connected with the spinal nerves by two types of fiber: (*a*) the *ramus communicans sympathicus*, gray and soft, formed by unmyelinated fibers or by fibers with only a very thin myelin sheath, which arises in the ganglion and is distributed to the periphery; (*b*) the *ramus communicans spinalis*, white and firm, which is formed by myelinated fibers and connects the spinal cord with the ganglion. At the same time (1851) Claude Bernard, in the course of his researches into the origin of animal heat, discovered the vasomotor nerves. Budge and Waller (1851) described the ciliospinal center in the upper thoracic segments of the spinal cord, and Bernard[2] showed that stimulation of the floor of the fourth ventricle provoked glycosuria and polyuria, thus demonstrating the influence of the central nervous system on visceral function.

Gaskell (1856) made a careful study of the distribution in the spinal roots and in cranial nerves of the fine myelinated fibers that form the white rami. His work, confirmed and extended by Langley and his associates, finally established the structural architecture of visceral motor innervation. More recently Karplus and Kreidl (1909–1924) discovered the centers in the diencephalon (hypothalamus) that control organic functions, and evidence has now been obtained that cortical centers also exert an influence on the activity of the viscera, thus giving factual support to the suggestion, put forth by Hughlings Jackson in 1876, that there is cortical representation of visceral function.[3]

ORGANIZATION OF VISCERAL INNERVATION

Gaskell[1] observed that in some of the ventral roots there were not only the large myelinated motor fibers, but others, also myelinated but much finer, with a diameter varying between 1.8 and 3.6 μ and exceptionally 4 μ. They are found in all the thoracic ventral roots, in the first, second, and third lumbar, in the second and third sacral, and sometimes in the first and fourth sacral, ventral roots. They are also found in the oculomotor (third), facial (seventh), glossopharyngeal (ninth), and vagus (tenth) nerves. They are not found in other spinal roots or cranial nerves. Later work has confirmed the results of Gaskell's pioneer observations, but small differences in the distribution of the fibers are found in different species and individual cases. Thus, in man white rami occur from the first thoracic to the second lumbar, and the third sacral to the fourth sacral; in the monkey, dog, and cat the first thoracic has no white ramus in some individuals, but the third lumbar and, in some cases, the fourth contain white sympathetic fibers; the first, second, and third sacral nerves also contain fine fibers. In the rabbit white rami are found from the first thoracic nerve to the fifth lumbar and from the second to the fourth sacral.

These fibers have been called "preganglionic fibers" by Langley, because they run from the cranial nerve centers and spinal cord to the ganglia. The axons of ganglionic neurons innervate visceral effectors (smooth muscle and glands); they are known as "postganglionic fibers." They have no myelin sheath, or only a very thin myelin sheath that does not extend throughout the whole length of the fiber, except those emitted by the ciliary ganglion, which are completely myelinated. Their diameter is seldom greater than 2.5 μ (Fig. 488).

The preganglionic fibers can be divided into three groups: (*a*) the *cranial* outflow, the neurons of which are situated in the tegmentum of the midbrain, the pons, and medulla, the fibers forming part of the oculomotor, facial, glossopharyngeal, and vagus nerves (fibers going from the hypothalamus through the hypophyseal stalk to the hypophysis are also included in this group); (*b*) the *thoracolumbar* outflow, the neu-

[1] GASKELL, W. H., "The Involuntary Nervous System," Longmans, New York, 1916.

rons of which are situated in each segment of the spinal cord from the first thoracic to the second lumbar, and the fibers in the corresponding ventral roots; (*c*) the *sacral* outflow, with neurons in the second and third sacral segments and fibers in the corresponding ventral roots.

tem" to the cranial and sacral divisions, and that of "autonomic nervous system" to the whole. Visceral innervation has also been called the nervous system "of organic life" or "of the ganglia" (Bichat), "of vegetative life" (Reil), and "the involuntary nervous system" (Gaskell).
Fig. 488. The visceral reflex arc and sympathetic chain.

The first and last groups usually, but not in all cases, produce effects opposite to those produced by the second group. Langley[1] has given the name of "sympathetic system" to the thoracolumbar outflow, that of "parasympathetic sys-

[1] Langley, J. N., "The Autonomic Nervous System," Part I. Heffer. Cambridge. 1921.

At one time visceral innervation was supposed to constitute a separate and different nervous system from that which innervated somatic structures. It is now understood that there is only one nervous system.

According to Gaskell and Langley, the autonomic nervous system with its two divisions

(sympathetic and parasympathetic) is exclusively motor and peripheral. This restricted concept of visceral innervation is no longer currently accepted. The viscera are innervated

1. *Afferent neurons,* situated in the dorsal-root ganglia, or the corresponding ganglia in the facial (geniculate ganglion), glossopharyngeal (g. petrosum), and vagus (g. nodosum)
FIG. 489. Diagram of afferent and efferent fibers and centers of the visceral nervous system. *n.*, nerve; *g.*, ganglion.

in a similar way to the somatic structures, *i.e.*, by a spinal reflex arc and higher centers, with internuncial neurons connecting the different levels of integration. The elementary visceral reflex arc (Fig. 488) is made up of

nerves. The afferent fibers are usually fine and unmyelinated.

2 *Preganglionic neurons,* situated in the intermediolateral column of the spinal cord and the motor nuclei of the oculomotor nerve

(Edinger-Westphal nucleus), facial (superior salivatory nucleus), glossopharyngeal (inferior salivatory nucleus), and vagus (dorsal motor nucleus) nerves. The axons of these neurons are myelinated and form the white rami communicantes which end in the sympathetic ganglia, or the visceral efferent fibers of the cranial nerves ending in peripherally situated parasympathetic ganglia.

3. *Motor neurons* in the ganglia, which emit postganglionic fibers to the effectors.

Above the spinal level of integration, three other levels have been found: (*a*) pontobulbar integration of certain complex visceral functions, such as the blood pressure and heart rate; (*b*) diencephalic (hypothalamus) integration of still more complex patterns; (*c*) cortical integration.

Three aspects of visceral innervation can therefore be considered: (*a*) visceral sensibility (see Chap. 73); (*b*) visceral motility; (*c*) central integration of visceral activity (Fig. 489).

cervical to the second or third lumbar segment. It is formed by small cells, approximately half the size of the motor neurons in the ventral horn, having a large nucleus and relatively little cytoplasm. They are closely packed, and there is some degree of segmentation, *i.e.*, they are more numerous at a certain level of each segment. Removal of the sympathetic ganglion chain provokes chromatolysis and other signs of retrograde degeneration in these cells. Their axons are included in the ventral roots but diverge from these roots to form the white rami communicantes which go to the ganglia. Preganglionic fibers run up or down the ganglionic chain through several segments, emitting collaterals to the ganglia. They have a myelin sheath, which is sometimes lost before they end.

Sympathetic ganglia are found on each side of the spinal column throughout its whole length. They arise from the neural crest, but in the course of embryonic development they become

The fibers of the thoracolumbar outflow arise in neurons situated in the intermediolateral column of Stilling, which extends from the last

separated from the dorsal-root ganglia and migrate to the periphery. Ganglionic cells are small multipolar motor neurons, which connect only with the terminals of spinal neurons. No sensory or connector cells have been found in the ganglia.

There are *three cervical ganglia* on each side of the spinal column: the superior, middle, and

inferior cervical ganglia. The middle ganglion is not found in some cases, and the inferior ganglion is usually fused with the first thoracic (stellate) ganglion. Preganglionic fibers for the superior and middle cervical ganglia leave the spinal cord in the first, second, and third thoracic ventral roots. Postganglionic fibers of the superior cervical ganglion form the plexuses of the internal and external carotid and superior thyroid artery, the superior cardiac nerve, and the gray rami for the first to the third or fourth spinal nerves. Part of the fibers emerging from the superior cervical ganglion form the internal carotid nerve or plexus which accompanies the homonymous artery. Some of these are post-synaptic unmyelinated fibers; a considerable number (one-third of the fibers leaving the SCG) are myelinated, and these have been considered preganglionic fibers ending on ganglionic cells in the carotid plexus. There are many of these cells, and they form nodes which are mostly microscopic but in some cases are visible to the naked eye.[1] Postganglionic fibers of the middle cervical ganglion form the gray ramus of the fifth cervical spinal nerve, the plexus of the inferior thyroid artery, and the middle cardiac nerve.

The *stellate ganglion* receives preganglionic fibers from the first to the eighth or ninth thoracic roots, and its postganglionic fibers form the gray rami of the sixth, seventh, and eighth cervical and first and second thoracic nerves and the plexuses of the subclavian, internal mammary, and vertebral[2] arteries; some of them also form part of the nerves in the brachial plexus.

There are ten or eleven *thoracic ganglia* as well as the stellate ganglion, which receive preganglionic fibers from the spinal nerves and send out postganglionic fibers to them. It is not possible to distinguish macroscopically the white from the gray rami because myelinated and unmyelinated fibers are included in the same fillets. Microscopic analysis of the fibers is necessary to distinguish one type from the other. Preganglionic and postganglionic fibers form plexuses surrounding the aorta, the azygos veins, and the esophagus, together with the superficial and deep cardiac and pulmonary plexuses. These plexuses receive fibers from the vagus nerve as well, and they contain ganglion cells.

Fibers from the fifth to the ninth thoracic ganglia form the *maior splanchnic nerve*, which pierces the diaphragm and ends in the celiac ganglion. Fibers from the tenth and eleventh thoracic ganglia form the *smaller splanchnic nerve*, which also ends in the celiac ganglion. In some cases a *third* or *lowermost splanchnic nerve*, ending in the renal plexus, is formed by fibers from the last thoracic ganglion. The fibers of the splanchnic nerves are myelinated preganglionic fibers, which arise in the spinal cord and not in the thoracic ganglia through which they pass.

There are usually four pairs of *lumbar ganglia* and four pairs of *sacral ganglia*. The lateral ganglionic chains frequently join each other at the caudal end in a single *coccygeal ganglion*. The preganglionic fibers of these ganglia emerge from the spinal cord in the first, second, and in some cases third, lumbar roots.

The large arteries of the abdomen are surrounded by dense plexuses formed by fibers and ganglion cells of the sympathetic and parasympathetic. The largest of these plexuses is the *aortic plexus*, which is the continuation of the thoracic aortic plexus. The celiac artery is surrounded by the *celiac*, or *solar*, *plexus*, on each side of which is a ganglionic mass, known as the celiac ganglion. This plexus receives fibers from the aortic plexus, the splanchnic nerves, the last thoracic and first lumbar white rami, and the vagus nerve. Its efferent fibers form the hepatic, gastric, pancreaticoduodenal, and splenic plexuses around the corresponding arteries, and they end in the viscera of the upper abdomen.

The superior mesenteric artery is surrounded by the *superior mesenteric plexus*, which includes ganglion cells; it is a continuation of the aortic plexus. Laterally it emits the renal and spermatic or ovarian plexuses, which surround the homonymous arteries and innervate the kidney and testes or ovaries. The *inferior mesenteric plexus*, attached to the inferior mesenteric artery, sends out fibers to the descending, sigmoid, and pelvic colon.

The lower or caudal end of the aortic plexus is joined to the *hypogastric plexus*, sometimes called "hypogastric nerve." Its caudal extremity, known as the *pelvic plexus*, also receives the pelvic nerves of the parasympathetic and

[1] Mitchell, G. A. G., *Nature, London*, **170**, 533, 1952.

[2] The plexus of the vertebral artery also receives fibers from each one of the cervical gray rami.

contains numerous ganglion cells. It innervates the pelvic viscera through the hemorrhoidal, vesical, uterine, vaginal, and prostatic plexuses.

Preganglionic and postganglionic fibers. Several methods have been used to determine the paths and endings of sympathetic fibers. The following may be mentioned:

1. Section of a ventral root is followed by degeneration of the corresponding preganglionic fibers, which can be traced by means of serial sections stained with the Marchi stain.
2. Nicotine injections provoke symptoms of generalized sympathetic stimulation, but when the drug is applied locally to a ganglion the symptoms are restricted to the territory innervated by the fibers emitted by the ganglionic neurons. After the excitatory effect has subsided, stimulation of the preganglionic fiber provokes no response, although stimulation of the postganglionic fiber provokes the usual effects. Nicotine blocks the ganglion so that preganglionic impulses are not transmitted to the ganglionic neuron. Langley used this method in tracing the distribution of the preganglionic and postganglionic fibers.
3. Action potentials of the different fibers have been registered by means of a cathode-ray oscillograph, and the excitability and speed of conduction of the fibers and the synaptic delay have been determined. The site of synaptic delay indicates where the axon of the spinal sympathetic neuron ends.

There are several types of preganglionic fibers. Four groups have been found in the cervical sympathetic with conduction speeds of 12, 8, 3, and 0.5 m. per sec., respectively. Fibers in the three fastest groups are myelinated; the slowest group is formed by unmyelinated gray fibers. Unmyelinated preganglionic fibers connect with neurons in the superior cervical ganglion that emit unmyelinated postganglionic fibers. Myelinated preganglionic fibers connect with neurons that emit myelinated or unmyelinated fibers. Approximately one-third of the fibers that leave the superior cervical ganglion are myelinated. The fastest fibers innervate the iris, the nictitating membrane, and the smooth muscle in the eyelids. Those of intermediate velocity are vasomotor and pilomotor fibers. The destination of the slow myelinated and unmyelinated fibers is as yet unknown.[1]

There are more postganglionic than preganglionic fibers. In the superior cervical ganglion the ratio is 1:16; but in other ganglia different ratios are found; *e.g.*, 1:2 in the ciliary ganglion. A preganglionic impulse can, therefore, be transmitted to several ganglionic neurons, and large action potentials are observed in the postganglionic fibers following preganglionic stimulation, owing to synchronized activation of several ganglionic neurons. Impulses sent out by a neuron in the central nervous system can thus have a widespread effect.

Stimulation of a preganglionic fiber produces effects in a large area, because it runs through several segments of the sympathetic chain and emits collaterals to the respective ganglia. On the other hand, the effects of stimulation of a postganglionic fiber are restricted to a single segment. Langley demonstrated this fact by the following experiment: the ramus communicans of a thoracic nerve was stimulated and the hair was raised along a wide area placed caudally to the stimulated root. The strength of the stimulus was then increased so as to stimulate the postganglionic fibers also, and a narrow area of piloerection appeared which was situated cephalically to the first area and separated from it by a quiescent area. Nicotinization of the sympathetic ganglion suppressed the wide caudal area of piloerection due to preganglionic stimulation, but left unchanged the narrow cephalic area due to postganglionic stimulation.

Functions of the ganglia. The structural architecture of the ganglia endows them with certain characteristics. They are formed exclusively by motor neurons; there are no sensory or internuncial neurons. All the afferent fibers come from a higher center, none from the periphery; therefore they are not reflex centers.

Kunz maintains that reflexes can be integrated in the celiac ganglion. He has observed that distention of the colon, or electrical stimulation of the mesenteric nerves, provokes a decrease in the flow of bile after all the central connections of the celiac ganglion have been severed and the duodenum cut so as to

[1] Bishop, G. H., and P. Heinbecker, *Am. J. Physiol.*, **100,** 519, 1932.

prevent the spread of impulses along the enteric plexuses.[1] Kunz and Saccomanno[2] have seen that the enteric reflex (inhibition of a proximal segment of a transected gut by dilatation of a distal segment) takes place in animals after the thoracic, lumbar, and sacral cord has been destroyed and the vagi nerves cut and after time enough has passed so that the fibers from the nerve centers have degenerated. The afferent neuron of this reflex, according to K'.nz, is situated in the wall of the gut.

The terminals of a preganglionic fiber are connected with several ganglionic neurons, and each one of these neurons is connected with several preganglionic fibers. Overlapping thus provides the structural basis for convergence, occlusion, divergence, spatial summation, and facilitation. All these phenomena have been demonstrated in the superior cervical and stellate ganglia.[3] Impulses traveling in preganglionic fibers are transmitted to the postganglionic fibers, but an antidromic volley of the latter spreads only as far as the ganglion and is not transmitted to the preganglionic fibers. Unidirectional conduction, according to Sherrington's law of forward direction, also obtains in sympathetic ganglia as in other synaptic systems.

A single impulse in the preganglionic fibers is followed by a single impulse in the postganglionic fibers; therefore the ganglionic neurons do not discharge repetitively. Repeated stimulation of preganglionic fibers at frequencies below 50 per second does not provoke repetitive discharge, but if higher frequencies are applied repetitive discharge may be observed. The frequency of physiologic impulses from the spinal sympathetic neurons never rises above 20 per second; therefore repetitive discharge of ganglionic neurons does not play a significant part in the normal transmission of impulses through the ganglia.

Repetitive stimulation, however, is followed by progressively increasing action potentials in the postganglionic fibers, because the central excitatory state spreads in the ganglion and the ganglionic neurons are recruited from the subliminal fringe as summation of the successive impulses takes place.

[1] Kunz, A., and C. van Buskirk, *Proc. Soc. Exper. Biol. & Med.*, **46**, 519, 1941.
[2] Kunz, A., and G. Saccomanno, *J. Neurophysiol.*, **7**, 163, 1944.
[3] Bronk, D. W., *J. Neurophysiol.*, **2**, 380, 1939.

The excitability of the ganglionic neuron is modified by conduction of an impulse transmitted by a preganglionic fiber, or by an antidromic volley, in the same way as conduction alters the excitability of neurons in the central nervous system. The absolute refractory period lasts approximately 2 msec.; it is followed by a phase of hyperexcitability which lasts 50 to 100 msec., coinciding with the negative afterpotential. Finally there is a period of hypoexcitability which sometimes lasts for more than 1 min., coinciding with a positive after-potential of low voltage. Repeated antidromic volleys may cause an accumulation of the phases of hypoexcitability of the ganglionic neuron, and its capacity to transmit preganglionic impulses is thus considerably depressed.

Table 115 summarizes the localization of the spinal center, the roots by which preganglionic fibers leave the spinal cord, the ganglia where they end, and the effects produced by stimulation of the different parts of the sympathetic. The facts have been obtained by observing the results of stimulation or extirpation of the different fibers in experimental animals and in human cases. The statements made should not be given too precise significance, because there are differences between species and between individuals of the same species.

The Parasympathetic or Craniosacral Division

Mesencephalic, Pontobulbar, and Spinal Centers. Parasympathetic Nerves

The preganglionic neurons of the cranial parasympathetic form a discontinuous column of nuclei called the "general visceral efferent column."[1] This extends from the tegmentum of the midbrain through the pons to the medulla and is continued as Stilling's intermediolateral column in the spinal cord. The nuclei are formed by small, closely packed neurons similar to those in the spinal centers of the sympathetic. A caudal prolongation of Stilling's column in the sacral cord contains the cells that give rise to the sacral parasympathetic (pelvic nerve).

In the tegmentum of the midbrain, close to the nucleus of the oculomotor nerve, there is

[1] Ranson, S. W., "The Anatomy of the Nervous System," Saunders, Philadelphia, 1942.

a group of small cells, the more rostral part of which fuses with the rostral end of the contralateral nucleus, forming a single median structure known as the Edinger-Westphal nucleus. The axons emitted from it form part of the oculomotor nerve and end in the ciliary ganglion. Postganglionic fibers are fully myelinated in their whole length. These fibers innervate the constrictor muscle of the pupil and the ciliary muscle. Probably the fibers for the sphincter of the pupil arise in the rostral median part of the nucleus, and those for the ciliary muscle in the caudal lateral part. The pupillary constrictor fibers apparently do not pass through the ciliary ganglion, as removal of this ganglion does not prevent the constriction of the pupil that accompanies voluntary convergence of the eyes. The fibers, possibly, end on the ganglion cells of the intraocular ciliary plexus.

The *nucleus salivatorius superior* is not well defined, nor has it been located exactly. Apparently it is formed by cells scattered in the reticular formation at the junction of the pons and the medulla. The efferent fibers of this nucleus are incorporated into the facial nerve; they separate at the level of the genu of the nerve forming the chorda tympani and end in the *submaxillary ganglion*. The postganglionic fibers innervate the submaxillary and sublingual glands and, when stimulated, provoke abundant salivary secretion, vasodilatation, and constriction of the glandular ducts. Stimulation of the nerves of these glands after partial denervation produces histological signs of activity in

Table 115. Distribution and Effects of Stimulation of the Sympathetic Division

Spinal center	*Preganglionic fibers*	*Ganglion*	*Postganglionic fibers*	*Effect of stimulation*
C_{VIII}–Th_{III}	Th_{I}–Th_{III}	Superior cervical	Plexus of internal carotid artery	Dilatation of pupil. Retraction of eyelids and nictitating membrane. Exophthalmos (not in man). Intracranial vasoconstriction
C_{VIII}–Th_{III}	Th_{I}–Th_{III}	Superior cervical	Plexus of external carotid artery	Vasoconstriction and dilatation, piloerection and sweating of head. Salivary secretion
C_{VIII}–Th_{III}	Th_{I}–Th_{III}	Superior cervical	Gray rami of C_{I-III} or C_{IV}	Vasoconstriction and dilatation, piloerection and sweating of upper part of neck
C_{VIII}–Th_{III}	Th_{I}–Th_{III}	Median and inf. cervical	Gray rami of $C_{IV-VIII}$	Same of lower part of neck
Th_{I}–Th_{III}	Th_{I}–Th_{VIII}	Stellate	Brachial plexus	Same of upper limb
C_{VIII}–Th_{I-VII}	Th_{I}–Th_{V}	Sup., med. and inf. cervical, stellate	Cardiac nerves and plexus	Increase in heart rate. Coronary dilatation
Th_{I}–Th_{II}	Th_{I}–Th_{III}	Stellate	Pulmonary plexus	Tracheobronchial dilatation. Vasomotion of lung
Th_{IV}–Th_{IX}	Th_{IV}–Th_{IX}	Thoracic	Gray rami of thoracic nerves	Vasomotion, piloerection, and sweating of trunk above the umbilicus
Th_{IX}–L_{II}	Th_{IX}–L_{II}	Thoracic and lumbar	Lumbar plexus	Same below the umbilicus
Th_{IX}–L_{II-III}	Th_{IX}–L_{III}	Lumbar	Lumbar and sacral plexuses	Same of lower limb
Th_{IV}–Th_{XII}	Splanchnic nerves	Celiac and upper mesenteric	Aortic, gastric, hepatic, splenic, upper and lower mesenteric plexuses	Abdominal vasomotion. Inhibition of gastrointestinal motility. Gastrointestinal secretion. Glycogenolysis. Adrenaline secretion (preganglionic)
Th_{XII}–L_{I}	Minor splanchnic nerve	Renal	Renal plexus	Vasomotion of kidney
$L_{I-II-III}$	L_{I-II} or III	Inf. mesent., cells in hypogastric plexus	Hypogastric plexus	Inhibition of descending sigmoid and pelvic colon. Inhibition of evacuation of rectum and bladder. Ejaculation. Uterine motility?

some of the cells, while neighboring cells remain quiescent. The existence of neurosecretory units, analogous to the motor units in skeletal muscle, has been postulated.[1]

Close to this nucleus there is another group of cells, the fibers of which also form part of the facial nerve but run in the greater superficial petrosal nerve to the *sphenopalatine ganglion*. The postganglionic fibers innervate the lacrimal glands and the small buccal and nasal glands.

The caudal portion of the nucleus salivatorius, at the level of the upper part of the nucleus ambiguus, is known as the *nucleus salivatorius inferior;* its efferent fibers form part of the glossopharyngeal nerve and run in the lesser superficial petrosal nerve to the *otic ganglion*. The postganglionic fibers (auriculotemporal nerve) innervate the parotid gland and produce the same effects in this gland as the chorda tympani produces on the submaxillary and sublingual glands.

[1] Hillarp, N. A., *Acta physiol. Scandinav.*, 17, 120, 1949.

The most important nucleus of the cranial parasympathetic is the *dorsal motor nucleus of the vagus*, in which the efferent fibers of the vagus nerve arise. These fibers end in the cardiac ganglia, the ganglia in the hilum of the lungs, the plexuses of the esophagus, the upper abdomen, and Auerbach's and Meissner's plexuses in the wall of the gut.[1] Stimulation of the vagus inhibits the heart, provokes constriction of the small coronary vessels and tracheobronchial constriction, increases gastrointestinal peristalsis and tonus, diminishes the tonus of the ileocolic sphincter, and stimulates the secretion of gastric and intestinal glands and the endocrine and exocrine secretions of the pancreas.

Fibers from the hypothalamic nuclei, which pass through the hypophyseal stalk to the different parts of the hypophysis, are now considered part of the cranial parasympathetic.

[1] Langley has suggested the name of "enteric system" for the intestinal plexuses, because it is not possible to affirm that they are part of the parasympathetic.

Table 116. Distribution and Effects of Stimulation of the Parasympathetic Division

Nerve center	*Preganglionic fibers*	*Ganglion*	*Effect of stimulation*
Hypothalamus	Hypophyseal stalk	....	Secretion of antidiuretic hormone and gonadotrophin?
Edinger-Westphal	Oculomotor (III) nerve	Ciliary Ciliary plexus?	Accommodation in near vision. Constriction of pupil
Upper salivary	Facial (VII) nerve (chorda tympani)	Submaxillary	Secretion, vasodilatation, and constriction of ducts in submaxillary and sublingual salivary glands
Lacrimal	Facial (VII) nerve (great superf. petrosal)	Sphenopalatine	Same in lacrimal, nasal, and buccal glands
Lower salivary	Glossopharyngeal (IX) nerve (lesser sup. petrosal)	Otic	Same in parotid glands
Dorsal motor	Vagus nerve	Cardiac	Decrease in heart rate; coronary constriction
Nucleus of the vagus (X) nerve	Vagus nerve	In hilum of lung	Tracheobronchial constriction
Nucleus of the vagus (X) nerve	Vagus nerve	Plexus of the esophagus	Motility of esophagus (smooth muscle)
Nucleus of the vagus (X) nerve	Vagus nerve	Semilunar, celiac, upper mesenteric, Auerbach and Meissner's plexuses	Gastrointestinal secretion. Internal and external secretion of pancreas. Gastrointestinal motility. Inhibition of ileocolic sphincter. Constriction of pancreatic and biliary ducts
SI or II–SIII or IV	Pelvic nerve (n. erigens)	Pelvic plexus	Evacuation of rectum and bladder. Pelvic vasodilatation. Erection. Secretion of glands of genital tract (prostate, Cowper's, etc.). Uterine motility?

Fibers that innervate muscles formed from the branchial clefts arise from a column of cells situated in the ventrolateral part of the reticular formation of the pons and medulla. This discontinuous mass of cells is formed by the motor nuclei of the trigeminal, and facial nerves and the *nucleus ambiguus*, which gives rise to the motor fibers of the glossopharyngeal, vagus, and bulbar portion of the accessory spinal. The fibers emerging from these nuclei innervate muscles that take part in digestive functions (sucking, chewing, and swallowing) and in the expression of emotion (facial and laryngeal muscles). The nuclei are sometimes considered as part of the visceral system, and the column they form is called the "special visceral efferent column." Their constituent cells, however, are large motor neurons with axons of great diameter and high speed of conduction, *i.e.*, with the characteristics of somatic motor neurons, and innervate striated muscles. Other authors call this group of nuclei the "lateral somatic efferent column."

The *sacral parasympathetic* consists of fibers that emerge from the cord in the second and third (in some cases also in the first and fourth) sacral ventral roots and form the *pelvic nerve*. These fibers end on the ganglion cells in the pelvic plexus which emits postganglionic fibers to the pelvic organs. Stimulation of the pelvic nerve relaxes the anal sphincter and increases peristaltic contraction of the lower part of the colon; it inhibits the sphincter vesicae and stimulates contraction of the bladder muscles exclusive of the trigonum. Parasympathetic impulses therefore play an important part in defecation and micturition. They also cause pelvic vasodilatation and erection; hence the name of "nervus erigens," which is also given to the pelvic nerve. In the female, fibers of this nerve end in the uterus, but their action is unknown, and normal labor has been observed in animals after the sacral cord has been destroyed. The spinal centers of defecation, micturition, and erection are found in the sacral segments, but it has not been possible to locate them more precisely.

Parasympathetic ganglia are placed near or even within the organ innervated by their postganglionic fibers, which are short and distributed within a limited area. The effect of parasympathetic stimulation is therefore more restricted than that of sympathetic stimulation. Moreover, a humoral mechanism (hydrolysis of acetylcholine by cholinesterase) also confines parasympathetic effects to a small area (see "Humoral factors in the transmission of visceral nerve impulses," page 1070). The distribution of parasympathetic centers and fibers and the effects of parasympathetic stimulation are summarized in Table 116.

Reciprocal Action of Sympathetic and Parasympathetic Nerves

Most of the viscera are provided with double innervation, *i.e.*, they receive sympathetic and parasympathetic fibers. There are, however, certain exceptions to this rule; thus the nictitating membrane, piloerector muscles, adrenal medulla, and sweat glands are innervated only by sympathetic fibers, which provoke contraction or secretion in these structures.

The effects produced by sympathetic impulses in viscera with double innervation are usually, but not always, opposite to those produced by parasympathetic impulses. Thus, parasympathetic stimuli provoke constriction of the pupil, and sympathetic stimulation is followed by dilatation of the pupil;[1] the heart is stimulated by sympathetic impulses and inhibited by the parasympathetic; the bronchi are dilated by the sympathetic and constricted by the parasympathetic. Many other examples of a similar nature could be given. In these cases the two systems act in a manner similar to the reciprocal innervation of antagonistic somatic muscles; the final result is due to inhibition and stimulation. The main difference, in this respect, between visceral and somatic innervation is the site of inhibition. Somatic structures receive only one type of nerve, which is exclusively excitatory, and inhibition is a central process that takes place within the central nervous system. Visceral structures receive two types of nerve, excitatory and inhibitory, and inhibition takes place in the periphery, *i.e.*, in the innervated organ. For example, flexion of a limb is provoked by impulses that travel along the nerves (excitation) of the flexor muscles (protagonists of the movement), and simultaneously the impulses in the nerves of the extensors (the

[1] Reflex dilatation of the pupil is due mainly to inhibition of parasympathetic impulses (Ury, B., and E. Gellhorn, *J. Neurophysiol.*, 2, 286, 1939). According to Kunz and Richins (*J. Neurophysiol.*, 9, 1, 1946) maximal dilatation is not obtained solely by inhibition of the circular muscle; probably it requires active contraction of the radial muscle innervated by the sympathetic. Kunz and Richins also report evidence of adrenergic (pupillodilatory) fibers arising in the ciliary ganglion.

antagonists of the movement) are diminished or suppressed (inhibition). In the visceral functions, the process is different. In the case of the heartbeat, for example, it is as follows: Tachycardia is provoked by an increase in the frequency of sympathetic (excitatory) impulses and a decrease in the frequency of vagal (inhibitory) impulses; both nerves act on the pacemaker of the heart. Bradycardia is produced by an increase in the vagal impulses and a decrease of the sympathetic impulses to the pacemaker. The importance of inhibition is demonstrated in the following experiment: The superior cervical ganglion is removed, and the pupil contracts owing to the predominance of parasympathetic impulses; if the light falling on the eye is then diminished, the pupil dilates owing to inhibition of these impulses.

In some cases both systems have similar effects; *e.g.*, stimulation of the parasympathetic provokes salivary secretion, which is also obtained by stimulation of the sympathetic. In other cases the effects of stimulation are modified by the conditions of the effector. Thus, parasympathetic stimulation usually increases gastrointestinal peristalsis and decreases the tonus of the sphincters, and sympathetic stimulation has the opposite effects; but when the gut is abnormally active, parasympathetic stimulation may inhibit the intestine, and a strongly contracted sphincter may be made to relax by stimulation of the sympathetic.

Tonic Effects of Visceral Nerves

Visceral nerves exert a continuous, or tonic, effect on the structure they innervate. If the nerves corresponding to one of the divisions of the autonomic system are cut, signs of stimulation of the other division appear. Thus, section of the cervical sympathetic or extirpation of the superior cervical ganglion, or destruction of the spinal cord at the level of the eighth cervical segment to the second thoracic is followed by the following effects due to the predominance of the parasympathetic (Bernard-Horner syndrome): (*a*) constriction of the pupil due to paralysis of the dilator of the iris and predominance of the constrictor; (*b*) narrowing of the palpebral fissure owing to ptosis of the upper lid caused by the loss of tonus in its smooth muscle; (*c*) expansion of the nictitating membrane provoked by the predominance of the fibers of the external rectus inserted on it; (*d*) the eye appears to be sunken in the orbit (enophthalmos) (*e*) vasodilatation and reddening of the skin, the conjunctiva, and the nasal mucosa, owing to paralysis of the vasoconstrictors; (*f*) dryness of the skin, due to the lack of sweat secretion; (*g*) abolishment of the piloerector reflexes in an area extending from the eye to the ear; (*h*) in some cases, a purulent secretion on the conjunctiva and nasal mucosa. In regard to (*d*) it may be noted that accurate measurements made in man have shown that the sympathetic has no influence on the position of the eye in the orbit. Stimulation of the cervical sympathetic does not cause the eye to protrude (exophthalmos), and section of the cervical sympathetic does not cause it to sink into the orbit. In certain species that have a well-developed Müller's muscle, the sympathetic has a slight effect on the position of the eyeball.[1]

The tonic effect of visceral innervation is easily demonstrated by cutting the nerves of the heart. Extirpation of the stellate ganglion is followed by bradycardia due to predominance of vagal impulses, which are no longer balanced by the sympathetic impulses. If the vagi are then cut, the heart rate increases because the continuous or tonic vagal impulses are suppressed.

Impulses travel along visceral nerves more or less continuously or periodically, a fact that has been demonstrated by registration of their action potentials.[2] These impulses are originated in different ways. Some arise in visceral receptors; thus at each heartbeat, systolic dilatation of the aorta and carotid sinuses stimulates stretch receptors which send impulses along the aortic nerve and Hering's nerve. These impulses are relayed in the nucleus of the tractus solitarius to the cardiac center, and inhibitory impulses are sent down the vagus which decrease the heart rate; at the same time sympathetic accelerator impulses are inhibited.

The activity of one center in some cases irradiates to neighboring visceral centers and causes them to discharge periodically; *e.g.*, the vasomotor center in the medulla is stimulated by the respiratory center, and at each respiratory movement volleys of impulses are sent down the vasomotor nerves. Automatic activity of the centers may also contribute to the tonic effect of visceral innervation.

[1] Pochin, E. E., *Clin. Sc.*, **4**, 79, 1939.
[2] Adrian, E. D., D. W. Bronk, and G. Phillips, *J. Physiol.*, **74**, 115, 1932.

Automatism of Visceral Nerve Centers

Visceral nerve centers are relatively independent of the centers situated at higher levels. Thus, destruction of the hypothalamus or section of hypothalamic efferent tracts is followed by ocular signs of suppression of the sympathetic (Bernard-Horner syndrome). After a few days or weeks, however, these signs disappear, and destruction of the ciliospinal center will again provoke the syndrome. After a time the effects again diminish, but extirpation of the superior cervical ganglion will then provoke a marked and lasting Bernard-Horner syndrome. Another example of recovery of tone after destruction of sympathetic centers is observed when the spinal cord is transected at progressively lower levels. After each section the blood pressure falls and then rises, but not to its original level, as the tonus in the arterial wall muscles is reduced and then partially restored.

Immediately after the destruction of a center, the absence of its impulses is made evident by the appearance of certain signs, but later the lower centers restore the normal tonus, at least in part. Visceral nerve centers do not receive impulses exclusively from higher visceral centers, but also from afferent neurons and somatic centers; recovery of tonus may therefore be due to the action of these impulses on the intact nerve centers. Ganglionic neurons, however, exert a tonic influence after they have been disconnected from the centers, and as they do not receive impulses from peripheral structures, this tonic effect must have its origin in the activity of the ganglion, *i.e.*, it must be automatic.

Most visceral structures innervated by the sympathetic and parasympathetic have a considerable degree of autonomy, and their functions are not greatly disturbed after complete denervation. This contrasts with the strict dependence of somatic muscles on their innervation, not only with respect to function (contraction) but also with respect to the maintenance of their normal structure.

The Effects of Drugs on Visceral Innervation

Certain drugs, called "sympathomimetic substances," produce effects similar to those obtained by stimulation of the sympathetic. Others produce effects similar to those due to parasympathetic stimulation; they are called "parasympathomimetic substances." Drugs of another type suppress the effects of stimulation of the sympathetic or the parasympathetic; they are known as "sympatholytic" and "parasympatholytic" drugs.

Sympathomimetic drugs are derivates of adrenaline, which together with noradrenaline is secreted by the adrenal medulla (see Chap. 85). These substances and sympatholytic drugs act on the sympathetic myoneural junction, as was suggested many years ago by Dale.[1] They do not all act with the same potency at different sites; some are mainly excitatory, others mainly inhibitory, but at sufficiently high doses they all produce all the effects of sympathetic stimulation. According to their pharmacological affinity, sympathetic receptors have been classified into two groups, α and β.[2] Stimulation of the α adrenotropic receptors by nerve impulses or drugs produces mainly excitatory effects—vasoconstriction in the viscera and skin, contraction of the uterus, ureter, and nictitating membrane, dilatation of the pupil—and one inhibitory effect, *i.e.*, intestinal inhibition. The β adrenotropic receptors are mainly associated with inhibitory effects—vasodilatation in skeletal muscle and the coronary circuit, inhibition of bronchial muscles and the uterus—and one excitatory effect, *i.e.*, increase in heart rate. Hyperglycemia and the decrease of adrenal ascorbic acid are difficult to classify. The activity of adrenaline on the α receptors is slightly greater than that of noradrenaline, but the latter has very little activity on the β receptors, which are very sensitive to isoprenaline (isopropylnoradrenaline). The order of activity of adrenaline (1), noradrenaline (2), and isoprenaline (3) on α receptors is 1-2-3; on β receptors it is 3-1-2. Sympatholytic drugs, such as ergot and its alkaloids (ergotamine, dihydroergotamine, etc.), iohimbin, and piperidylmethylbenzodioxane (Fournier's 933); suppress α effects but not β effects.

Acetylcholine is the most important of the parasympathomimetic drugs, because it is the most powerful. It acts as a chemical mediator in synaptic transmission in the ganglia, in the skeletal muscle end-plate, in parasympathetic and some of the sympathetic peripheral receptors, and there is evidence that it plays a part in

[1] Dale, H. H., *J. Physiol.*, **34**, 163, 1906.

[2] Ahlquist, R. P., *Am. J. Physiol.*, **153**, 586, 1948.

the conduction of the nerve impulse and in central synaptic transmission. Choline, pilocarpine (extracted from several species of *Pilocarpus*), and muscarine (an alkaloid in the mushroom *Amanita muscaria*) are also parasympathomimetic drugs. The latter acts only at the parasympathetic nerve endings. Atropine, the alkaloid of belladonna (deadly nightshade), is the prototype of parasympatholytic drugs; it is active at peripheral junctions, and much less at the ganglia. Drugs which inhibit cholinesterase and prevent hydrolysis of acetylcholine, such as eserine, prostigmine, di-isopropylfluorophosphate, enhance cholinergic effects or may produce them by potentiating subliminal amounts of acetylcholine released at cholinergic nerve endings.

Several drugs block sympathetic and parasympathetic ganglia, but by different mechanisms:

1. Nicotine, acetylcholine, and some of the quaternary ammoniums, *e.g.*, tetramethylammonium, depolarize the ganglionic neurons, as is shown by electrical records. The ganglionic neuron is first stimulated and discharges impulses which produce peripheral effects, *e.g.*, dilatation of the pupil in the case of the SCG; depolarization persists, and if there is a sufficiently high dose of the drug, preganglionic volleys do not evoke ganglionic potentials and the ganglionic neurons do not discharge. Large doses of eserine block a single impulse without producing depolarization, but repetitive stimulation releases sufficient ACh (which is potentiated by eserine) to block by persistent depolarization.
2. Curare and curare alkaloids (*d*-tubocurarine), tetraethylammonium, and large doses of decamethonium do not depolarize the ganglion or prevent the release of ACh by preganglionic impulses, but they block these impulses by competing with ACh for the substrate (receptor substance) on which ACh acts to produce depolarization[1] (see Chaps. 67 and 69).

Humoral Factors in the Transmission of Visceral Nerve Impulses

Elliott,[2] in his classic work on the action of adrenaline, suggested that sympathetic stimulation released it in the tissues, where it could act as a mediator for the transmission of excitation from the nerve to the effector. Shortly after, Dixon[1] suggested that muscarine could act as a chemical mediator in the peripheral transmission of parasympathetic impulses, but as this substance has not been found in animal organisms, the hypothesis did not have sufficient evidence to support it and did not receive further consideration. Later, choline and acetylcholine, substances with muscarinelike effects, were found to be normal components of the tissues. Several years after this work, Loewi[2] discovered that stimulation of the vagus in the perfused heart of the frog released a substance that produced the effects of vagal stimulation when added to the perfusion fluid in an isolated heart. The unknown active principle was called the "vagus substance."

Acetylcholine. The vagus substance has been identified as acetylcholine by pharmacologic analysis of its effects. It has not been possible to isolate it by chemical methods because it is found in blood and perfusion fluids in concentrations of the order of 1×10^{-8}.

The vagus substance loses its activity very quickly in the blood or when in contact with the tissues, because blood and tissues contain an enzyme, cholinesterase, which hydrolyzes acetylcholine into acetate and choline.[3] Eserine, and other drugs that act as anticholinesterases, such as prostigmine, di-isopropylfluorophosphate (DFP),[4] etc., protect acetylcholine and increase and prolong its effects.

The protective action of eserine has been used to demonstrate the presence of acetylcholine in venous blood and perfusates of organs in different circumstances. The experimental animal is injected with eserine or another cholinesterase inactivator, or this is added to the perfusion fluid, and the venous blood or perfusate is collected in order to test it for acetylcholine on an eserinized organ or tissue. Among the biological tests most frequently used to detect acetylcholine in blood or perfusates are contraction of the dorsal muscle of the leech, inhibition of the isolated heart of the frog, inhibition of the isolated auricle of the

rabbit, and vasodilatation and fall in blood pressure in the cat.

The following conditions must be fulfilled in order to conclude that there is acetylcholine in an organic fluid: (*a*) atropine and curare (which do not prevent release of ACh) suppress the effects of the fluid where they suppress those of ACh; (*b*) perfusate left standing with blood or tissues in alkaline medium loses its effects, which are restored by acetylation; (*c*) boiling in acid medium does not destroy the activity of the blood or perfusate; (*d*) eserine and other drugs with anticholinesterase activity prevent destruction of the active principle and potentiate its effects; (*e*) when the fluid is tested comparatively with acetylcholine on different biological effectors, the same quantitative effects are observed; other esters of choline have greater or lesser activity on the different effectors.[1]

Liberation of acetylcholine after parasympathetic stimulation has been demonstrated in the following organs by perfusion with saline or blood (eserinized) or in eserinized animals using as indicator a denervated organ, *e.g.*, the submaxillary gland or the blood pressure: (*a*) heart; (*b*) gastrointestinal tract; (*c*) submaxillary gland; (*d*) ciliary body and iris (aqueous humor); (*e*) urinary bladder; (*f*) blood vessels of the tongue; (*g*) lung.

Stimulation of sympathetic nerve fibers liberates acetylcholine in the following cases: (*a*) in venous blood from active sweat glands and in sweat[2] (this fact explains the paradoxical action of pilocarpine, a parasympathomimetic drug, on the sweat glands, which are innervated by sympathetic fibers, reported by Langley many years ago); (*b*) in venous blood after stimulation of certain vasodilator fibers;[3] (*c*) in heart blood after stimulation of the stellate ganglion followed by coronary dilatation.[4]

These fibers have been called by Dale[5] "cholinergic fibers with muscarine action" because on stimulation they provoke the release of acetylcholine, which has effects similar to those of muscarine.

Liberation of acetylcholine in the muscle end-

plate and in sympathetic ganglia (cholinergic fibers with "nicotine action"), and in stimulated nerves and nerve centers, together with its significance in the transmission of excitation, has been considered in Chaps. 67, 68, and 69.

The fact that acetylcholine exerts an effect on an organ is not sufficient proof that the organ is supplied with cholinergic innervation. Thus the nictitating membrane responds to ACh[1] yet its innervation is adrenergic.

The sweat glands are sensitive to sympathomimetic drugs. Thus intradermal injection of adrenaline or noradrenaline into the forearm or palm of human subjects, in which the regional nerves have been blocked by procaine, provokes local sweating. This response is suppressed by previous local injection of sympatholytic drugs (ergot alkaloids, etc.). This fact has led to the suggestion that sweat glands have not only cholinergic but also adrenergic innervation.[2] Intradermal injection of atropine suppresses reflex thermal sweating, or sweating induced by insulin hypoglycemia in the area of skin thus treated. Sympatholytic drugs do not have this effect when injected locally; therefore it is unlikely that the sweat glands are innervated by adrenergic fibers.[3]

Sympathin. Stimulation of the sympathetic provokes liberation on the periphery of a substance that has many of the properties of adrenaline. Loewy[4] was the first to observe this; a cardioaccelerator substance appears in the fluid of the perfused heart of a toad after the cardiac sympathetic has been stimulated. Cannon and Bacq[5] demonstrated a similar fact in intact animals. Stimulation in the cat of the sympathetic fibers which innervate the tail provoked piloerection and vasoconstriction in the tail and acceleration of the denervated heart. If the tail veins were tied, piloerection and vasoconstriction were observed but the heart rate did not vary; on reestablishing the venous circulation from the tail, tachycardia was observed. The humoral cardioaccelerator factor liberated by sympathetic stimulation was called sympathin.

Sympathin is more stable than acetylcholine and can therefore act not only locally but also

on distant organs. It can be demonstrated in venous blood proceeding from an organ in which the sympathetic has been stimulated. This blood is tested on an organ or tissue that responds to sympathomimetic substances. The following biological tests are among those most frequently used: contraction of the nictitating membrane, dilatation of the pupil, acceleration of the denervated or isolated heart, constriction of the arterioles and hypertension, relaxation of the duodenum, contraction of the denervated spleen, relaxation of the retractor penis. Denervation not only suppresses the influence of the nerve centers, but also increases sensitiveness to sympathin; therefore denervated structures should be used whenever testing a fluid for this substance. Sensitiveness can also be increased by previous treatment with cocaine.

Liberation of sympathin after stimulation of the cervical sympathetic has been demonstrated in the aqueous humor and in the venous blood from the salivary gland; also after stimulation of the stellate ganglion, the abdominal sympathetic chains, the hepatic nerves, the splenic nerves, etc. Dale has called those nerve fibers which on excitation release sympathin, "adrenergic fibers."

Cannon and Rosenblueth[1] demonstrated that stimulation of sympathetic nerves released two different sympathins. They obtained evidence for this by experiments such as the following: The nictitating membrane and the uterus of a female virgin cat were denervated and their movements were recorded. Stimulation of the abdominal sympathetic chain provoked contraction of the nictitating membrane (excitatory effect) and relaxation of the uterus (inhibitory effect). Stimulation of the hepatic nerves provoked contraction of the nictitating membrane but not relaxation of the uterus (Fig. 490). They therefore supposed that the chemical mediator (M) released in the tissues, combined with a receptor substance E or I producing excitatory

FIG. 490. Sympathins E and I. Upper tracing, contraction of the nictitating membrane. Lower tracing, contraction of denervated nonpregnant uterus. *A*, stimulation of hepatic nerves, liberation of sympathin E; *B*, stimulation of right splanchnic nerve, liberation of sympathins E and I; *C*, stimulation of right splanchnic followed by injection of adrenaline (0.3 cc., 1:200,000); *D*, stimulation of duodenohepatic nerves, liberation of sympathins E and I; *E*, stimulation of duodenohepatic nerves after cutting the duodenal branches, liberation of sympathin E. (*Cannon, W. B., and A. Rosenblueth, Am. J. Physiol., vol. 104, p. 577, 1933.*)

[1] CANNON, W. B., and A. C. ROSENBLUETH, "Autonomic Neuroeffector Systems," Macmillan, New York, 1937.

sympathin E (ME) or inhibitory sympathin (MI). Thus stimulation of liver nerves provokes the release of sympathin E almost exclusively, because the liver contains only the E receptor. In the greater part of the tissues both types of receptor substances are found, also both types of sympathin; therefore, after stimulation of the stellate ganglion acceleration of the heart would be due to release of sympathin E and dilatation of the coronary arteries to release of sympathin I.

The presence in sympathetic nerves and other tissues of a substance similar to adrenaline, which is released by excitation, has been reported by several workers.[1] More recently von Euler[2] extracted from the spleen a blood-pressure-raising substance which resembled noradrenaline and which differed from adrenaline by several of its pharmacologic properties and by its behavior in color and fluorescence reactions. Later it was found in larger amounts in extracts of the thoracic and lumbar sympathetic chain[3] and in the splenic nerves of cattle, also in the blood of man and cattle.[4] Noradrenaline has now been found in the adrenal medulla and in the blood of the adrenal vein (see Chap. 85).

A mixture of adrenaline and noradrenaline is released on stimulation of the hepatic nerves and can be found in the blood of the hepatic veins.[1] Adrenaline and noradrenaline are also released in the perfused rabbit's ear following sympathetic stimulation. Stimulation of the splenic nerve causes the appearance of noradrenaline, and in some cases of smaller amounts of adrenaline, in the blood of the splenic veins.[2] There is now general agreement that sympathin, *i.e.*, the substance released by stimulation of adrenergic nerves, is a mixture in variable proportions of adrenaline and noradrenaline, as was suggested by Bacq and Fischer.[3] Metabolic products of adrenaline oxidized in the tissues, such as adrenochrome, also seem to exert physiologic effects, *e.g.*, acceleration of blood coagulation.[4]

Preganglionic fibers
Acetylcholine

FIG. 491. Diagram of chemical mediators in sympathetic and parasympathetic innervation.

Histamine. Histaminelike substances are released from stimulated nerves[5] and in the periphery by antidromic stimulation of the dorsal roots, which provokes vasodilatation.[6] There may be histaminergic nerves, as well as cholinergic and adrenergic nerves.

Summary. Stimulation of sympathetic and parasympathetic preganglionic fibers liberates acetylcholine in the ganglia, and stimulation of somatic motor fibers liberates it at the neuromuscular junction (cholinergic fibers with nicotinelike action). Stimulation of postganglionic

parasympathetic fibers liberates acetylcholine in the periphery (cholinergic fibers with muscarinelike action). Stimulation of certain postganglionic sympathetic fibers, such as those which innervate the sweat glands, and some of the vasodilator fibers also releases acetylcholine. Acetylcholine is hydrolyzed immediately by the action of cholinesterase; therefore its effects cannot spread or last very long (Fig. 491).

Stimulation of most of the postganglionic sympathetic fibers causes the release of a chemical mediator (sympathin), which is a mixture in variable proportions of adrenaline and noradrenaline (adrenergic fibers).

CENTRAL COORDINATION OF VISCERAL FUNCTIONS

Integration of visceral function is carried out at different levels of the central nervous system. The spinal cord integrates simple reflex responses, while more complex patterns are integrated in centers situated in the pons and medulla, and even more complex patterns in the hypothalamus. There is a cortical level of visceral integration, and perhaps the cerebellum also plays a part in the regulation of visceral functions.

Spinal Visceral Reflexes

A first degree of integration of visceral functions is carried out in the spinal cord. Visceral reflexes are depressed in the spinal animal during the period of shock, but later certain visceral functions are integrated at the spinal level. Thus defecation, micturition (with incomplete evacuation of the bladder), certain sexual reflexes (erection), vasomotor responses, and sweating provoked by heat, cold, and nocuous stimuli that normally cause pain are among the visceral reactions that are observed after transection of the spinal cord. The response to stimulation is sluggish, but after the reflex has developed it tends to spread and persist, giving abnormally intense and widespread responses (mass reflex). Thus distention of the bladder may cause hypertension and profuse sweating (see "The spinal animal," Chap. 81).

Medullary and Pontine Centers

Several fairly complex visceral reactions are integrated at the medullary level; *e.g.*, regulation of the blood-sugar level, the heart rate, and the blood pressure. Integration of visceral and somatic responses also takes place at this level, *e.g.*, vomiting, swallowing, and coughing.

Toward the middle of the last century, Claude Bernard[1] demonstrated that a prick with a needle ("piqûre") on the floor of the fourth ventricle provoked glycosuria. Later it was shown that mechanical or electrical stimulation must be applied in the vicinity of the dorsal nucleus of the vagus to obtain this effect. Impulses are discharged from a center situated in this spot; they travel down the spinal cord and through the splanchnic nerves to the liver and adrenals. Hepatic glycogenolysis and hyperglycemia are produced by a double mechanism: (*a*) nerve impulses pass down the splanchnic and hepatic nerves and stimulate the liver cells directly; (*b*) nerve impulses also pass down the splanchnic nerves to the adrenal medulla, and adrenaline is discharged and carried by the circulation to the liver, where it provokes glycogenolysis.[2]

If the stimulus is applied slightly above this center, hypoglycemia is provoked, perhaps by stimulation of the pancreatic islets and insulin secretion.

It has been argued that "piqûre" of the floor of the fourth ventricle does not act on pontobulbar centers but stimulates the paths descending from the hypothalamus. However, the existence of reflex centers is demonstrated by the fact that certain types of reflex hyperglycemia and hypoglycemia can be provoked after the brain stem has been cut immediately below the mesencephalon, but not after the pons and medulla have been destroyed. There is, therefore, satisfactory evidence of a pontobulbar control of the blood-sugar level.

Bernard also observed that "piqûre" provoked polyuria, and later an increase in renal elimination of salt was observed. Water metabolism and the osmotic equilibrium of the body are, therefore, controlled by mechanisms integrated in pontobulbar centers.

Sweat secretion is integrated in part in pontobulbar centers. This has been demonstrated by means of the so-called "galvanic reflexes," in which the electrical resistance of the skin is determined, because variations in electrical resistance are due to changes in the amount of sweat secreted. Some of these reflexes are local

[1] Bernard, *op. cit.*

[2] Houssay, B. A., and E. A. Molinelli. *Rev. Asoc. méd. argent.*, 37, 235, 1927.

or segmental reflexes integrated in the spinal cord; others cannot be provoked in spinal animals but are observed if the pons and medulla are intact. Another reflex of this type, the so-called "psychogalvanic reflex," is integrated in the cortex.

The bulbar vasomotor center was discovered many years ago in Ludwig's laboratory by means of the following experiment: The blood pressure of an animal was recorded, and the nerve centers were transected at different levels. No significant changes in blood pressure were observed until the section was made below the medulla, in which case the blood pressure fell. Stimulation of the upper part of the floor of the fourth ventricle caused hypertension due to vasoconstriction. Stimulation of a neighboring area caused vasodilatation and a fall in blood pressure. These vasomotor centers are located in the reticular formation of the upper part of the medulla. Reflexes provoked by centripetal stimulation of the cardioaortic and carotid sinus nerves are integrated in these centers; they cannot be obtained in the spinal animal but are intact in the bulbospinal animal.

The vomiting center is located in the dorsolateral reticular formation; if this area is destroyed, dogs no longer vomit when injected with apomorphin or given copper sulfate by mouth. An emetic trigger zone has been found in the area postrema;[1] if it is destroyed, animals cease to respond to apomorphin, although their vomiting center remains intact and they vomit after ingestion of copper sulfate. The emetic trigger zone is also part of the mechanism responsible for motion sickness; animals which vomit on being swung cease to be sensitive to swinging if this zone is destroyed[2] (see "Flocculonodular lobe," Chap. 83).

The dorsal motor nucleus of the vagus is an important center for visceral reflexes; the heart rate, bronchial musculature, and gastrointestinal motility are regulated by impulses discharged from this nucleus down the vagus. Reflexes that assure the normal evacuation of the bladder are also integrated in the medulla; the spinal animal and patients who have suffered transection of the spinal cord have permanent disturbances in micturition (see Chap. 64).

[2] WANG, S. C., and H. I. CHINN, *Federation Proc.*, **11**, 400, 1952.

Reflex regulation of the diameter of the pupil, including the consensual reflex, is integrated in the mesencephalon (Edinger-Westphal nucleus).

The Hypothalamus

The importance of subcortical centers situated above the corpora quadrigemina in the regulation of visceral functions was demonstrated many years ago. Goltz's decorticate dogs had little or no disturbance in visceral functions, but transection of the central nervous system at the level of the corpora quadrigemina caused considerable loss in the control of visceral functions. The centers that take part in this control are situated in the diencephalon, one of the oldest parts of the brain considered from the phylogenetic and ontogenetic point of view.

Anatomic organization (Fig. 492). The hypothalamus forms the floor of the third ventricle. Above, it is separated from the thalamus by the sulcus hypothalamicus. Anteriorly it is continued into the paraolfactory region of the telencephalon (the preoptic and septal areas). Its rostral limit has been established conventionally by a transverse plane passing immediately in front of the anterior border of the chiasma, thus excluding the median and lateral preoptic nuclei. The caudal limit of the hypothalamus is given by a plane passing immediately behind the mammillary nuclei, although there is no definite cleavage between the hypothalamic nuclei and those of the tegmentum of the mesencephalon. Laterally the hypothalamus is continuous with the subthalamic area, *i.e.*, the subthalamic nuclei of Luys, the zona incerta, the capsula interna, and the cerebral peduncle.

The medial forebrain bundle, which runs backward from predominantly olfactory centers (olfactory bulb, olfactory tubercle, paraolfactory area) to the tegmentum, occupies the most lateral part of the hypothalamus and permeates the lateral nuclei. It is more highly developed in the lower vertebrates than in mammals. In microsmatic animals, such as the primates, it is less important. This bundle establishes connections between the olfactory centers and the hypothalamus.

The hypophysis is placed immediately below the hypothalamus, and the pars nervosa of this gland is an outgrowth of the floor of the third ventricle. Important vascular and neural connections between the hypothalamus and the hypophysis are established through the pituitary stalk.

"The hypothalamus of mammals may, for descrip-

tive convenience, be subdivided into three regions from before backwards: 1) the pars supraoptica (in relation to the optic chiasma); 2) the tuber cinereum, to which is attached the stalk of the hypophysis, and 3) the pars mammillaris."[1]
FIG. 492. Diagram of hypothalamic region (sagittal section). *A*, anterior commissure; *Ch*, optic chiasma; *Hyp*, hypophysis; 1, n. preopticus lateralis; 2, n. preopticus medialis; 3, n. paraventricularis; 4, anterior hypothalamic area; 5, n. suprachiasmaticus; 6, n. supraopticus; 7, n. hypothalamicus dorsomedialis; 8, n. hypothalamicus ventromedialis; 9, n. hypothalamicus posterior; 10, n. mammillaris medialis; 11, n. mammillaris lateralis; 12, n. premammillaris; 13, n. supramammillaris; 14, n. interpeduncularis; 15, n. hypothalamicus lateralis; 16, stria habenularis; 17, fornix; 18, fasciculus retroflexus of Meynert. The medial forebrain bundle passes through 1 and 15. (*Le Gros Clark, W. E., et al., "The Hypothalamus," Oliver & Boyd, Ltd., Edinburgh and London, 1938.*)

The following classification and nomenclature of the hypothalamic nuclei and areas, based on the work of Le Gros Clark, have been generally adopted[2] (Fig. 492).

1. Periventricular region.
   a. Periventricular system.
   b. N. preopticus periventricularis.
   c. N. arcuatus periventricularis.
2. Lateral region.
   a. Lateral hypothalamic area.
   b. Lateral nuclei of the tuber.
3. Medial rostral or supraoptic region.
   a. N. supraopticus.
   b. N. paraventricularis.
   c. N. suprachiasmaticus.
   d. N. supraopticus diffusus.
4. Medial tuberal or infundibular region.
   a. N. hypothalamicus ventromedialis.
   b. N. hypothalamicus dorsomedialis.
   c. Posterior hypothalamic area.
   d. Perifornical area.
5. Caudal medial or mammillary region.
   a. N. premammillaris.
   b. N. supramammillaris.
   c. N. mammillaris medialis.
   d. N. mammillaris lateralis.
   e. N. intercalatus.

The periventricular region has small cells distributed in rows in the wall of the third ventricle; it is continued posteriorly into the gray substance of the aqueduct. The lateral hypothalamic area has mostly small and median cells dispersed throughout it; there are also a few large cells similar to those of the supraoptic and paraventricular nuclei. These cells are more numerous in man than in other species, especially in the caudal part of the area. There are two or three small groups of cells in its ventral part, which are known as the lateral nuclei of the tuber.

Above the chiasma (the medial rostral region), there are two main nuclei: the supraoptic and paraventricular nuclei. They are formed by closely packed large cells, with vacuolae containing colloids and lipids, and the Nissl granules in a peripheral position. These nuclei have a very active circulation, and secretory activity has been attributed to them (Roussy's "neurocrinia" and Scharrer's "*Zwischenhirndrüse*"). Hypophysectomy or transection of the hypophyseal stalk causes these nuclei to atrophy owing to retrograde degeneration. Most of the cells of the supraoptic nucleus and, in man, a large proportion of the cells of the paraventricular nucleus are lost after these operations, which, however, do not cause lesions in any other hypothalamic nucleus.

There are two principal nuclei in the medial tuberal region, the n. hypothalamicus ventromedialis and n. hypothalamicus dorsomedialis, both formed by small cells. The hollowing out of this region by the infundibulum of the third ventricle is less marked in man than in other species. The posterior hypothalamic area is well developed in man; it is formed by scattered cells which give rise to the fibers of the periventricular system, which is the principal efferent pathway of the hypothalamus.

[1] LE GROS CLARK, W. E., *et al.*, "The Hypothalamus," Oliver & Boyd, Edinburgh and London, 1938.
[2] LE GROS CLARK, W. E., The Hypothalamus, *Proc. Assoc. Res. Nerv. Ment. Dis.*, **20**, New York, 1940.

The mammillary region has a median nucleus formed by large cells, and premaxillary and supramaxillary nuclei well developed in macrosmatic animals. The n. intercalatus, formed by large cells, is situated between the mammillary nuclei and the fornix, from which it receives fibers.

The afferent fibers of the hypothalamus are as follows:

1. The mammillary nuclei receive fibers from the brain stem which form the spinobulbar and pontobulbar hypothalamic tracts in lower vertebrates but which are collaterals of the median lemniscus in mammals. These fibers conduct impulses from the receptors of general sensibility. Probably some of these fibers conduct impulses from the gustatory fibers in the cranial nerves.
2. The supraoptic nucleus is connected to the vagus by an unknown path. Evidence of this is given by the fact that centripetal stimulation of the vagus provokes hypertension, which does not occur if the hypophysis is removed or the hypophyseal stalk is transected [see No. 2 (supraoptic-hypophyseal tract) under "The efferent fibers," below].
3. Fibers ascending in the periventricular system arise in the tegmentum (corpora quadrigemina). They have been well demonstrated in lower vertebrates, but less clearly in mammals. They pass through the mammillary peduncle and end in the lateral mammillary nucleus.
4. The median lemniscus sends fibers to the hypothalamus, which, together with the thalamohypothalamic fibers, conduct somatic afferent impulses. Visual and auditory impulses may reach the thalamus through the geniculate bodies and the subthalamus.
5. Fibers which come from the striatum by way of the median forebrain bundle, and from the globus pallidus (pallidohypothalamic tract) by way of the subthalamus.

The efferent fibers of the hypothalamus are as follows:

1. Fibers to the nuclei in the tegmentum, which form part of the mammillotectal tract.
2. Fibers from the supraoptic paraventricular nuclei and cells in the anterior part of the infundibular eminence, which form the supraoptic-hypophyseal tract and pass through the hypophyseal stalk into the hypophysis, mainly into the pars nervosa.
3. Fibers for lower centers, arising principally in the posterior hypothalamic area, passing down the periventricular system into the dorsal longitudinal bundle, and scattered fibers which do not form a compact bundle. By means of stimulation and transections it has been possible to establish that these fibers are situated in the tectal part of the pons and laterally in the reticular formation of the medulla; in the spinal cord they form part of the anterolateral column. They decussate at different levels and end in the visceral centers of the midbrain, pons, medulla, and spinal cord.

The hypothalamus is related to the limbic cortical system in a way similar to the relations existing between the thalamus and the neocortex.[1] Fibers in the medial forebrain bundle arise in the olfactory and paraoltactory areas (considerably developed in macrosmatic animals); fibers in the fornix connect the hippocampus with the mammillary body; fibers in the mammillothalamic tract connect the mammillary bodies with the anteroventral nucleus of the thalamus, which projects to the gyrus cinguli. These paths seem to be two-way systems, as are also hypothalamic-neocortical projections. A large unmyelinated motor projection from the posterior part of the orbital gyri (area 13) to the ventromedial and lateral nuclei of the hypothalamus has been found in monkeys and man.[2] The posterior orbital gyrus receives impulses from the afferent fibers of the vagus, relayed in the medial part of the posterior nucleus.[3]

Projections to and from the neocortex are usually relayed in intermediate nuclei, but there is a direct unmyelinated projection from the precentral neocortex. The nucleus ventralis posterolateralis projects impulses arising in splanchnic nerve fibers to ipsilateral and contralateral somatic sensory areas I and II in the region corresponding to the trunk.[4] Other impulses of splanchnic origin are relayed through the posterior hypothalamus and caudal thalamus. The hypothalamus is also connected to the frontal cortex by a two-way projection relay: (*a*) the dorsal nuclei of the thalamus; (*b*) anterodorsal nuclei of the septum (neocortical septal and septohypothalamic tracts); and (*c*) the zona incerta of the subthalamus.

The hypothalamic nuclei are interconnected by many fibers.

The hypothalamus has an active circulation supplied by arteries from the arterial circle of Willis. Popa and Fielding[5] described a portal circulation formed by capillaries in the hypothalamus, opening

into vessels in the hypophyseal stalk, which again ramify into capillaries in the hypophysis. They maintained that blood flows from the hypophysis to the hypothalamus. Later work[1] has shown that blood flows in the opposite direction, *i.e.*, from the hypothalamus to the ventral aspects of the pars distalis of the hypophysis.

Stimulation of the hypothalamus. The different parts of the hypothalamus have been stimulated by implanting electrodes and applying the stimulus when the animal has recovered from the effects of the operation and anesthetic. Occasionally, in the course of surgical operations, the hypothalamus has been stimulated in man. The optimum rate of stimulation is high compared with that for visceral effectors, and this is important because lowering the rate (without changing the situation of the electrodes) may reverse the effects provoked, *e.g.*, a pressor response may be converted into a depressor response.[2] After stimulation, signs of visceral activity or inhibition of visceral activity, mediated by the sympathetic and parasympathetic, may be observed. The response is frequently a complex pattern integrated with somatic reactions.

According to Hess and his associates,[3] it is more convenient to refer to longitudinally located zones than to specific centers for definite responses. Hess divides the hypothalamus in this respect into medial, intermediate, and lateral zones. The medial area is relatively unresponsive; the caudal hypothalamus gives mainly sympathetic responses, and the rostral areas are concerned with the integration of complex patterns coupled to somatic movements, such as defecation.

Dilatation of the pupil, contraction of the nictitating membrane, vasoconstriction, tachycardia, and other signs of sympathetic activity have been provoked by stimulation of the hypothalamus. Dilatation of the pupil in the cat is caused by two different mechanisms with separate locations; one inhibits the oculomotor (parasympathetic) center, the other stimulates the sympathetic. In the monkey the latter is the more important, because section of the cervical sympathetic diminishes or abolishes the dilator response to hypothalamic stimulation, while in the cat the inhibitory mechanism is more important.[1] Destruction of the lateral and caudal areas of the hypothalamus is followed by a Bernard-Horner syndrome, which is more marked if the destruction is bilateral but which does not last long. It would seem, therefore, that hypothalamic centers exert a tonic influence on the innervation of the pupil.

Other local effects of hypothalamic stimulation will be considered later, but widespread activation of sympathetic visceral effectors may be due to an increase in the secretion of adrenaline provoked from the hypothalamus (see Chap. 85). Release of sympathin has also been obtained by hypothalamic stimulation.[2]

Typical vagal effects on the intestine (increased peristalsis) have been observed following stimulation at the level of, or caudal to, the infundibulum; double vagotomy abolished these effects. Stimulation of more rostrally situated parts caused vasoconstriction and inhibition in the gut, followed by a marked excitatory response; since these effects were not abolished by vagotomy,[3] they were probably due to excitation and subsequent inhibition of the abdominal sympathetic. Inhibition of peristalsis in the stomach, intestine, and colon (*i.e.*, sympathetic effects) has been obtained by stimulation of the lateral areas of the hypothalamus.[4] Salivation and an increase in gastric secretion and acidity have also been reported following hypothalamic stimulation.

Stimulation of the anterior hypothalamus provokes activity in the bladder, mediated by the pelvic and hypogastric nerves. Movements of defecation have also been observed following stimulation of this part of the hypothalamus.

The effects provoked by stimulation of the hypothalamus are not due to stimulation of paths descending from the cortex; they have been obtained after decortication and degeneration of corticofugal fibers. Moreover, local cocainization of the hypothalamus abolishes them, and the administration of barbiturates

(amytal, nembutal) depresses hypothalamic excitability.

Functional patterns integrated in the hypothalamus. Several complex visceral synergies, sometimes coupled with somatic reactions, are integrated in the hypothalamus; *e.g.*, the regulation of body temperature, water metabolism, certain aspects of carbohydrate and fat metabolism and of sexual functions, general bodily activity, sleep, etc.

Temperature regulation. Over forty years ago, Isenschmidt and Schnitzler[1] suggested that the hypothalamus was concerned in heat regulation, a fact that has been given definite proof by later work. Keller and Hare[2] demonstrated that the chief central mechanism controlling heat production is located in the hypothalamus. Transection of the brain immediately caudal to the mammillary nuclei converts a homeothermic animal into a poikilothermic one. On the other hand the hypothalamic animal (*i.e.*, an animal in which the forebrain has been removed but the hypothalamus remains intact) regulates its body temperature and maintains it at a constant level. This is achieved by a complex hypothalamic mechanism that integrates visceral and somatic reactions to heat and cold. Thus an animal placed in a cold environment responds by vasoconstriction, piloerection, and increased secretion of adrenaline (visceral reactions), which diminish heat loss, and by shivering, a somatic reaction, which increases heat production. The response to heat involves activation of visceral mechanisms such as vasodilatation and sweating and the somatic response of panting (heat polypnea).

The different parts of the hypothalamus have been stimulated locally by introducing electrodes heated by means of low-voltage high-frequency currents. Warming of the anterior hypothalamus causes a fall in rectal temperature by activation of mechanisms that increase loss of heat: there is cutaneous vasodilatation and sometimes vasoconstriction in the splanchnic area. If the skin is cooled at the same time as the hypothalamus is warmed, vasodilatation is diminished or suppressed. Cooling of the anterior hypothalamus causes vasoconstriction in the skin if the cutaneous vessels are dilated, but not otherwise. Warming the anterior hypothalamus also provokes polypnea and sweating.[1] Stimulation of the lateral and caudal hypothalamus is followed by cutaneous and splanchnic vasoconstriction and dilatation of blood vessels in muscles. The latter response is mediated by cholinergic vasodilator sympathetic fibers, and it can be suppressed by atropine or sympathetic denervation of the muscles.[2] Simultaneously there is cutaneous piloerection, discharge of adrenaline from the adrenal medulla, hyperglycemia due to increased glycogenolysis, and a rise in temperature.

Bilateral destructive lesions of the rostral (preoptic) area provoke a postoperative rise in temperature in monkeys, which may reach a fatal level if it is not treated. The heat-loss mechanism is paralyzed; there is no vasodilatation or sweating, and the threshold of thermic polypnea is raised considerably. The heat-conservation mechanism is maintained and is perhaps exaggerated; heat production continues. Pentobarbital causes a fall in temperature in these animals, which is due to suppression of the activity of the heat-conservation mechanism (there is peripheral vasodilatation, and piloerection ceases) and to a decrease in heat production (shivering ceases).[3] In man lesions in the vicinity of the third ventricle produce hyperthermia due to vasoconstriction and cessation of sweating, *i.e.*, to paralysis of the mechanism controlling loss of heat.

Destructive lesions in the caudal part of the lateral hypothalamus are followed by a fall in temperature owing to damage to the centers that regulate the reactions to cold.[4] If the animals are placed in a cold environment they do not respond with shivering, cutaneous vasoconstriction, or piloerection, which increase heat production or decrease the loss of heat. These

lesions also destroy efferent paths from the more rostrally situated centers which control the reactions to heat, and the animals become completely poikilothermic.

After a time these disturbances are compensated to a certain extent, and the animals can maintain a fairly constant body temperature, but when they are submitted to stress, *e.g.*, when they are placed in an ice chest or in a warm room, their thermic reflexes are sluggish and the body temperature may fall or rise.

The temperature-regulating centers in the hypothalamus are brought into activity by stimulation of cutaneous receptors that are sensitive to hot and cold, and by changes in the temperature of the blood circulating through the centers. The importance of the temperature of the blood in the regulation of body temperature was demonstrated by Sherrington by means of the following experiment: The spinal cord of a dog was transected at the level of the upper thoracic segments, so as to disconnect the hindquarters of the animal from the higher nerve centers. The hind limbs were then submerged in cold water, and soon the forelimbs and head began to shiver. This response could not be of reflex origin, because all nerve paths from the hind limbs had been suppressed; therefore it must have been due to cooling of the blood as it passed through the skin submerged in cold water. Later, Barbour[1] showed that warming the carotid blood caused hypothermia and that cooling it caused hyperthermia. In the first case, warm blood arriving at the hypothalamus stimulated the centers that control the rise of body temperature and provoked excessive heat loss and a fall in temperature. In the second case, cool blood stimulated the centers that control the fall of body temperature and provoked excess heat production and reduced the loss of heat so that the body temperature was increased.

The hypothalamus seems to be of secondary importance in the control of vasomotor responses to changes in the temperature of the environment, which are mainly regulated by reflexes initiated in the superficially placed receptors sensitive to warming and cooling of the skin. Changes in the internal temperature stimulate receptors placed deeply in the skin (which provoke sweating on being warmed)[2] and

the hypothalamus. Integration of visceral (vasomotor reactions, sweating, piloerection, etc.) and somatic (shivering, panting) responses to changes in internal and also in external temperature, performed at the hypothalamic level, is of major importance in the maintenance of a constant body temperature.

Regulation of water metabolism. The maintenance of a constant body temperature is closely connected with the water balance and the osmotic equilibrium of the body. Cooling provokes concentration, and warming provokes dilution, of the blood. Destructive lesions of the hypothalamus disturb these reactions. Thus permanent polyuria is caused by destruction of the supraoptic nucleus or by transection of the supraopticohypophyseal tract or the hypophyseal stalk.[1] The syndrome of diabetes insipidus, observed in man and characterized by great thirst (polydipsia) and the daily elimination of large quantities of urine of low specific gravity, is thus reproduced experimentally. On the other hand, water diuresis can be inhibited in rabbits by stimulation of the supraoptico-hypophyseal tract[2] (see Chap. 52). This is a cholinergic mechanism. Injection of small amounts of acetylcholine into the supraoptic nuclei releases the antidiuretic hormone of the posterior pituitary; and the same effect can be obtained by intracarotideal injection of ACh in unanesthetized, atropinized dogs. Di-isopropylfluorophosphate injected into the supraoptic nuclei also produces marked and long-lasting inhibition of the rate of urine flow owing to accumulation of ACh; later (4 to 19 days) there is polyuria, probably due to an excess of ACh.[3]

Cardiovascular control. Stimulation of the anterior and middle parts of the hypothalamus as well as the posterior part may provoke an increase in blood pressure. Sometimes a fall in blood pressure is observed by lowering the frequency of stimulation without changing the position of the stimulating electrode.[4] Stimula-

tion of the preoptic area causes a decrease in heart rate, and stimulation of the hypothalamus causes an increase in heart rate.[1] Records of the electrical activity of the inferior cardiac nerves and the cervical sympathetic[2] show that during hypothalamic stimulation there is an increase of activity in these nerves which ceases when stimulation is stopped. Probably hypothalamic impulses are relayed in the medullary sympathetic centers. Destructive lesions of the hypothalamus cause no change in the electrical activity of sympathetic nerves, nor are they followed by changes in heart rate or blood pressure; therefore, hypothalamic centers do not exert a "tonic" effect on the circulation.

Carbohyarate metabolism. Hypothalamic mechanisms play a part in the regulation of carbohydrate metabolism through the sympathico-adrenal glycogenolytic mechanism. Certain hyperglycemic reactions, *e.g.*, that provoked by cold, do not take place or are depressed in animals after the hypothalamus has been destroyed. Lesions in the neighborhood of the paraventricular nucleus provoke hypoglycemia and hypersensitiveness to insulin (see Chap. 41).

Fat metabolism. A hypothalamic mechanism regulating fat metabolism has been postulated because in certain cases of tumors of the brain, located in the diencephalon, adiposity or emaciation have been observed. Some of the cases are characterized by adiposity together with atrophy of the reproductive organs (Fröhlich's syndrome, or dystrophia adiposogenitalis). Marked obesity has been observed following hypothalamic lesions in the dog and rat.

In the rat this condition is provoked by bilateral destruction of a zone extending backward from the ventromedial nuclei to the region dorsolateral to the mammillary bodies.[3] It is caused by interrupting connections arising in the hypothalamus and descending in the brain stem. It is not provoked by interruption of the hypothalamic paths to the hypophysis, nor is it prevented by removal of the hypophysis.

In rats[4] oxygen consumption was found to be low and RQ high. Obesity seems to be due

mainly to an enormous increase in appetite. The animals eat twice as much as the controls, but in paired feeding experiments (the experimental animal being fed the same amount as the control) the rat with the hypothalamic lesion increased in weight only slightly more than the litter-mate control. Decrease in activity is also a factor in the obesity of these animals. On the other hand, lesions in the lateral hypothalamus, at the level of the ventromedial nucleus, lead to the refusal of food, even in animals with hyperphagia caused by previous destruction of the ventromedial nucleus.[1] Ingestion of food is controlled by a dual hypothalamic mechanism; impulses integrated in the lateral hypothalamus increase hunger, which is inhibited by impulses from the more medially placed ventromedial nucleus. These reactions are integrated at the cortical level in the posterior orbital gyrus (area 13).

Sexual functions. Evidence of the importance of the hypothalamus in the control of sexual function is given not only by cases of Fröhlich's syndrome but by several other facts (see Chap. 52). Thus a bulbospinal female cat does not present the usual estral behavior whether the estrus has occurred naturally or has been provoked by the injection of estrogens; while the decorticate cat, which has an intact hypothalamus, shows no significant changes in estral behavior.[2] The nuclei that control sexual behavior have not yet been located. In species such as the rabbit, in which ovulation does not occur spontaneously, the importance of the hypothalamic-hypophyseal mechanism has been demonstrated (see Chaps. 52 and 58). Stimulation of the hypothalamus provokes liberation of the luteinizing hormone and ovulation in the rabbit; this effect is not obtained by direct stimulation of the hypophysis. This also seems to be a cholinergic mechanism, because banthine suppresses copulatory ovulation in the rabbit.[3]

Emotional expression. Integration of the visceral and somatic reactions of emotional states takes place in the hypothalamus. A cat that has been recently decorticated shows marked somatic

[1] Anand, B. K., and J. B. Brobeck, *Proc. Soc. Exper. Biol. & Med.*, **77**, 323, 1951; *Yale J. Biol. & Med.*, **24**, 123, 1951.

and visceral reactions typical of intense emotion. The slightest stimulus provokes movements of flight; the animal struggles vigorously, puts out its claws, cries, and switches its tail. The hairs are erected, there is tachycardia, the pupils are dilated, the blood sugar rises, and adrenaline is secreted; *i.e.*, there are signs of intense and widespread activity of the sympathetic. This condition, which has been called "pseudoaffective" by Sherrington, and "sham rage" by Cannon, is quickly suppressed by transection of the brain immediately below the hypothalamus.[1] Normally the cortex inhibits the diencephalic centers that integrate emotional expression, and when these inhibitory stimuli are missing, emotional reactions are exaggerated. Thus the pseudoaffective state is a release phenomenon, similar to decerebrate rigidity. A chronic bulbospinal or mesencephalic animal shows only fragmentary and incomplete expression of emotion, which is in marked contrast with the violent behavior of the decorticate or hypothalamic animal.[2]

"Sham rage" has been provoked by stimulation of the lateral areas of the hypothalamus in unanesthetized cats by Ranson and his associates and has later been confirmed by many others (Hess, Masserman, etc.). Local strychninization of the hypothalamus (Dusser de Barenne) or injection of strychnine into the third ventricle[3] causes spontaneous, sometimes violent, pseudoaffective reactions and increases the response to hypothalamic stimulation. "Sham rage" and other emotional reactions provoked by stimulation of the hypothalamus do not last long. Visceral responses also usually cease soon after stimulation is discontinued. In the intact animal, on the other hand, emotional disturbances often persist for a very long time after the stimulus has ceased to act.

Extensive bilateral destruction of the hypothalamus in cats and monkeys causes stupor, alternating with pseudoaffective manifestations of rage when the animal is annoyed or restrained.[4] Localized destruction of the ventromedial nuclei in cats was followed by a marked change in the response of the animals to friendly treatment and

handling; any interference provoked a savage and malevolent reaction.[1]

Changes in emotional behavior and other mental disturbances have been reported in cases in which the hypothalamus has been damaged. The patients presented two types of symptoms:

1. There was psychic excitation of a maniacal character, with great loquacity, absence of control of behavior with the performance of sexual misdemeanors, anxiety, fear, strong emotional reactions, and in some cases hallucinations. Intellectual deficiencies similar to those observed in cases of frontal lobotomy have been observed, although there were no cortical lesions.
2. When the area near the mammillary nuclei was found to be destroyed, the patients had been somnolent and apathetic, and had had a tendency to hypothermia.

The hypothalamus should not be considered as a mechanism for the production of emotion, but as part of the effector mechanism of emotional expression[2] which integrates visceral and somatic reactions, stimulating and perhaps inhibiting emotional activity.

General activity and sleep. The level of general activity of the cortex (sleep, somnolence, restful waking, alertness) is conditioned by impulses from the hypothalamus and other parts of the diencephalon and from the reticular formation. This will be discussed in Chap. 88, Sleep.

Stress. There is some evidence that the hypothalamus plays a part in the reaction to stress. Thus insulin, adrenaline, hypoxia, *i.e.*, stimuli which provoke stress, increase the electrical activity of the posterior hypothalamus.[3] Electrical stimulation of the posterior part of the tuber cinereum and the mammillary bodies is followed by lymphopenia similar in its course to that observed in stress.[4] Section of the pituitary stalk, however, does not prevent corticoadrenal response to acute stress.[5]

Striatohypothalamic and pallidohypothalamic pathways have been found, but their physiologic significance is still unknown.

The part played by the cerebellum in the integration of visceral function is not known. It has been reported that extirpation of the cerebellum is followed by retarded gastric evacuation and severe constipation; also that stimulation of the cerebellar cortex inhibits gastrointestinal motility and exerts a depressor action on the medullary centers regulating the circulation. Several years ago Fulton[1] remarked that "there is some reason to believe that any form of representation existing in the motor regions of the cerebral cortex probably also exists in the cerebellum" and suggested that "further work may lead to a conception of ataxia and asynergia in autonomic regulation similar to that now held for cerebellar disturbances in the somatic sphere."

Cortical Integration of Visceral Functions

Visceral responses are integrated (in some cases with somatic movements) at the cortical level mainly in the rhinencephalon, but also in the neocortex.[2]

Observations made in cats, dogs, monkeys, and anthropoids and in man have shown that stimulation of several areas in the rhinencephalon evokes visceral, somatovisceral, and somatic responses.[3] These areas can be divided into two groups: (*a*) the rostral part of the anterior limbic cortex, around the genu of the corpus callosum, and (*b*) the posterior orbital gyrus, the anterior part of the insula, the anterior part of the hippocampus gyrus, and the adjacent temporal cortex. These areas are directly related with the anterior thalamus, hypothalamus, epithalamus, and pontine structures.

Stimulation of either of these areas slows down the respiratory rhythm and may produce temporary apnea. Acceleration of the respiratory rhythm is evoked from the posterior part of the anterior limbic area, from the anterior and ectosylvian gyri, and from the anterior sigmoid gyrus in cats and dogs.[4] Vasomotor responses are obtained from the same two areas that inhibit respiratory movements, independently of the respiratory effect. Pressor and depressor reactions are observed, depending on the site of stimulation and in some cases on the frequency of the stimulus; low frequencies (10 to 20 c.p.s.) evoke depressor and high frequencies (40 to 80 c.p.s.) pressor reactions. Section of both vagi abolishes or greatly reduces depressor responses but has no effect on pressor responses.

Movements associated with the ingestion and digestion of food can be evoked from these areas.[1] Well-coordinated chewing movements follow stimulation of the pyriform area and amygdala; licking, salivation, swallowing, and in some cases retching can be provoked by stimulation of the olfactory tubercle and the adjacent pyriform cortex. Inhibition of peristalsis and tonus of the pyloric antrum has been obtained by stimulating (*a*) the rostral part of the anterior limbic cortex, and (*b*) the postorbital with the adjacent insular cortex, the anterior part of the hippocampal gyrus, and the adjacent temporal lobe. Augmentation of peristalsis and tonus can also be obtained from the second of these areas.[2]

Other autonomic effects observed after stimulating these areas were piloerection in monkeys (supracallosal portion of the anterior limbic cortex and olfactory tubercle) and slight pupillary dilatation (from the respiratory inhibitory areas); micturition and defecation occurred frequently on stimulating the pyriform cortex and amygdala.

Ablation of different parts of the rhinencephalic area produces certain autonomic effects. Thus ablation of area 13 is followed by vasodilatation and increase in skin temperature.[3] Bilateral ablation of the limbic gyrus provokes an increase in gastric motility.[4] Bilateral removal of area 13 causes hypermotility in the gastrointestinal tract and hyperphagia.

Somatic movements initiated in the neocortex are integrated with changes in the circulation and other visceral reactions. Thus stimulation

of area 6 in the frontal lobe provokes tachycardia, hypertension, and vasoconstriction in the splanchnic area and the skin, so that the circulating blood is shunted toward the muscles, brain, and lungs. Stimulation of neighboring areas may provoke vasodilatation and a fall in blood pressure. The pressor and depressor areas frequently overlap. Stimulation of the motor cortex of the dog between the sulcus cruciatus and a more caudal sulcus homologous to the Rolandic sulcus provokes vasodilatation in the limb muscles, through activation of cholinergic vasodilators, and vasoconstriction in the skin and splanchnic area; the blood flow through the muscles is thus increased. The same effects are obtained by stimulation of the supraoptic region near the mid-line in the cat and dog.[1] Stimulation of areas 6 and 8 in the frontal cortex is followed by augmentation of gastrointestinal movements,[2] though in some cases inhibitory effects are observed.[3] Stimulation of the cortical centers that provoke movements of the tongue also causes salivary secretion, and certain movements of the hand induced by cortical stimulation are accompanied by sweat secretion, which increases sensitiveness to touch. Stimulation of the frontal eye fields provokes not only movements of the eye muscles but also dilatation of the pupil, which is suppressed by removal of the superior cervical ganglion.[4] Another cortical center that provokes dilatation of the pupil has been found in the cat[5] in the medial aspect of the hemispheres, above the corpus callosum and anterior to the cruciate junction. Constriction of the pupil can be obtained by stimulation of the preoccipital area. Peripheral sympathetic and parasympathetic denervation modifies these responses; thus, removal of the stellate ganglia suppresses tachycardia following cortical stimulation, and section of the vagi increases it.

In all these cases somatic movements are integrated with adequate visceral reactions. Interconnections between somatic and visceral motor innervation are therefore established at all levels of integration.[1]

[5] SIEBENS, A. A., and C. N. WOOLSEY, *Federation Proc.*, **5**, 95, 1946.

Vasomotor responses are disturbed by certain cortical lesions.[2] It is a well-known fact that in cases of hemiplegia there is at first an increase in the temperature of the skin on the paralyzed limbs, due to vasodilatation, and that later the paralyzed limbs are colder than the contralateral limbs, owing to vasoconstriction. Experimental destruction of the frontal cortex disturbs vasomotor reactions. Thus in the dog cold does not provoke vasoconstriction, and in the monkey heat does not provoke vasodilatation.

The reactions for regulating body temperature are sluggish in animals in which the frontal cortex has been destroyed, but once established they have a tendency to persist and outlast their need. The "psychogalvanic" reflex (decrease in the electrical resistance of the skin when certain auditory, visual, or tactile stimuli are applied, owing to an increase in sweat secretion) is integrated in the frontal cortex, since it is abolished by destruction of area 6. Stimulation of this area, and of the anterior part of the temporal lobe, provokes sweat secretion in the cat, even after the hypothalamus has been destroyed; the impulses travel along the frontopontine and temporopontine pathways.

Visceral functions are integrated at different levels, in a way similar to that of somatic activity. Simple local reactions are integrated by means of segmentary spinal reflexes. More complex patterns, such as the regulation of blood pressure and vomiting (which has also somatic components), are integrated in the medulla. Still more complex synergies, such as temperature regulation, are integrated at a hypothalamic level. Finally there is also a cortical level of integration at which visceral and somatic responses are coordinated.

PHYSIOLOGIC SIGNIFICANCE OF VISCERAL INNERVATION

Most organs function in apparently normal condition after complete denervation. Thus, gastrointestinal motility and secretion suffer only transitory disturbances after denervation. The salivary glands, however, are an exception

[1] KENNARD, M. A., *Psychosom. Med.*, **9**, 29, 1947.

[2] PINKSTON, J. O., P. BARD, and D. McK. RIOCH, *Am. J. Physiol.*, **109**, 515, 1934; PINKSTON, J. O., and D. McK. RIOCH, *Am. J. Physiol.*, **121**, 49, 1938.

to this rule, and salivary secretion is abolished permanently after the secretory nerves have been cut. The muscles of the blood vessels and orbital smooth-muscle structures soon recover their tonus after denervation. Likewise completely denervated or grafted endocrine glands, with the exception of the adrenal medulla and the pars nervosa of the hypophysis, function normally.

Moreover both vagi can be cut[1] and the whole sympathetic chain can be removed on both sides, from the superior cervical to the coccygeal ganglion, together with the solar plexus, with survival of the subjects.[2] Totally sympathectomized cats, dogs, and monkeys behave apparently normally in quiet conditions. No changes are observed in somatic motility, in growth, or in digestive, nutritive, and sexual functions (estrus, fertilization, pregnancy, parturition, and lactation). There are no apparent changes in psychic behavior; the temperament of the animal remains as before the operation, whether it was docile and affectionate or surly and aggressive. Somatic expression of emotion is not altered. A mother cat will defend her kittens from a dog by arching her back, spreading her claws, and hissing, just as a normal cat does; but her hairs do not stand on end, the heart rate does not increase, and there is no hyperglycemia; *i.e.*, visceral reactions are absent.

The inferiority of sympathectomized animals as compared to normal ones is evident when they are placed in conditions of emergency or stress. For example, if a sympathectomized cat is placed in a room at 0 to 5°C., its rectal temperature falls one or two degrees, owing to the absence of reflexes (piloerection, cutaneous vasoconstriction) that diminish the loss of heat. The BMR of these animals is within the normal range, although it is low, and heat production rises when they are placed in a cold environment, by an increase in muscle tonus and shivering, as in normal animals.[3] Another instance of the limited capacity to resist stress

[1] This should be done below the emergence of the inferior laryngeal nerve, in order to avoid laryngeal paralysis and choking. Complete vagotomy in man is followed by disturbances in gastric function.

[2] Cannon, W. B., J. T. Lewis, and J. W. Britton, *Boston Med. & Surg. J.*, **197**, 574, 1927.

[3] Cannon, W. B., H. F. Newton, E. M. Bright, V. Menkin, and R. M. Moore, *Am. J. Physiol.*, **89**, 84, 1929.

is the difficulty with which they recover a normal blood sugar after hypoglycemia, whence their increased sensitiveness to insulin. There are, however, differences between species. Thus, sympathectomized cats are hypersensitive to anoxia, and their capacity to perform physical exercise is reduced; sympathectomized dogs resist anoxia and cold better than cats and can perform physical exercise fairly well.[1]

Visceral innervation is not, therefore, indispensable for life, but it is not without physiologic significance. Careful study of a denervated organ shows that it does not respond normally to functional stress. For example, a grafted (therefore completely denervated) pancreas secretes insulin in greater or lesser amounts according to the level of the blood sugar (more when it is high, less when it is low); but if the rate of recovery of the normal blood-sugar level after hyperglycemia or hypoglycemia in normal animals is compared with that in animals with a grafted pancreas, it will be seen that the former recover the normal level faster than the latter.[2] Many other examples of delayed response or inaccurate adjustment to conditions of stress could be given.

In emergencies that involve the whole body, hyperactivity of the sympathetic is a prominent feature. The architecture of this system is such that general reactions are facilitated, although the mechanism for localized response also exists. In strenuous muscular exercise, asphyxia, intense emotion, and other conditions that require mobilization of all the resources of the organism ("fright, flight, or fight" pattern of behavior) there are tachycardia, vasoconstriction in the splanchnic area and the skin, evacuation of blood depots (spleen, skin), increase in circulating blood volume, and shunting of the blood from the abdominal viscera to the locomotor apparatus (muscles, lungs, brain). The bronchi are dilated, and the red cell count increases; liver glycogen is converted to glucose, and the blood sugar rises. The sympathetic plays a major part in this type of response, and its action is reinforced by an increase in adrenaline secretion. The body reacts to generalized emergencies by mobilizing its reserves and increasing the expenditure of energy.

[1] McDonough, F. K., *Am. J. Physiol.*, **125**, 530, 1939.

[2] Houssay, B. A., J. T. Lewis, and V. G. Foglia, *Rev. Soc. argent. de biol.*, **4**, 859, 1928; **5**, 1, 1929.

The parasympathetic becomes active in "localized emergencies," *i.e.*, stress applied to a single organ or group of organs. The architecture of this system is well adapted to this purpose. The ganglia are situated near the innervated viscera, and they serve a relatively limited area. The chemical mediator (acetylcholine) is rapidly inactivated after it has been released, so that it cannot exert its effects on distant organs, as is the case with the chemical mediator (sympathin) of the sympathetic. For example, the ingestion of food creates an "emergency" in the digestive tract, and the glands and muscle of this tract are brought into activity by parasympathetic impulses. The parasympathetic is usually active when the body, especially the locomotor apparatus, is at rest, and the result of its activity is the accumulation of energy.

Visceral innervation has not only an intermittent activity in moments of stress, but also a continuous or "tonic" action. Tonic impulses arise mainly, although not exclusively, in reflexes from the receptors in the aorta and the carotid sinus. Changes in blood pressure, in oxygen and CO_2 pressure, in acid-base equilibrium, and many other factors (see Chap. 17) act on these vascular receptors and cause a reflex increase or decrease of sympathetic and parasympathetic impulses, which tend to restore the normal equilibrium. For example, a rise in blood pressure stimulates the stretch receptors in the aortic wall and the carotid sinus, thus provoking reflex stimulation of the vagus and inhibition of the cardioaccelerator fibers in the sympathetic, so that bradycardia results; at the same time the vasoconstrictors are inhibited, and the secretion of adrenaline diminishes. All these reactions tend to lower the blood pressure and restore it to the normal level.

The visceral nervous system contributes to the rapid and accurate adaptation of the organism in changing circumstances. It is, therefore, an important mechanism of "homeostasis,"[1] helping to maintain that fixity of the *milieu intérieur* which, as Claude Bernard so clearly stated, is a condition of free life.

CHAPTER 85

The Secretion of the Adrenal Medulla

THE SECRETION OF the adrenal medulla, adrenaline (epinephrine) and noradrenaline (norepinephrine), produces the same effects as stimulation of the adrenergic sympathetic. The nervous and humoral mechanisms that activate sympathetic effectors have a common origin in the embryo and they form a functional unit, the sympathicoadrenal system. For this reason medulliadrenal secretion is discussed in this section rather than in Sec. VI, with the functions of the adrenal cortex and other internal secretions.

Embryonic origin of the adrenal glands. The cortical tissue arises from the mesenchyma, in the part of the celomic epithelium situated near the site of origin of the kidneys and the sexual glands. At an early stage of development many buds appear. Some are reabsorbed; others conglomerate and form the adrenal cortex; a few remain isolated and constitute accessory corticoadrenal glands. These are more frequently found in some species, such as the rat and rabbit, than in others, such as man, dog, cat, and guinea pig. They are usually situated near the gonads, in the epididymis or the broad ligament, and in the retroperitoneal tissue, along the course taken by the gonad in its fetal migration.

The tissue of the medulla arises in the ectoderm, in cells that form part of the buds for the spinal ganglia and later develop in one of two ways. Some of them, the sympathoblasts, are converted into sympathetic ganglion cells; others, the pheochromoblasts, take on a glandular aspect and form the adrenal medulla. The latter give typical histochemical reactions, because of the substance from which adrenaline is made: they stain blue with ferric chloride, and a dark brown with chromates. The latter reaction has given them the name of chromaffin cells. In the early stages of development many buds of chromaffin cells appear; some are reabsorbed, while others conglomerate into the adrenal medulla. A few groups remain isolated and form the accessory chromaffin organs found in the retroperitoneal tissue (Zuckerkandl's body) and near the sympathetic ganglia (paraganglia).

The adrenal is well provided with blood vessels, and has a very active circulation.

Chemical structure of adrenaline. Oliver and Schäfer[1] were the first to report that adrenal extracts produce a rise in blood pressure as a result of vasoconstriction. The extract exerts its effects on peripheral structures and is therefore active in pithed animals and on denervated organs. This fundamental observation led to the discovery of adrenaline. Abel[2] and others purified the extracts, and in 1901 Takamine[3] and Aldrich[4] obtained the pure substance and established its chemical structure. Later Stolz and then Dakin[5] prepared it by synthesis. Adrenaline is the characteristic component of chromaffin cells, which are identified by the histochemical reactions of adrenaline or the pharmacologic effects of their extract.

Adrenaline is α-methylamine-β-3,4;dioxyphenylethanol. The hydroxyl groups on C^3 and C^4 of the benzene ring place it among the cathecols; C^1 of the benzene ring is joined to

Key structural formula of the most common sympathomimetic substances (Hug)

In the benzene ring and the side chain, different chemical groups can be substituted for hydrogen. $C^3(R^2)$ and $C^4(R^1)$ in the ring, $C\beta(R^3)$ and $C\alpha(R^5)$ in the side chain, and the amine $N(R^4)$ are the most frequent sites of substitution. Thus in adrenaline (epinephrine) OH is substituted for three hydrogen atoms, one each at $C^4(R^1)$, $C^3(R^2)$, and $C\beta(R^3)$, and one hydrogen atom of the amine (R^4) by CH_3.

Adrenaline forms part of the group of substances known as alkaloids, and as such has some properties in common with these; *e.g.*, it is only slightly soluble in water but is readily soluble in organic solvents, and the saturated solution is alkaline; with acids it forms soluble salts. As it is a cathecol, it acts as a reducing agent and gives typical color reactions. It has an asymmetric carbon, that of the secondary alcohol in the side chain, which endows it with optical activity. The gland secretes the levorotatory form, which has a specific rotation of $-53°$ when in a 1 per cent solution in 0.1 N H_2SO_4 at 20°C. The racemic form has been prepared by synthesis and the dextrorotatory form has then been separated from it. Natural adrenaline is less stable but has from 10 to 20 times the pharmacodynamic activity of D-adrenaline. The racemic form is approximately one-half as active as L-adrenaline. The relative activity of the optical isomers varies in different effectors.

The normal adrenal medulla of most animals, including man, contains not only L-adrenaline but also L-noradrenaline, *i.e.*, the nonmethylated form.[1] The relative amounts of the amines vary. There is very little or no noradrenaline in rabbits and guinea pigs; in cattle, cats, and dogs, adrenaline constitutes about 80 per cent of the total; in the toad there is 2.5 to 5 mg./gm., made up of approximately equal parts of both amines.[2] In whales there is 4 to 5 mg./gm. of medulliadrenal tissue, 70 to 100 per cent of which is noradrenaline.[3] Chromaffin-cell tumors removed from human subjects have been found to contain large amounts of noradrenaline (5.3 to 6.3 mg./gm. of tumor tissue) and smaller quantities of adrenaline (0.32 to 3.7 mg./gm).[4] In other cases adrenaline was the predominant amine.[5]

Denervation of the adrenals slightly increases the catechol content but does not change the

relative amounts of adrenaline and noradrenaline. Prolonged stimulation of the adrenal, *e.g.*, by insulin or urethane, decreases the adrenaline content but increases the relative, and in some cases the absolute, amount of noradrenaline.[1] oxidized into a cathecol before it is decarboxylated. Decarboxylation takes place before the side chain is modified; after introduction of an *N*-methyl group, or a hydroxyl group in the position β, the compounds are no longer
Possible steps in the formation of adrenaline: *a*, phenylalanine; *b*, tyrosine; *c*, dihydroxyphenylalanine; *d*, dihydroxyphenylethylamine; *e*, adrenaline; *f*, noradrenaline; *g*, dihydroxyphenylserine; *h*, adrenochrome.

The formation of adrenaline. Phenylalanine (*a*), labeled with C^{14} or tritium, has been shown to be converted *in vivo* into tyrosine (*b*), 3, 4-dihydroxyphenylalanine (*c*), dihydroxyphenylethylamine (*d*) and eventually into adrenaline (*e*).[2] The first stage is the oxidation of the ring; phenylalanine is oxidized to tyrosine. The conversion of L-phenylalanine into L-tyrosine is catalyzed by a highly specific enzyme system found in rat liver, which is active in the presence of DPN (diphosphopyridine nucleotide) and oxygen.[3] Further oxidation converts tyrosine into 3,4-dihydroxyphenylalanine (DOPA). Oxidation of the ring precedes oxidation of the side chain; hydroxytyramine is converted into adrenaline by adrenal tissue, but phenylhydroxyethylamine is not.[4] The second stage is decarboxylation, catalyzed by DOPA decarboxylase. This enzyme acts on dihydroxyphenylalanine[5] but not on tyrosine,[6] *i.e.*, the ring is catalyzed by DOPA decarboxylase. The last stage in the process is *N*-methylation, *i.e.*, the conversion of noradrenaline (*f*) into adrenaline by a process of transmethylation in which methionine acts as methyldonor.[1] It is also possible that noradrenaline is formed by decarboxylation of dihydroxyphenylserine (*g*) which can be considered as the carboxylic acid of noradrenaline; this process has been demonstrated *in vitro*, catalyzed by guinea-pig liver and kidney extracts in anaerobic conditions.[2] Methylation of noradrenaline by the adrenals has been demonstrated *in vitro* by incubating it with minced adrenal tissue, and *in vivo* by perfusing the adrenal glands of dogs with heparinized blood containing noradrenaline; in both cases adrenaline increased and noradrenaline decreased.[3] Conversion of noradrenaline into adrenaline is also performed by other tissues.[4]

Inactivation of adrenaline. Adrenaline in solution undergoes a slow process of auto-

oxidation; adrenochrome (*h*), which gives a pink color to the solution, is formed, and part of the pharmacodynamic activity is lost. This process is accelerated *in vitro* by the cytochrome–cytochrome oxidase system and by other enzymes found in plants, such as catecholoxidase and tyrosinase. Prolonged oxidation gives rise to melanin. In the first stages of oxidation it is probable that a very unstable orthoquinone of adrenaline is formed.

Adrenaline is inactivated in the organism by an enzymatic mechanism probably similar to those acting *in vitro*, but no satisfactory proofs have been given that a particular system is the principal or only one responsible.

When large doses of adrenaline are taken by mouth, sulfoconjugated compounds of adrenaline increase in the urine.[1] The intestine and the liver are important sites of sulfoconjugation, and it is possible that on passing through these organs adrenaline is inactivated by this process, but sulfoconjugation is of doubtful importance as a means of adrenaline inactivation in muscle.

In blood and in certain tissues adrenaline is more stable than in watery solutions. This stability is due to the presence of protecting substances acting as reducing agents, among which there are several amino acids, glutathione, and ascorbic acid. The adrenal gland contains large quantities of glutathione and ascorbic acid, but it is not known whether these substances play a part in the stabilization of adrenaline secreted by the gland.

The action of adrenaline on the organism. Langley,[2] studying the effects of adrenal extracts, and Elliott,[3] studying those of adrenaline, demonstrated that the active principle of the adrenal medulla has the same effect on the organism as stimulation of the sympathetic nerves. There are a few exceptions to this rule. In some cases the sympathetic fibers are cholinergic, *e.g.*, the innervation of the sweat glands in some species, and some of the sympathetic vasodilators. There are also adrenergic fibers in the parasympathetic (see Chap. 84).

Adrenaline acts on what Langley called the "receptive substance" of the effector. The chemical nature of this substance and the way

[1] RICHTER, D., *J. Physiol.*, **98**, 361, 1940.
[2] LANGLEY, J. W., *J. Physiol.*, **27**, 237, 1901.
[3] ELLIOTT, T. R., *J. Physiol.*, **32**, 401, 1905.

it reacts with adrenaline are still unknown. Denervation not only does not suppress the effects of adrenaline but sensitizes the tissue to these effects.[1] Hypersensitiveness to adrenaline and to sympathetic stimulation is produced in some cases, *e.g.*, the salivary glands, by suppressing parasympathetic impulses by denervation or treatment with atropine for several days.[2] Hypersensitiveness is established gradually after denervation and reaches its maximum in a few days. It can be produced by section of the preganglionic fibers, but is more marked after postganglionic denervation.

Adrenaline must be in a certain minimum concentration to produce its effects; below this minimum either there is no response or even a contrary effect is obtained. Thus, adrenaline provokes hypertension due to vasoconstriction, but very small doses provoke vasodilatation and hypotension. On increasing the dose of adrenaline, the effect increases up to a maximum. For example, in anesthetized dogs, with both vagi cut so as to suppress the cardiomoderator reflex, intravenous injection of 0.2 μg per kg. provokes a small rise in blood pressure; on increasing the dose to between 0.5 and 0.7 μg per kg., there is a considerable increase in the hypertension, but a further increase in the dose provokes very little increase in the effect. The relation between dose and response has been determined in several effectors (contraction of arterial strips, contraction of the nictitating membrane, contraction or relaxation of the uterus, rate of the denervated heart, blood pressure, etc.). The results correspond to rectangular hyperbolas (Fig. 493) when the response of the effector is not modified by the interference of homeostatic mechanisms.[3]

Sensitiveness to adrenaline varies according to the effector concerned. In the dog the denervated heart responds with tachycardia to very small doses, but the blood pressure is an even more sensitive indicator of adrenaline. Contraction of the spleen is obtained with smaller doses than those necessary for constriction of the kidney, and the vasomotors of

[1] CANNON, W. B., and A. ROSENBLUETH, "Supersensitivity of Denervated Structures," Macmillan, New York, 1949.
[2] EMMELIN, N., and A. MUREN, *Nature, London*, **166**, 610, 1950.
[3] ROSENBLUETH, A., *Am. J. Physiol.*, **101**, 149, 1932.

the limbs are less sensitive. Relatively large doses are necessary in order to produce glycogenolysis and hyperglycemia.

The different animal species are not equally sensitive to adrenaline. In man continuous intravenous injection of 0.05 μg per kg. per min. increases the blood pressure; in the dog, 10 times this dose is needed to obtain a similar response, and in the rat, 20 times. Subcutaneous injection of adrenaline produces local vasoconstriction and thus retards the absorption of the drug. Perhaps it is for this reason that in the dog and the rat it has no effect on the circulation when injected subcutaneously, while man, being more sensitive, responds with hypertension, tachycardia, increased cardiac output, and a larger respiratory minute volume.

An increase in sensitiveness to adrenaline can be obtained in several ways: (*a*) by denervation, as has already been mentioned; (*b*) by suppressing the regulatory mechanisms that oppose the effects of adrenaline; *e.g.*, if the depressor fibers are cut, reflex bradycardia, provoked by dilatation of the aorta and the carotid sinus caused by adrenaline hypertension, is suppressed; (*c*) by the administration of certain drugs, such as cocaine. Thus, dogs can be sensitized to adrenaline by suppressing the cardiomoderator mechanism (either by cutting the vagi or injecting atropine) and injecting cocaine, following which they will respond with an increase in blood pressure to the intravenous injection of 0.005 μg per kg., and in some cases to even smaller doses. Hypothermia, on the other hand, decreases sensitiveness to adrenaline.[1]

The effects of adrenaline are of very short duration. The increase in blood pressure reaches its maximum in 1 or 2 min., returns to the initial level in 5 or 6 min., and then falls below this level. The secondary hypotension has been attributed to the formation of adrenoxine,[2] a product of oxidation of adrenaline, which has an inhibitory effect on vasoconstrictors. Another explanation given is that adrenaline concentration drops to an inhibitory level. The briefness of the action of adrenaline may be due in part to its destruction by the tissues, but it has been shown that effectors cease to respond after a time, even when there are still large amounts of adrenaline in the blood. Thus, if blood is drawn from a dog more than 30 min. after the effects of injecting a large dose (10 mg.) have ceased and is injected into another dog, it provokes hypertension and other effects of adrenaline.[1] Adrenaline can, therefore, be considered a "potential drug,"[2] *i.e.*, a substance that produces an effect depending not so much on the total concentration in the tissues as on the ratio between the concentrations within and without the cells on which it acts. When the internal and external concentrations are equalized, there are no longer any effects, although large amounts of the drug may still be found in the blood.

FIG. 493. Concentration-action curve of adrenaline. Cat with pithed brain and denervated heart. Abscissa, dose of adrenaline (unit = 2.5 μg). Ordinate, maximal increase in frequency of heart rate in 15 sec. over the basal rate of 35 beats in 15 sec. (*Rosenblueth, A., Am. J. Physiol., vol. 101, p. 149, 1932.*)

Adrenaline and noradrenaline have remarkable effects on the circulation. They cause a rise in blood pressure, mainly due to vasoconstriction; the pressor effect of L-noradrenaline is approximately 60 per cent greater than that of L-adrenaline.[3] The effects on the blood vessels vary in different vascular territories: Adrenaline constricts the vessels of the splanchnic area and the skin. In small doses it dilates the blood vessels of the muscles; in large doses it constricts them. It has little or no effect on the pulmonary and

cerebral circulations, and it dilates the coronary arterioles. Noradrenaline has similar effects, but it has only a constrictor action on muscular blood vessels; in man peripheral resistance is increased by noradrenaline and lowered by adrenaline. Both amines provoke constriction of the spleen, thus increasing the circulating blood volume and the erythrocyte concentration. The heart rate and the strength of the heartbeat are increased, but in the intact animal the rise in blood pressure stimulates the receptors in the aorta and the carotid sinus, and reflex vagal bradycardia follows after the initial tachycardia. Adrenaline, therefore, accelerates the circulation and shunts the blood to the locomotor apparatus: muscles, central nervous system, heart and lungs, *i.e.*, establishes circulatory conditions favorable for the performance of physical effort.

Adrenaline provokes constriction of the capillaries, an effect which is often used in therapeutics with the object of reducing the circulation locally, or to counteract capillary dilatation, *e.g.*, in certain allergic conditions.

Adrenaline increases oxygen consumption by 15 to 30 per cent. The calorigenic effect of noradrenaline is about 10 per cent that of adrenaline and can be accounted for by the increase in lactic acid due to hypoxia caused by constriction of muscular blood vessels.[1]

Adrenaline produces hyperglycemia; noradrenaline has a small hyperglycemic effect; only 5 to 10 per cent that of adrenaline. Adrenaline hyperglycemia is due to:

1. An increase in glycogenolysis. The hepatic glucose output, determined in normal men by catheterization of the hepatic vein, increases considerably (noradrenaline produces only a slight increase).[2] Moreover adrenaline hyperglycemia is reduced if the hepatic glycogen stores have been depleted.
2. Inhibition of glucose consumption by the tissues, as shown by the arteriovenous difference in blood-glucose concentration after injecting adrenaline.[3] Adrenaline decreases glucose tolerance in eviscerated rats,[4] and inhibits glucose utilization by the diaphragm.

The glucose uptake by muscle extracts is not reduced by previous administration of adrenaline until adenosinetriphosphate concentration becomes the limiting factor. It seems that adrenaline acts on ATP, not on hexokinase.[1] Apparently when adrenaline is oxidized one of its products can bind phosphate,[2] thus interfering with the utilization of glucose (see Chap. 41).

Adrenaline accelerates recovery after fatigue and increases the twitch tension of nonfatigued striated muscle. This effect is associated with an increase in the resting potential and a decrease in the rate of potassium loss from muscle.[3]

The significance of adrenaline and noradrenaline in the transmission of sympathetic impulses has already been discussed (see Chap. 84). Adrenaline has many other effects such as mydriasis, bronchial dilatation, and inhibition of intestinal movements.

The action of noradrenaline on many effectors is equal to that of adrenaline. Some of its excitor effects are slightly greater than those of adrenaline, *e.g.*, the pressor effect, but others are less, *e.g.*, the action on the heart rate. Noradrenaline has much less inhibitor action on the arterioles and on the uterus (rat, virgin cat, pregnant guinea pig), but its inhibitory action on the intestine is greater than that of adrenaline (see "The effects of drugs on visceral innervation," Chap. 84).

Biological assay of adrenaline. Isolated effectors are often used in the assay of adrenaline. The following are some of the methods used most frequently:

1. A strip of rabbit intestine, preferably the duodenum, is submerged in Ringer's solution and the spontaneous rhythmic contractions are registered. On adding adrenaline the movements cease and the intestine relaxes.
2. The rate of contraction of the isolated heart of a frog or toad increases on adding adrenaline to the perfusion fluid.
3. The Läewen-Trendelenburg method consists in the perfusion of the hindquarters of a frog or toad

by the introduction of a cannula into the abdominal aorta, through which the perfusion fluid is sent at a constant pressure. Another cannula is placed in the abdominal vein in order to collect and measure the fluid passing through the blood vessels. The rate of flow depends on the diameter of the vessels. Adrenaline provokes vasoconstriction and reduces the amount of fluid passing through the system.
4. The enucleated eye of a frog or toad, when submerged in a solution containing adrenaline, shows mydriasis, and the pupil takes on a rounded shape.
5. Contraction of the nictitating membrane, the rate of the denervated heart, the rise in blood pressure, vasoconstriction in a denervated limb or a rabbit's ear, and many other organic responses to adrenaline have been used in order to assay the adrenaline content of blood or tissue extracts. If the active substance is adrenaline, the effects will be potentiated by cocaine and suppressed by sympatholytic drugs, such as ergotamine, iohimbin, dibenamine, etc.

Sympathomimetic drugs. Several drugs, structurally related to adrenaline, have a similar pharmacodynamic effect. Their activity differs from that of adrenaline in one or more of the following ways: (*a*) they are less potent; (*b*) they have a greater effect on some effectors and a lesser effect on others; (*c*) they do not provoke some of the effects of adrenaline, *e.g.*, they have no inhibitory action; (*d*) they differ in the response to potentiating and sympatholytic drugs. Two of these drugs are of particular interest in medicine:

1. Ephedrine, obtained by Chen[1] from ma huang (*Ephedra vulgaris*), a Chinese medicinal plant. Its potency on the blood pressure is a hundred times less than that of adrenaline, but its effects are more lasting. It has greater stability and is active when given by mouth.
2. Benzedrine (amphetamine), which has a weak peripheral activity[2] and a powerful action on the central nervous system. It provokes a condition of wakefulness, with great lucidity, euphoria, and loquacity.[3] It can have harmful effects.

[1] CHEN, K. K., and C. F. SCHMIDT, *J. A. M. A.*, **87**, 936, 1926.
[2] Benzedrine has little activity on the periphery when given in systemic doses, but produces effects when applied locally.

THE SECRETION OF ADRENALINE

Almost a century ago, Vulpian[1] observed that a blue color is obtained when adrenal blood is mixed with ferric chloride; this effect is due to adrenaline secreted by the gland. Later, adrenal blood was shown to provoke hypertension, vasoconstriction, mydriasis, intestinal relaxation, etc.

Methods for measuring adrenal secretion. There are several methods for measuring the adrenaline secreted in different physiologic states. The following are among those most frequently used:

1. Adrenal blood is collected during a given time, either directly or in a pocket made out of the vena cava by tying off all its tributaries except the adrenal vein. The action of this blood is tested on an appropriate effector, *e.g.*, an isolated strip of duodenum, and its effect is compared with that of a known amount of adrenaline.[2]
2. The adrenal vein is clamped, and after a time, during which adrenal blood has accumulated, the clamp is removed. The effects on a denervated sympathetic effector, such as the nictitating membrane, the iris (mydriasis), the spleen (contraction), or the heart (acceleration), are observed. The same procedure is followed after denervating the adrenal or extirpating the adrenal medulla.
3. The adrenal vein is joined to the jugular vein of another animal, and the adrenal blood is thus diverted into the receptor (Fig. 103, page 194), on which the effects of adrenal discharge are observed by registering the variations of an appropriate sympathetic effector (blood pressure, denervated heart or spleen, blood sugar, etc.).[3]
4. The adrenal gland is perfused with heparinized blood, and the adrenal hormones in the blood leaving the adrenal are measured by chemical or biological methods.

Operative proceedings and certain anesthetics, *e.g.*, ether, increase adrenaline secretion. In all the methods, the adrenaline secreted is

not always collected without loss; therefore the figures given must be considered as only approximations to the true figures.

Adrenaline in the blood. There is a very small amount of adrenaline in arterial blood, and the methods available for assaying it are not reliable. Chemical methods give results far above the true amounts, because substances that are not adrenaline are measured at the same time. Biological methods have shown that the concentration of adrenaline in the blood of the general circulation is around 0.0001 to 0.01 μg per cent. Adrenaline in the blood of the adrenal vein dialyzes through collodion membranes; therefore it cannot be bound to a protein.[1] A lactilic ester of adrenaline has been extracted from adrenal tissue, but there is no proof that circulating adrenaline is esterified. According to Bülbring and Burn,[2] 20 to 80 per cent of the activity of adrenal blood collected during stimulation of the splanchnic nerve is due to noradrenaline.

The rate of secretion and destruction of adrenaline (or equivalent sympathomimetic substances) has been calculated from the results of continuous infusion of adrenaline into dogs in which the sympathetic system has been blocked by complete spinal anesthesia with procaine. The blood pressure in these animals falls from the normal 125 to 130 mm. Hg to 6 mm. Hg, but it can be raised and kept at a normal level by continuous infusion of adrenaline at a rate of 0.45 μg/kg./min. The total amount of adrenaline (or its equivalents) active in the body has been calculated to be 0.71 μg/kg. It is being eliminated or destroyed continuously at a rate directly proportional to the total amount.[3]

The urine of normal men contains adrenaline, noradrenaline, and hydroxytyramine. The daily output of adrenaline has been found to be 11.5 ± 6 μg and that of noradrenaline 29 ± 12.3 μg.[4]

Secretory innervation (Fig. 494). Stimulation of the splanchnic nerves provokes the discharge of as much as 100 μg of adrenaline. The amount of adrenaline released is conditioned by

1. Adrenaline stored in the gland. Thus glands containing an average of 1.09 mg./gm. secreted 4 μg/min. on splanchnic stimulation, and glands with an average of 2.3 mg./gm. secreted 9.3 μg per min.[1]
2. The concentration of adrenaline in the blood. High concentrations obtained by intra-arterial injection of adrenaline or adding adrenaline to the blood perfusing isolated adrenals, inhibit adrenaline secretion and the gland does not respond to splanchnic stimulation for several minutes. Later the response is greater than before adrenaline injection (facilitation).[2] Bülbring and her associates have found the response to splanchnic stimulation increases when adrenaline is added to the perfusion fluid up to an optimal concentration; at higher concentrations it diminishes progressively and may be completely inhibited.

The secretory fibers emerge from the spinal cord in the thoracic and the first lumbar roots and reach the gland by the major and minor splanchnic nerves. The nerve fibers ramify and innervate several cells, forming neuroglanduiar units, similar to motor units. Chromaffin cells are modified nerve cells, similar to ganglionic neurons, and they secrete adrenaline, *i.e.*, they are adrenergic, as are most of the postganglionic fibers of the sympathetic. The adrenal medulla is innervated by preganglionic cholinergic fibers. Excitation of the splanchnic nerves releases acetylcholine, and this substance provokes adrenaline secretion. The gland responds to drugs in the same way as a sympathetic ganglion does. For example, nicotine stimulates the secretion of the chromaffin cells but blocks the secretory impulses from the splanchnic nerve; atropine in small doses has no effect, but in large doses it temporarily blocks the splanchnic nerve.

Nerve centers of adrenal secretion. There is a *spinal center* (or centers) for adrenal secretion situated in the upper thoracic segments, which exerts a continuous, or tonic, action on the adrenal medulla. In anesthetized or decerebrate animals, the adrenal secretes from 0.1 to 1 μg adrenaline per kilogram of body weight per

[1] Bülbring, E., J. H. Burn, and F. J. de Elio, *J. Physiol.*, **107**, 223, 1948.

[2] King, E. E., and A. S. Marrazzi, *Am. J. Physiol.*, **171**, 612, 1952.

minute.[1] Transection of the cord at the level of the lower cervical segments does not suppress this "spontaneous" secretion, but if the section is made below the third thoracic segment, adrenaline secretion is reduced to a minimum. The center is bilateral; semisection of the spinal cord suppresses secretion by the ipsilateral gland, but does not disturb the secretion of the contralateral one.[2] Denervation of the gland does not suppress adrenaline secretion completely. By means of the adrenojugular transfusion method, with a sensitized receptor, a secretion of approximately 0.005 μg per kg. of body weight per minute has been demonstrated.[3] The denervated adrenal does not atrophy; the histologic aspect remains normal, and several months after denervation adrenaline secretion can be provoked by means of acetylcholine and other drugs that act directly on the chromaffin cells.[1]

There is a *secretory center in the pons and the medulla*. Electrical stimulation of the upper half of the floor of the fourth ventricle provokes adrenaline discharge. A section of the brain stem immediately caudal to the posterior colliculi does not suppress reflex adrenaline secretion produced by centripetal stimulation of an afferent nerve, but if the section is made 2 mm. caudal to the posterior colliculi, secretion does not occur; this reflex is therefore integrated in a center located between the two sections.[2] Stimulation of the *hypothalamus* also produces adrenaline discharge, but in smaller quantities than stimulation of the medulla.[3] Both these centers send their impulses to the gland through the splanchnic nerves, and section of these nerves suppresses the effects of stimulating the

centers (Fig. 494). Stimulation of the cerebral cortex provokes adrenal discharge only when it produces muscular activity; a localized center of adrenal secretion has not been found in the cerebral cortex. According to Rogoff and his associates,[1] there is *an inhibitory center for adrenaline secretion*, located in the region of the brain stem bounded by the optic chiasma and the superior colliculi.

Physiologic conditions in which adrenaline secretion increases. *Centripetal stimulation of an afferent nerve* (*e.g.*, the sciatic, the brachial, the vagus) or any stimulus sufficiently strong to provoke pain produces adrenaline discharge (reflex secretion).[2]

Muscular contraction produces metabolites, which pass into the blood and stimulate the adrenal nerve centers. Even small active movements, but not passive ones, increase adrenaline secretion.[3] Exercise may cause an increase in the adrenaline content of the blood of trained animals and men, but a decrease occurs in untrained subjects.[4]

Emotional states, whatever their nature (rage, fear, etc.), that are accompanied by sympathetic activity also produce adrenaline secretion in relation to their intensity.[5]

Cold applied on the skin or the digestive tract (by means of iced drinks) increases adrenaline secretion. Thus the calorigenic effect of cold is reinforced by that of adrenaline, which also contributes to diminish the loss of heat by constricting the cutaneous blood vessels. Animals with denervated adrenals when put into a cold environment shiver intensely, more markedly than normal animals; thus the lack of the calorigenic effect of adrenaline is compensated by vigorous muscular activity.

[5] CANNON, W. B "Bodily Changes in Pain, Hunger, Fear and Rage," 2d ed., Appleton-Century-Crofts, New York, 1929.

Hypotension produced by hemorrhage, by stimulation of the vagus, or in any other way provokes adrenaline discharge. Adrenaline secretion is regulated by the arterial blood pressure through the receptors in the aorta (de Cyon's nerve) and the carotid sinus (Hering's nerve). A decrease in pressure in these vascular sensory areas increases adrenaline secretion; hypertension diminishes it. Bilateral section of the aortic and carotid sinus nerves increases adrenaline secretion. The sensory mechanism of the arteries has the same effect on the adrenal medulla and its secretion as it has on sympathetic "tonus" (see "Physiologic significance of visceral innervation," Chap. 84).

Asphyxia provokes adrenaline discharge. The important factor is the fall in oxygen pressure; accumulation of CO_2 is of little importance. Inhibition of tissue oxidations by cyanide also provokes adrenaline secretion. Anoxia acts directly on the adrenaline secretory centers and reflexly by stimulating the vascular sensory areas. Denervation of the adrenals suppresses the adrenaline discharge of anoxia.[1] In the perfused gland, however, hypoxia provokes adrenaline discharge; therefore in this condition it acts directly on the chromaffin cells.[2]

Insulin hypoglycemia stimulates the adrenaline secretory centers, and adrenaline is discharged if the adrenal nerves are intact. The amount of adrenaline secreted is sufficient to produce hyperglycemia in another animal that receives the adrenal blood of the first[3] (Fig. 495). The increase in adrenaline secretion plays an important part in the recovery of the normal blood-sugar level following hypoglycemia. Adrenalectomized animals are hypersensitive to insulin.

Several drugs stimulate the adrenaline secretory centers. Among these are anesthetics (ether, urethane, etc.), strychnine, morphine, and picrotoxine. Drugs that have a nicotinic cholinergic activity (nicotine, acetylcholine, quaternary ammoniums, etc.) stimulate the chromaffin cells directly and provoke adrenaline discharge even after denervation of the gland. Other drugs increase adrenaline secretion by disturbing an organic equilibrium; substances

that produce hypotension (histamine) or hypoglycemia (insulin) act in this way.

Hypersecretion of adrenaline by adenomas of the adrenal medulla. Several cases of tumors made up of chromaffin cells (paragangliomas) have been reported. The patients have hypertensive crises provoked by exercise, emotional stress, and other conditions that normally increase adrenaline secretion. Removal of the tumor is immediately followed by a considerable fall in the blood pressure, which can be so marked and prolonged that it induces a condition of shock. While the paraganglioma is actively secreting adrenaline, the sympathetic tonus is kept low; the fall of arterial blood pressure on removal of the tumor is caused by the absence of sympathetic tonus. Usually after a few hours sympathetic tonus is recovered and the blood pressure returns to a normal level, but care must be taken to avoid the catastrophic hypotension that occurs after extirpating the tumor.[1]

Physiologic Significance of Adrenaline Secretion

In physiologic emergencies adrenaline is discharged into the blood. The increase in adrenaline secretion, produced through stimulation of the sympathetic, helps to reestablish the organic equilibriums that have been disturbed (homeostasis). Nevertheless adrenaline secretion is not of vital importance; it has been suppressed experimentally either by removing one adrenal and denervating the other or by extirpating the

[1] LERICHE, R., *Lyon chir.*, **31**, 355, 1934; BANER, J., and R. LERICHE, *Presse méd.*, **2**, 1384, 1932.

medulla,[1] the animals surviving in apparent good health. Nevertheless careful study of the animals deprived of adrenaline secretion shows that they are less adaptable to those circumstances which will provoke adrenaline secretion in the intact animal.

The importance of adrenaline secretion in conditions of emergency has been well demonstrated and is universally admitted. The same cannot be said about the secretion of adrenaline at rest, or in basal conditions, the existence of which Cannon has denied. Nevertheless the fact that adrenaline secretion is controlled in the same way as sympathetic tonus, by reflexes initiated in the vascular sensory areas, suggests that there is normally a basal secretion of adrenaline, apart from that artificially produced by experimental conditions. The physiologic significance of this basal secretion is so far unknown.

To summarize, adrenaline secretion is an auxiliary of the sympathetic, playing a prominent part in conditions of physiologic emergency. It is carried by the blood to the whole body and ensures the activation of all the effectors controlled by the sympathetic; it is thus an important factor in homeostasis.

CHAPTER 86

Conditioned Reflexes

THE CLASSIC WORK of Pavlov and his associates on conditioned reflexes has given us new knowledge of the processes of association that take place in the cerebral cortex. It has also created a method for the objective study of cerebral activity which has been of great use not only in physiology but also in psychology. Pavlov did most of his work on dogs, but many other species including man have been studied. The relation of conditioned reflexes to another cortical function, *i.e.*, behavior, has been the object of much important work.

INBORN AND CONDITIONED REFLEXES

Reflexes are regular responses of the organism, which follow the application of certain stimuli in the same way as an effect follows the cause.

Reflexes are due to the transmission along definite nerve paths of an excitatory state from the receptor to the effector. They contribute to the maintenance of the internal bodily equilibrium and to the adaptation of the organism to its environment. They are related to instincts, which are much more complex phenomena but, according to Pavlov, do not differ fundamentally from reflexes.

Reflexes can be divided into two groups having typical characteristics. One group is made up of inborn, or unconditioned, reflexes and the other of acquired, or conditioned, reflexes.[1]

[1] All reflexes are "conditioned," inasmuch as certain definite conditions must be present for them to take place. The so-called "conditioned reflexes" could be more appropriately called "associated reflexes" or "reflexes acquired by association." The term introduced by Pavlov is now in common use and has a definite meaning; it should therefore be retained. When introducing new terms it is more important that the new meaning attached to them should be clearly defined than that they should be accurately descriptive.

Inborn, or unconditioned, reflexes are transmitted by heredity to all the individuals of the species, and they appear as soon as the nerve paths necessary for their performance are fully developed. They do not need the establishment of special conditions in the individual organism created by the previous application of stimuli. They follow certain definite preestablished paths and do not require the activity of the cortex. According to their object they may be considered as protective, postural, alimentary, sexual, etc. Some of them, such as the knee jerk, are simple two-neuron reflexes, others are much more complex, *e.g.*, the labyrinthine reflexes.

Acquired, or conditioned, reflexes do not appear spontaneously but are "learned" in the course of the individual's life. They are unstable, and they are easily lost either transitorily or permanently. They are established on another reflex, either inborn or previously conditioned. An unlimited number of stimuli acting on any of the receptors can provoke them, but they always follow nerve paths used by inborn reflexes. They appear after a formative process has been completed, in which the essential feature is the repeated application of the stimulus to be conditioned, associated with an efficient stimulus (Table 118 and Fig. 496).

Table 118. Characteristics of Inborn and Conditioned Reflexes

Inborn	*Conditioned*
Inherited by all the individuals of the species	Acquired by each individual
Stable	Unstable
Relatively few	Many
A special nerve path for each one	Nerve paths of other reflexes utilized
The cortex not indispensable	The cortex usually part of the reflex mechanism
No training needed	Training necessary

Pavlov demonstrated by the following experiment the difference between the two types of reflexes in the same individual: Five puppies were separated from their mother at birth and artificially fed on milk. After a few months they were shown meat for the first time. Although meat is the natural food of the species, they saw and smelled it without secreting saliva. Meat was then placed in their mouths, and saliva was secreted. The flow of saliva provoked by seeing or smelling meat is therefore a conditioned reflex acquired by the individual animal, and it does not exist until there has been a previous period of training. This reflex is built up on an inborn reflex, *i.e.*, salivary secretion provoked by meat placed in the mouth.

Fig. 496. Diagram of the path of a visual conditioned reflex. (*After Lovatt-Evans, modified.*)

Conditioned reflexes can be *positive*, *i.e.*, provoke excitation, or *negative*, *i.e.*, provoke inhibition.

CONDITIONS NECESSARY FOR THE FORMATION OF ACQUIRED REFLEXES

Positive and negative conditioned reflexes are produced by a special technique. They have been obtained in rabbits, sheep, dogs, cats, rats, monkeys, and man, and also in lower animals such as the tortoise, but the species most frequently used in this work has been the dog. Certain individual animals appear to be more intelligent and respond more readily than others; in some, positive reflexes are obtained more easily than negative reflexes, while the opposite is observed in others. A good physical condition is an important factor; reflexes are conditioned with difficulty, or not at all, in diseased animals. Psychic alertness is also necessary; distraction due to any cause prevents the establishment of these reflexes. Distraction is prevented by strict isolation. Pavlov placed his dogs in especially constructed soundproof chambers, which were also protected from any other kind of vibrations. The observer was placed in another room, from which he could see the animal through a periscope. The stimuli (food, light, sound, electrical stimulation of the skin, etc.) were applied and the effects (salivary flow, etc.) recorded by means of special devices (Fig. 497).

A great variety of stimuli, applied on any receptor, may provoke conditioned reflexes. Stimuli of great intensity, however, produce them with difficulty, and it is essential that they do not endanger the life of the animal. Among those that may be used are the following: auditory stimuli consisting in the vibrations of a tuning fork, giving a pure note, or complex sounds such as the blowing of a trumpet; visual stimuli varying in color, brightness, size, shape (*e.g.*, geometrical figures), duration, etc.; stimulation of the skin by tactile, thermal, and painful stimuli; and different odors to stimulate the sense of smell. In all these cases, if other necessary conditions are fulfilled, it is possible to build up a conditioned reflex.

The response can also be greatly varied, *e.g.*, muscular contractions, such as a knee jerk; a vasomotor reaction; dilatation or constriction of the pupil; secretion from one gland or another; etc. Pavlov frequently used salivary secretion as the response to be observed, because it can be easily collected from a fistula and accurately measured. The basis for this type of conditioned reflex is the inborn reflex of salivary secretion in response to food placed in the mouth. Defense reflexes, such as blinking when air is blown on the cornea, or the flexion reflex on application of a painful stimulus on the paw, are frequently used.

POSITIVE OR EXCITATORY CONDITIONED REFLEXES

There are many reflexes of this type, which vary according to the nature of the stimulus and the reflex on which they are based. A positive conditioned reflex is established by a procedure fundamentally the same as that followed in the conditioning of a sound to provoke salivary secretion: A parotid fistula is made in a dog, and after the wound has healed, the animal is placed in the soundproof chamber mentioned above, with a device adapted to the fistula so as to collect the saliva excreted. Meat is given

to the animal shortly after a bell has begun to ring. After this procedure has been repeated several times at suitable intervals, the sound of the bell alone will provoke salivary secretion, even if meat is not given. The sound of the bell, which previously did not provoke salivary secretion, has acquired the property of doing so by having been associated with an inborn salivary reflex. The auditory stimulus has become a conditioned stimulus (Table 119).

Source: Anrep.

In the experiment referred to above, the originally neutral stimulus was applied at the same time as the stimulus that provoked the inborn reflex; this type of reflex is known as a *simultaneous conditioned reflex* (Fig. 498). If the originally neutral stimulus is applied some time before and maintained until the stimulus for the basic reflex is applied, the response is obtained after a latent period which lasts as long as the interval between the two stimuli and may be of several minutes duration. This type is known as a *delayed conditioned reflex.* If the conditioned stimulus precedes the stimulus for the basic reflex, but the latter is not applied until a short time after the former has ended, the reflex is called a *trace reflex.* The response is usually not so great as in the preceding types of reflexes. A stimulus can be conditioned using a previously conditioned reflex as a basic reflex, *e.g.*, the sound of a bell is conditioned to provoke salivary secretion, and when this reflex is well established, a colored light is shown to the animal before the bell rings. After this procedure is repeated a sufficient number of times, the colored light will become a conditioned stimulus and will provoke salivary secretion even if the bell does not ring. This is known as a conditioned reflex of the second order, and it can also be used as a basic reflex for the establishment of third-order conditioned reflexes, the latter

FIG. 497. Chamber for producing conditioned reflexes. The dog is in a soundproof compartment, completely isolated from the observer, who can see the animal through a periscope and controls the stimulating and recording apparatus without being seen by the animal. (*Pavlov, I. P., "Lectures on conditioned reflexes," trans. by W. Horsley Gantt, New York, 1928.*)

serving to build up conditioned reflexes of the fourth order, and so on. It is important that the conditioned stimulus should precede the stimulus for the basic reflex by an interval of approximately 10 sec. (Fig. 498).

e.g., if the sound of a tuning fork has been conditioned to provoke the secretion of 30 drops of saliva, and a tactile stimulus has been conditioned to provoke the same effect, *i.e.*, the secretion of 30 drops of saliva, simultaneous application of both stimuli will provoke the secretion of 60 drops of saliva.
FIG. 498. Positive conditioned reflexes. On the left, the neutral stimulus at first provokes no response; the stimulus for the inborn reflex provokes a response. Both stimuli are applied together four times. The neutral stimulus is then applied alone, and a response is obtained; the animal has become conditioned to this stimulus. On the right, different types of conditioned reflexes obtained by varying the interval between the application of the neutral and the efficient stimulus.

The following are the essential conditions necessary for the establishment of a conditioned reflex: (*a*) the conditioned stimulus must be of at least threshold strength; (*b*) it must be applied repeatedly; (*c*) it must be applied at the same time as, or before, the stimulus for the basic reflex (if it is applied afterward it will not become conditioned); (*d*) it must be periodically reinforced, *i.e.*, accompanied by the stimulus for the basic reflex, otherwise it will rapidly lose its property of evoking the conditioned response (experimental extinction).

Conditioned reflexes have the following properties:

1. *Longer latent period; i.e.*, much longer than in inborn reflexes.
2. *Specificity*, *i.e.*, the response is evoked exclusively by the conditioned stimulus and not by other stimuli applied to the same or other receptors.
3. *Summation*, *i.e.*, two reflexes that use the same effector path in the same sense (excitation or inhibition) reinforce each other; *e.g.*, if the sound of a tuning fork has been conditioned to provoke the secretion of 30 drops of saliva, and a tactile stimulus has been conditioned to provoke the same effect, *i.e.*, the secretion of 30 drops of saliva, simultaneous application of both stimuli will provoke the secretion of 60 drops of saliva.
4. *Instability*, *i.e.*, they are easily lost, *e.g.*, when not reinforced.

Positive conditioned reflexes have been used in the study of the capacity of the sense organs of animals to respond. Thus it has been shown that dogs hear sounds of a much higher pitch (greater frequency of vibration) than can be heard by the human ear. Combining the conditioned-reflex method with the production of lesions limited to a definite part of the receptor (*e.g.*, the cochlea) or the nerve centers (*e.g.*, the cerebral cortex), it has been possible to localize the site in the receptor where certain stimuli produce their effects and the nerve paths and centers of the different sense organs.

NEGATIVE OR INHIBITORY CONDITIONED REFLEXES

Well-established conditioned reflexes can be extinguished (*i.e.*, suppressed) by processes of external or internal inhibition.

External inhibition. If during or shortly before the application of a conditioned stimulus another stimulus of any kind is applied, which provokes another reflex or simply distracts the attention of the animal, the response to the conditioned stimulus is suppressed or considerably diminished. This is known as external inhibition, or interference. It is rapidly established but acts only temporarily, and if the "extrastimulus" is repeated it soon loses its inhibitory effect (Fig. 499). External inhibition may be the cause of fluctuations in the response to conditioned stimuli. Pavlov discovered it when he tried to make a public demonstration of conditioned reflexes; the animals did not respond, and the demonstration could not be made. This led him to realize the importance of isolating the animals strictly from other stimuli besides those which are being studied.

Internal inhibition. This type of inhibition differs from external inhibition because it is necessary to apply the stimulus repeatedly before it becomes efficacious; it differs also in the slowness with which it is established. Four types of internal inhibition are distinguished, according to the method by which they are established: (*a*) extinction; (*b*) conditioned inhibition; (*c*) inhibition in delayed and trace reflexes; (*d*) differential inhibition.

Extinction. Positive conditioned reflexes that are not reinforced are soon lost. For example, if an animal is conditioned to secrete saliva on hearing the sound of a tuning fork by applying this stimulus simultaneously with feeding or before it, and if when the conditioned reflex is well established the animal is made to hear the tuning fork repeatedly without being given food, saliva is secreted in progressively decreasing quantities until the sound of the tuning fork no longer provokes salivary secretion (Fig. 500). The extinction of the reflex is due not to fatigue but to inhibition. This can be demonstrated by applying an extrastimulus that will "dis-inhibit" the animal, *i.e.*, inhibit the inhibitory state that prevents salivary secretion; a copious flow of saliva will then be observed.

Extinction occurs more easily in recently established conditioned reflexes than in long-standing ones. The strength of inhibition can be measured by the time needed to reestablish the reflex. Extinction has an "after-effect" which increases the difficulty of obtaining a positive conditioned reflex.

Conditioned inhibition. If a strong extrastimulus is applied simultaneously with a conditioned stimulus without reinforcing the latter, after this procedure has been repeated several times a negative conditioned reflex will be established (Fig. 500), *i.e.*, the application of the extrastimulus will inhibit salivary secretion, although the application of the originally conditioned stimulus alone still provokes the secretion of saliva. The central inhibitory state thus created has a fairly prolonged after-effect, during which it is difficult to obtain a positive conditioned reflex. The inhibitory state can be inhibited by an extrastimulus, and its suppression provokes the reappearance of the underlying positive reflex.

FIG. 499. External inhibition. Percentage inhibition of a positive conditioned response after repeated application of an extrastimulus.

Conditioned inhibition is similar to extinction in that to provoke both of them the conditioned stimulus must not be reinforced. Conditioned inhibition and external inhibition are similar in that both require the addition of an extrastimulus. In external inhibition, however, the extrastimulus exerts its inhibitory effect immediately and then ceases to be efficacious, whereas in conditioned inhibition the extrastimulus

acquires gradually inhibitory properties owing to the absence of reinforcement.

Inhibition in delayed and trace reflexes. During the interval between the two stimuli in delayed and in trace reflexes, a state of conditioned inhibition is developed. As the interval is increased in trace reflexes the positive response diminishes until it is completely suppressed. If the interval is very long, *e.g.*, 30 min., the inhibitory state extends to other reflexes and the animal falls asleep. An extrastimulus applied in this condition suppresses inhibition and provokes the appearance of a positive response. This type of inhibition is obtained more easily with cutaneous and visual stimuli than with auditory ones.

Differential inhibition. Discrimination. There are two stages in the building up of a positive conditioned reflex. During the first stage a response is provoked not only by the specific stimulus but also by similar stimuli applied to the same receptor. In the second stage there is discrimination; only the specific stimulus provokes a positive response; responses to similar stimuli are inhibited. This process can be accelerated by applying the specific stimulus and reinforcing it, together with accessory stimuli without reinforcement, so that the latter undergo experimental extinction. By means of this method it is possible to determine objectively an animal's capacity to distinguish between two stimuli, *i.e.*, the analytical capacity of the central nervous system, according to Pavlov. The different mechanisms responsible for discrimination, *i.e.*, the receptors, nerve paths, and centers, have been called by Pavlov the "analyzers."

The auditory analyzer discriminates differences in pitch, intensity, quality, and direction with greater precision in the dog than in man. The visual analyzer of the dog discriminates differences in degree of luminosity, in the shape and position of objects, and in their movements, but differences in color are not perceived if there is no difference in luminosity. The cutaneous analyzer can distinguish degrees of smoothness or roughness of a surface, differences in temperature of about ½ to 1°C., the place where the stimulus is applied, the strength of pressure, and the duration of the stimulus.

In the process of establishing discrimination, internal inhibition plays an important part; in some cases inhibition spreads throughout the whole cortex, and the animals fall asleep. If the problem of discrimination exceeds the capacity of the animal, it is not only unable to establish final discrimination, but the whole structure of its nervous function is disturbed. For example, if the animal is made to distinguish a circle from a long oval, discrimination is perfect. If the oval is made progressively broader, so that finally there is little difference between the oval and a circle, not only does the animal not distinguish them but the whole pattern of its conditioned reflexes is upset (*e.g.*, inhibitory stimuli become positive and vice versa) and it is impossible to establish new conditioned reflexes. Moreover the animal becomes excitable and bad-tempered. Its behavior is similar to that of neurotic patients; hence the name of "experimental neurosis" given by Pavlov to this condition. Chimpanzees become angered, or they may remain indifferent and refuse to pay attention. Rats, rabbits, pigs, and sheep also show this phenomenon, but the behavior varies and is typical for each species. Disturbances in pulse rate, breathing, metabolism, urinary

FIG. 500. Internal inhibition. Left, experimental extinction is due to repeated application of the conditioned stimulus (*CS*) without reinforcement by the unconditioned (*UCS*) or efficient stimulus; at the fifth application there is no response (*R*). Center, conditioned inhibition is obtained by the application of an extrastimulus together with the positively conditioned stimulus but without reinforcement. Right, if the delay is gradually lengthened, the response will be inhibited.

secretion, and sexual functions have been observed, lasting up to 24 hr. after the stimulus was applied. Double frontal lobectomy causes fundamental changes in the behavior of these animals, which are no longer angered or disturbed when their discriminatory powers are exceeded.

General characteristics of inhibition. Inhibitory processes prevent reflex responses that have no useful purpose. Repeated application of the conditioned stimulus in experimental extinction and the application of a second stimulus in conditioned inhibition imply circumstances in which the positive response is no longer useful. Inhibition in delayed and trace reflexes retards the response until it can be useful. Differential inhibition in the process of discrimination also signifies the suppression of responses that are not adapted to the stimulus. Thus inhibition is an important mechanism in the prevention of wasteful expenditure of energy and matter.

Internal inhibition is not merely fatigue produced by repetition of the stimulus; it is an active process that takes place in the nerve centers. Proof of this statement is given by the following facts:

1. Inhibition can be suppressed by an extra-stimulus, and the positive response will appear; *e.g.*, a strange noise produced during the latent period of a trace reflex that produces salivary secretion provokes the immediate appearance of the response.
2. Negative (inhibitory) conditioned reflexes have an after-effect, *i.e.*, they are followed by a period during which it is very difficult to obtain a positive response to other conditioned reflexes. The inhibitory state produced by the negative reflex extends first to other reflexes in the same analyzer and then to other analyzers, gradually spreading throughout the whole cortex and to subcortical centers, eventually producing a condition similar to, if not identical with, sleep. The wave of inhibition then recedes and is reduced to the analyzer corresponding to the inhibited reflex (not to the analyzer that received the inhibiting stimulus).

NERVE CENTERS OF CONDITIONED REFLEXES

The establishment of a conditioned reflex requires the integrity of the whole analyzer, *i.e.*, not only of the receptor, of the peripheral paths that conduct the nerve impulses to the subcortical centers, of these centers, and of the central paths to the cortex, but also of the cortical centers. Pavlov maintained that the cortex was essential to the production of conditioned reflexes, because extirpation of the cortex suppresses all the conditioned reflexes acquired by the animal and also the possibility of acquiring new ones, although inborn reflexes remain. Later experiments carefully carried out by Zeljony and by Culler and Mettler have shown that it is possible to build up a few simple auditory, visual, and tactile conditioned reflexes in totally decorticate dogs and cats. Experimental extinction and discrimination, *i.e.*, inhibition, are characteristic of conditioned reflexes in these animals just as in animals with an intact cortex. It is therefore evident that in certain cases subcortical centers can replace the cortex in the associative function necessary for the building up of conditioned reflexes.

Partial extirpation of the cortex, *e.g.*, of both visual areas or both auditory areas, is followed by marked disturbances in the conditioned reflexes corresponding to the damaged analyzers. Immediately after the operation, all the conditioned reflexes of the animal are upset, especially those involving inhibitory processes, but a few days later they are reestablished, with the exception of those corresponding to the area extirpated. A few simple reflexes corresponding to these areas are nevertheless recovered. Thus Marquis and Hilgard have observed that dogs and monkeys in which the visual areas of the cortex have been removed can distinguish differences in the brightness of light, and that those which have undergone extirpation of the auditory areas can distinguish sounds of different pitch. Moreover a few new reflexes can be built up in these decorticate animals.

The site of association of the efficient with the neutral stimulus and the nature of the process by which they become associated are not known. This association does not take place at the level of the motor neuron, because it is not possible to establish a conditioned reflex on the basis of stimulation of this neuron (Loucks).

The behavior of animals confronted with a problem such as opening a box or finding their way in a maze has been of great use in the study of cortical function.

The work of Lashley,[1] Marquis, Hilgard, and others in rats, dogs, and chimpanzees has shown that extirpation of a limited area of the cortex does not produce any serious deficiency in performance because the functions of the area removed are taken up by other cortical and subcortical centers. Strict specialization of structures seems to be less important than the mass of functional tissue. Even in areas where there is a high degree of specialization (*e.g.*, the motor and visual areas), the subordinate parts can take on the functions of the whole. On the other hand, functional deficiency increases as larger areas are removed and the functioning mass of cortex diminishes. Conditioned reflexes and behavior are closely connected, and the knowledge acquired by work done in one field is in agreement with that in the other and throws light on it.

In summary, conditioned reflexes are built up by a central mechanism of association which takes place in cortical and subcortical centers.

THE EFFECT OF DRUGS ON CONDITIONED REFLEXES

Caffeine (25 to 50 mg. in dogs) increases all conditioned reflexes and diminishes inhibition. The effect begins 20 to 30 min. after the drug has been administered and lasts 24 hr. Strychnine has a similar action.

Bromides (1.5 gm.) have no effect on conditioned reflexes, but they increase inhibitory processes. Their action lasts for 2 or 3 days, owing to the slow rate at which they are eliminated.

SUMMARY

Conditioned reflexes are the result of the experience of the individual. They are of great importance for adaptation because conditioned stimuli are signs of forthcoming events for which the organism can anticipate an adequate response. Positive reflexes widen the scope of inborn reflexes by continuously adding responses to new and unaccustomed stimuli. Inhibitory reflexes are of great importance for accuracy and fineness in adaptation and for the conservation of energy and matter. A dog deprived of the cerebral cortex has very limited possibilities with respect to acquiring conditioned reflexes; Pavlov considered such an animal as a "great invalid." The establishment of conditioned reflexes has provided an objective method for the study of (*a*) the localization of sensory nerve centers and paths; (*b*) cortical and subcortical mechanisms of association; (*c*) the capacity and acuteness of the different analyzers in many animal species. It has also contributed facts of importance for the understanding of sleep and neurosis.

CHAPTER 87

The Electroencephalogram

THE CEREBRAL CORTEX continuously shows electric potential waves which are the resultant of the synchronized activity of a great number of neurons. They are due to a tendency to synchronized rhythmicity observed in central groups of neurons in vertebrates and invertebrates. Electric potential waves have also been picked up from the cerebellum, thalamus, diencephalon, geniculate bodies, and olfactory lobe and in the neural ganglia of invertebrates.

Frequency is the most typical characteristic of the electric activity of the brain and the one that has been most easily correlated with cortical function (Gibbs). It varies from 1 to 50, with voltages from 5 to 500 μv (*i.e.*, much lower voltages than those of the electric activity of the heart). Several rhythms of different frequencies blend into the complex potential of the electroencephalogram, but it is possible to separate and analyze different rhythms by means of special devices (Walter *et al.*). The EEG changes in different physiologic, psychic, and pathologic circumstances (Figs. 502, 503, and 504).

These potentials are evidence of the constant activity of the nerve centers, which are never completely at rest. In some cases fluctuations in the potentials coincide with the automatic rhythmic activity of the center. The waves from the cortex persist after the brain stem has been cut, *i.e.*, after many of the afferent impulses to the cortex have been eliminated.[1]

The electrical activity of the cortex was registered for the first time in 1874 and was repeatedly observed after that date,[2] but its registration and study in man begin with the observations of Hans Berger.[1] The record of the electrical activity of the brain is known as the electroencephalogram (EEG). It is obtained by means of an electroencephalograph, and the study of this electrical activity is known as electroencephalography. The record obtained by placing the electrodes directly on the cerebral cortex after the cranium has been opened in the course of an operation (the cortical electrogram) does not differ significantly from the record obtained by placing the electrodes on the skin of the head.

[2] Caton, 1874; Fleisch von Marxow, 1883; Gotch and Horsley, 1892; Berger, 1902; Neminski, 1925; Berger, 1924–1929; Adrian, 1934; Davis, Gibbs, Jasper, Lennox, 1935; Walter, 1936, etc.

Nonpolarizable electrodes are not necessary. The electrodes are small metal plates applied on the skin of the head, which has been previously wetted with saline; they are kept in position by means of collodion. The electrodes are connected with a cathode-ray oscillograph or other recording device, by means of amplifiers. The inscription is usually made by ink-writing recorders. Bipolar leads, with both electrodes placed over the cortex, or monopolar leads, with one electrode on an ear and the other over the cortex, are employed. In both cases the electrical activity of the cortical areas near the electrodes is recorded; that of more distant areas exerts only a weak influence or none on the record. Two to four electrodes are placed on each side of the head over the frontal, parietal, temporal, and occipital areas. The electric activity of the base of the brain is recorded by means of electrodes placed in the nasopharynx or on the tympanic membrane.

THE NORMAL ELECTRO-ENCEPHALOGRAM

The cortical electric pulse appears as a more or less sinusoidal oscillation, the frequency of which varies from 1 to 50 c.p.s. (Fig. 501), or an

[1] BERGER, H., *Arch. f. Psychiat.*, **87,** 527, 1929; **101,** 454, 1933.

even wider range if a good recording instrument is used. In the adult the voltage is usually from 10 to 50 μv, never more than 200 μv. Since the early days of encephalography, the waves have been classified according to their frequency in

FIG. 501. Frequency of cortical potential waves in different normal and pathologic conditions. (*Gibbs, F. A., and E. L. Gibbs, "Atlas of Encephalography," privately printed by the authors, Cambridge, Mass.*)

three groups named with the Greek letters α, β, and δ; it is better to consider them as a continuous spectrum of frequencies (Fig. 501). Several authors do not use the Greek-letter notation (alpha, beta, gamma, delta, theta) but give the frequency per second. Six wave bands are usually distinguished (Table 120).

In the normal EEG an α rhythm is predominant, with waves of an average frequency of 10 (8 to 13 per second) and a voltage of 20 to 50 μv (Table 120, Fig. 502). This is known as

Table 120. Wave Bands in the EEG

	δ		α		β	*Fast*
Frequency per sec.....	0.5–3	4–7	8–13	14–17	18–60	Over 30
Amplitude μv	20–200	...	20–50	.....	5–10	

Berger's rhythm; it is the usual one found in healthy resting subjects with their eyes shut. There is a more or less marked modulation of the α waves, which increase and decrease periodically. When this is marked, spindle-shaped groups of increasing α waves, followed by decreasing ones, are formed.

The β waves are more frequent (18 to 60 per second) and of lower voltage (5 to 10 μv). The δ waves are slow; there are 0.5 to 5 per second, and they are of relatively high voltage (20 to 200 μv). Normal waves are sinusoidal, but in abnormal cases large waves, with a round or flat summit, or spikes are observed (Fig. 504). The EEG does not lose its normal features after the three outer layers of the cortex have been destroyed; but if the deeper layers, *i.e.*, the large pyramidal cells, are destroyed, the normal rhythm disappears.

The EEG varies in different circumstances. The most important only will be mentioned here.

Age. The EEG of the newborn child shows slow irregular waves (0.5 to 2 c.p.s.) on which fast waves of low voltage are superimposed. As the child grows the waves become more regular and faster. At the age of nine or ten years the occipital record shows an α rhythm (10 per second), but up to nineteen years of age the full adult pattern may not have been attained.

Cortical areas. Kornmuller maintained that in the rabbit each cytoarchitectonic area of the cortex had a typical EEG. Such an extreme opinion is not shared by many observers, but in man regional differences have been reported. Thus records from the occipital area have a predominant α rhythm;[1] β waves (15 to 30 per second) are predominant in the frontal and parietal areas. An α rhythm is not always the predominant one in the occipital area, and it may be found in other areas.

Individual differences. The EEG of one individual differs from that of others, but the difference is not such that it is always possible to distinguish the EEG of one person from that of another with the same type of EEG. The individual pattern of the EEG remains stable. The electroencephalograms of identical twins are as similar as two records taken from the same individual at different times.

Levels of cortical activity. The EEG changes with the level of cortical activity. A subject physically and mentally resting with eyes closed has an α rhythm, *i.e.*, relatively ample waves (20 to 50 μv) of low frequency (8 to 13 per second). This is the typical EEG when *awake and resting* (Fig. 502). If the eyes are opened and

[1] ADRIAN, E. D., and B. H. C. MATTHEWS, *Brain*, 57, 355, 1934.

fixed on an object, or if in the dark an effort to see is made, or if the mind is concentrated on a problem, the α rhythm is replaced by small waves of higher frequency (20 to 50 per second). This is the EEG typical of general *alertness* (Fig. 502). Blocking of the α rhythm is a relatively slow process; it takes approximately half a second (0.45 sec.) to be completed. If no special stimuli are applied and the subject's attention wanders, the α rhythm reappears even if the eyes are kept open in a normally lit room. In a *somnolent* state the α rhythm gives way to a slow rhythm of 4 to 6 waves per second. Bursts of waves of progressively increasing and decreasing amplitude and 14 to 16 per second frequency suddenly appear; these are the so-called "sleep spindles." Occasionally large slow waves are seen (Fig. 503). During *sleep* only high-voltage slow waves (0.5 to 3 per second) are observed. These typical waves of normal sleep should not be mistaken for the large abnormal waves seen in subjects with a tendency to convulsions (Gibbs). *Hypnotics* and *anesthetics* have the same effect as sleep on the EEG.
Fig. 502. Electroencephalograms of adults with eyes open (*O*) and closed (*C*). (*Gibbs, F. A., and E. L. Gibbs, "Atlas of Encephalography," privately printed by the authors, Cambridge, Mass.*)
Fig. 503. EEG during sleep. 1, subject is awake (11:30 P.M.); 2, falling asleep (11:45 P.M.); 3, light sleep (12:00 M.); 4, moderately deep sleep (12:30 A.M.); 5, deep sleep (1:00 A.M.); 6, very deep sleep (2:00 A.M.). (*Gibbs, F. A., and E. L. Gibbs, "Atlas of Encephalography," privately printed by the authors, Cambridge, Mass.*)

When a sleeping subject awakens, the opposite changes take place. The slow rhythm gives place to another of higher frequency and lower voltage, the α rhythm, or that corresponding to alertness, according to the level of cortical activity. This *awakening reaction* does not begin in

any special part of the brain, not even in the cortical centers of the sensory area the stimulation of which has provoked it. Thus the EEG of awakening has been obtained in cats by stimulation of the vestibular apparatus after the respective cortical centers have been destroyed. On awakening, as in falling asleep, the whole cortex responds at the same time.

The large waves of the EEG are attributed to synchronization of the electrical activity of many neurons. Depression of cortical activity is accompanied by "recruitment" of neurons which enter into phase, and their electrical activity is synchronized. Activity, on the contrary, "disbands" the neurons and their electrical activity is desynchronized.

Significance of the waves. The spontaneous electric activity of the cortex has been attributed to (*a*) automatic, rhythmic activity of the neurons, especially of the large deep pyramidal cells; (*b*) rhythmic stimulation of the cortex by volleys of impulses from a diencephalic pacemaker; (*c*) impulses passing through the cortex in reverberatory action of thalamocortico-thalamic circuits.

The activity of subcortical centers modifies the EEG. This can be demonstrated by (*a*) simultaneous registration of cortical and subcortical phenomena; (*b*) section of paths between the cortex and subcortical nuclei; (*c*) observing the effects of stimulation of subcortical nuclei on the EEG.

A thalamocortical component has been demonstrated (Morison and Dempsey). There is an ascending activating system in the reticular formation, from the medulla to the diencephalon (Magoun *et al*). Sensory impulses also exert a certain influence (Adrian and Matthews).

Bremer maintains that the EEG is due to the automatic, rhythmic, synchronized activity of cortical neurons, sustained by continuous afferent impulses coming mainly from the thalamus.

THE EEG IN ABNORMAL CONDITIONS

"Normal abnormals." In 10 per cent of apparently normal subjects, the EEG shows changes similar to those seen in 90 per cent of epileptics. Some of these subjects are "difficult" children; others have disturbances in personality. According to some authorities, they are asymptomatic epileptics (Gibbs). The percentage of cortical dysrhythmia is significantly higher in the families of epileptics than in the general population.

Epilepsy. The EEG and other methods of exploration have shown that there is persistent cerebral dysrhythmia in epileptics.[1] The rhythm is either abnormally slow or abnormally fast, and usually fast and slow rhythms alternate. Regulation of wave frequency, *i.e.*, of the energy discharge, is disturbed, and there is a tendency to abnormally extensive and violent discharges. The three main types of epilepsy show distinctive patterns in the EEG.

Petit mal, with transitory disturbance or loss of consciousness and only slight spasms in the facial muscles, is characterized by an EEG with slow rhythm (3 per second) and waves of high voltage, in which usually a slow wave of rounded summit alternates with a spike potential (Fig. 504). When this rhythm is not in evidence it can be provoked by hyperventilation or hypoglycemia, and when present it has a tendency to disappear when the subject breathes 3 to 4 per cent CO_2. Stimulation of a small area of the thalamus provokes bilateral cortical discharges of waves and spikes.

Grand mal is the typical epileptic seizure with tonic followed by clonic convulsions, loss of consciousness, dilatation of the pupil, frothing at the mouth, relaxation of sphincters with involuntary emission of urine, etc. Slow waves appear before the seizure, and when the attack begins there is a sudden decrease in the amplitude of the waves. During the stage of tonic convulsions, voltage and frequency increase progressively; the frequency may be 15 to 40 per second. During the clonic convulsions slow waves predominate, and immediately after the seizure the record is flat without waves, or only a few slow waves are present. After a few minutes the subject's usual rhythm is reestablished (Fig. 504). Similar changes in the EEG have been observed in several types of experimental epilepsy.[2]

Psychomotor epilepsy is the type in which the seizure takes on a stereotyped behavior pattern, *e.g.*, an emotional outburst, an attack of rage or fear, flight, amnesia, somnambulism, etc. The EEG (Fig. 504) shows series of slow waves (2 to 4 per second) of high voltage with flat or serrated

[1] Gibbs, F. A., E. L. Gibbs, and W. G. Lennox, *Arch. Neurol. & Psychiat.*, **39**, 298, 1938.

[2] De Finis, M. L., and J. B. Odoriz, *Rev. Soc. argent. de biol.*, **19**, 217, 1943.

summits, on which fast (14 per second) waves are superimposed; finally only the slow waves are seen. Slow waves are observed 30 times more frequently in epileptics than in normal subjects.

The EEG gives important data for the diagnosis, localization, prognosis, and management of epileptics. In "difficult children" and in apparently normal members of epileptic families, it shows dysrhythmias and cortical disturbances that are not revealed by any other method.

In cases of epilepsy the area of the cortex in which the seizure begins can be localized by means of the EEG. The electrical disturbance (usually slow waves) starts in a definite area and may either spread to other areas or remain localized, being in the latter case the only manifestation of the attack. In certain cases, by taking simultaneous records from several areas, it is possible not only to determine the site of the focal discharge but also to follow the path along which the disturbance spreads.
FIG. 504. Types of normal and abnormal electroencephalogram. Left-hand column, nonparoxysmal patterns: above, those that are abnormally slow for adults; below, those that are abnormally fast; in the middle, patterns that fall in the 8½- to 12-per-sec. range, which is normal for adults. The scale of abnormality reads from 1 to 3, with 1 being slightly abnormal, 2, very abnormal, and 3, exceedingly abnormal. This scale, however, must be adjusted for age. Right-hand column, paroxysmal patterns, given descriptive names or named after the clinical type of seizure with which they are most commonly associated. The pattern referred to as "psychomotor" appears as a generalized disorder over the entire cortex during a clinical seizure of the psychomotor type. In seizure-free intervals, particularly during sleep, the psychomotor disorder appears as a focus of negative-spike seizure potentials in the anterior temporal region. The 14- and 6-per sec. positive spikes are in reality two patterns, which can appear independently as 16- or 6-per-sec. positive spikes. (*F. A. Gibbs, Bull. New York Acad. Med., p. 771, 1949.*)

Localization of brain lesions. Focal lesions in the cortex, such as those due to a brain tumor, subdural hematoma, abscesses, meningitis, encephalitis, etc., can be localized by means of the EEG. The method is especially valuable for showing the existence of cortical damage in cases of cranial trauma, Sydenham's chorea, encephalitis lethargica, etc. In recent years attempts have been made to localize subcortical

lesions by means of the EEG. In 90 per cent of cases of brain tumor it is possible to make an accurate diagnosis of the location of the tumor (Gibbs). Records are made from different parts of the cortex, and those of symmetric points on the hemispheres are compared. When there is focal damage the records taken from the damaged area or from neighboring areas show certain changes, usually slow waves and spikes.

Electroencephalography is also being applied to the study of psychiatric problems and in legal medicine.

Chemical factors. Many physical and chemical agents that have effects on metabolic processes provoke changes in the EEG. Thus anoxia, alkalosis, and hypoglycemia diminish the frequency of the waves and may completely abolish them. Acidosis, excess CO_2, and light ether increase the frequency of the waves. The effect of drugs on the EEG has also been studied. Thus changes similar to those seen in epilepsy are observed when convulsive doses of cortical stimulants are given.

CHAPTER 88

Sleep

SLEEP IS A PERIODIC and reversible physiologic state, which is necessary for the repair of the organism. During sleep consciousness is depressed, the threshold of sensory perception is considerably increased, and spontaneous movements and muscle tone are reduced to a minimum, while metabolism and visceral functions are not markedly diminished. The outstanding features of sleep are (*a*) absence of response to ordinary changes in the environment because the sensory threshold is raised; (*b*) unconsciousness, which can be dispelled by adequate stimulation; (*c*) muscular relaxation; (*d*) suppression of higher cortical activity; (*e*) total or partial suppression of normal mental activity, with the occurrence of dreams during light sleep. Periodic depression of activity or transient stages of resting may be observed in lower forms of life, including protozoa and plants. Such periods have been compared to the sleep periods of the higher vertebrates, including man. In fishes, for instance, characteristic "sleep positions" have been described.

The onset of sleep. The passage from the waking state to sleep takes place gradually. Drowsiness begins by an increasingly strong sensation of fatigue, indifference to environmental stimuli, and depression of the sensory activity. Motor responses become slow and inaccurate, and muscle tone diminishes. The eyelids drop over the eyes, the head nods fitfully, the jaw hangs down, the trunk becomes flexed, and the arms are pendant. Relaxation of the soft palate causes snoring. Immediately before sleep distorted visual and auditory sensations may be experienced.

The onset of sleep is favored by the suppression of stimuli and by facilitating muscular relaxation. Thus silence, darkness, an adequate temperature, a recumbent or sitting position, and mental composure are conducive to sleep. On the other hand, motor activity, strong stimuli, and mental worry or excitement retard the onset of sleep.

Duration and depth of sleep. On the average, man passes about one-third of his life asleep. The daily requirement of sleep varies with age and in different individuals. The young infant sleeps 20 hr. daily. Between the first and seventh year, sleep duration is reduced gradually from 14 to 10 hr. per day. On the average, adults require 7 to 9 hr. sleep in 24 hr. and old persons only 5 to 6 hr. In most adults the depth of sleep increases to a maximum during the first hour and then gradually diminishes until the time of awakening; in a large number of individuals there sets in a second period of deep sleep before waking. Sleep during the daytime is usually lighter than at night. The great majority of people sleep at night and are awake during the day, but the cycle can be reversed, as in the case of people who work at night, and in warm climates a short period of sleep at midday is customary.

PHYSIOLOGIC CHANGES DURING SLEEP

Sleep is accompanied by marked changes in somatic functions and by some changes in visceral activity.

Muscular activity. All the muscles are relaxed, except the flexors of the hand in children. There is some tone in the muscles that close the eyes and in the elevator muscles of the lower jaw, and the sphincters of the rectum and bladder are normally contracted. The eyeballs are turned upward and outward, and the pupils are contracted (myosis) but respond to light. The loss of muscle tone and of postural reflexes causes the subject to fall if a recumbent position

has not been adopted before sleep. In some species, *e.g.*, the horse, postural reflexes are usually not suppressed during sleep; in man they may persist in exceptional conditions, *e.g.*, in persons who fall asleep while driving a car and in sleepwalking. Spontaneous movements are considerably reduced but not completely abolished during sleep; movements decrease as the depth of sleep increases. During sleep, abnormal motility, *e.g.*, tics, chorea, athetosis, myoclonia, etc., and certain other muscular rigidities, such as those of Parkinson's disease, hemiplegia, etc., decrease considerably or are abolished.

Reflex activity. Tendon reflexes diminish together with muscle tone, and some of them, *e.g.*, the knee jerk, are completely suppressed. The threshold of cutaneous reflexes is raised proportionally to the depth of sleep. Stimulation of the plantar surface provokes flexion of the toes in light sleep and extension (positive Babinski) in deep sleep; sometimes there is a mass flexion reflex.

Sensory activity. There is marked depression of sensory perception, especially of smell and taste, and to a lesser degree ot touch and hearing. There are considerable differences in the depression of the senses during sleep; thus a mother will quickly waken if her child cries or moves, but may not respond to much stronger stimuli of another nature.

Circulation. The heart rate diminishes by 10 to 30 beats per minute and the systolic pressure by 10 to 20 mm. Hg. The decrease is greater as the depth of sleep increases. Dreams and nightmares may provoke tachycardia and a considerable increase in blood pressure.

Respiration. The respiratory rate is usually decreased; inspiration is prolonged (often there is snoring) and expiration is brief. In light sleep the respiratory movements are rhythmic, but in deep sleep they often become irregular and periodic. Pulmonary ventilation decreases 25 per cent, therefore CO_2 partial pressure in alveolar air and blood is usually slightly higher than when the subject is awake.

Digestion and secretion. Gastric motility continues and may increase in vigor, and there is little or no change in gastric secretion. Stomach-emptying time and digestion are not influenced by sleep. Salivary and lacrimal secretions diminish considerably. The urine becomes more highly concentrated and is eliminated in smaller volume per unit period. Urinary excretion of chloride and nitrogen diminishes and that of phosphate increases. Sweat secretion increases considerably.

Metabolism. The BMR diminishes 10 to 15 per cent during deep sleep. The body temperature drops a few tenths of a degree, and is usually at a minimum between 2:00 A.M. and 4:00 A.M.

Electrolytes. There are no significant changes in the concentration of electrolytes in the blood. Hypnotics and anesthetics cause a fall in the concentration of K in plasma (Marenzi and Gerschmann)—not an increase, as was reported by Cloetta. There is no evidence that sleep is due to an increase in Ca in the diencephalon and that awakening is caused by an increase in K (Demole).

Humoral factors. According to Pieron activity provokes the accumulation of metabolites which produce somnolence and sleep; if animals are prevented from sleeping, a "hypnotoxin" appears in the blood which produces sleep. Humoral factors cannot, however, be the sole, or even the main cause of sleep, because one of a pair of Siamese twins may be asleep while the other is awake.

Cortical activity. The activity of the cerebral cortex is diminished in sleep but not totally abolished. Mental functions are depressed, dissociated, and in part disintegrated. The EEG shows marked and typical changes during sleep (see Chap. 87).

Sleep requirement. During sleep the organism is in a condition of mental and bodily rest propitious for the restoration of energy, especially that of the nervous system and in particular of the cortex. If dogs are deprived of sleep, they die after 12 to 17 days; occasionally animals resist as long as 3 weeks. Puppies cannot survive sleeplessness for more than 4 to 6 days. Cytologic changes (chromatolysis, cell shrinking, etc.) are observed. A few hours of sleep are sufficient to repair the effects of prolonged insomnia.

In man temporary deprivation of sleep does not produce any serious disturbance. Kleitman, Tyler, and others have made careful observations in normal subjects who were kept awake for periods of 60 to 200 hr. No significant cardiac, respiratory, or biochemical changes were observed. Mental processes were apparently normal. The subjects were nevertheless irritable, and the threshold for pain was diminished, but the threshold for touch was increased. The right-

ing reflexes were not as efficient as normally (there was difficulty in standing with the eyes closed), attention was sustained only with difficulty, and there was marked indifference to environmental stimuli; occasionally hallucinations occurred. The subjects easily fell asleep if they were not being constantly stimulated.

THE MECHANISM OF SLEEP

Electroencephalography has shown that there are different levels of general cortical activity. In somnolence and in sleep there is progressive synchronization of the electrical activity of the neurons, and large slow waves appear in the EEG. The awakening reaction is accompanied by desynchronization of the electrical activity of the neurons and the establishment of a rapid rhythm of small waves (see Chap 87). Sleep is fundamentally a cortical phenomenon, but the role of subcortical centers in sleep was already postulated by Mauthner (1890) many years ago. Later, the study of lesions found in the brain stem in cases of encephalitis or tumors, in which lethargy, somnolence or prolonged sleep, or insomnia had been an outstanding feature, showed that diencephalic and mesencephalic centers played an important part in the regulation of sleep and waking.[1]

Sleep, or the opposite, an increase in cortical activity, has been provoked by experimental stimulation or destruction of limited areas of the diencephalon and the bulbomesencephalic reticular formation. Hess implanted protected electrodes into the diencephalon of cats, and when the animals had recovered from the operation and were awake, stimulation provoked adynamia, loss of postural tone, and a state similar to sleep. Stimulation of the posterior hypothalamus, on the contrary, increased general activity (dynamogenic area). These results have been confirmed[2] and it has been shown that stimulation with low voltage and low frequency (3 to 5 per second), with electrodes implanted in the internal medullary lamina of the thalamus, provokes in waking animals the somatic signs of sleep, *i.e.*, muscular relaxation, typical posture of sleep, slow deep breathing, myosis,

[1] Von Economo, C., in Bethe's "Handbuch der normalen und pathologischen Physiologie," **17**, 591, Springer, Berlin, 1926; *J. Nerv. & Ment. Dis.*, **71**, 249, 1930.

[2] Akert, K., W. P. Koella, and R. Hess, Jr., *Am. J. Physiol.*, **168**, 260, 1952.

and the EEG of sleep (large, slow waves). Stimulation at higher frequency (10 to 30 per second) causes abrupt blocking of all spontaneous electrical activity of the cortex. High-frequency stimulation (200 per second) produces electroencephalographic and somatic signs of cortical activation; in some cases the animals enter into the condition called "sham rage" (see "Emotional expression," under "The hypothalamus," in Chap. 84).[1]

Stimulation of the caudal hypothalamus, or of the reticular formation in all its length from the roof of the mesencephalon to the medulla, produces signs of cortical activation in animals anesthetized with dial or chloralose and in Bremer's "isolated-encephalon" preparation: the slow large waves and sleep spindles are replaced by rapid small waves.[2]

Bremer[3] has shown that, in cats, section of the brain stem at the level of the upper part of the mesencephalon (*cerveau isolé*) provokes somatic signs of sleep in the head (myosis, closing of the eyes) and an EEG typical of sleep. If the section is made more caudally so that the cortex is connected with the mesencephalon (*encephale isolé*), the aspect of the head and the EEG are those of a waking animal. In the rat a complete transverse section immediately caudal to the hypothalamus produces a condition of permanent somnolence;[4] the animals can be wakened only by means of strong stimuli, and they fall asleep soon after stimulation ceases. The EEG is typical of sleep, and stimulation of afferent paths provokes signs of activation (desynchronization of the electrical activity of cortical neurons) only while stimulation lasts.

The state of wakefulness has been attributed to the continuous arrival of sensory impulses at the cortex (Bremer), especially those from proprioceptive receptors (Kleitman). It is well known that a decrease in afferent impulses caused by fatigue, muscular relaxation, or the suppression of auditory, visual, and other sensory stimuli tends to cause somnolence, but this

is by no means the only or the main cause of sleep, because a subject may remain awake even when sensory stimulation has been reduced to a minimum.

Pavlov[1] attributed sleep to internal inhibition spreading to the whole cortex. He observed that in dogs summation of stimuli inhibitory for conditioned reflexes depressed all cortical activity and the animals appeared to fall asleep. Rhythmic repetition of a stimulus of low intensity (a monotonous voice, the hum of a motor, etc.) produces somnolence. Conditioned reflexes, such as the habit of retiring at a certain time, also produce sleepiness. Cortical activity can, therefore, be depressed by certain stimuli, just as it is increased by others.

General cortical activity is regulated by impulses arising in subcortical centers, but there is no evidence of a localized center producing sleep or waking. There is ample evidence that ascending stimuli from the reticular formation[2] and the caudal hypothalamus are necessary for the maintenance of waking, because their suppression causes lethargy or permanent somnolence, and stimulation of these areas increases cortical activity. Perhaps impulses from the anterior diencephalon depress cortical activity (Nauta). Impulses from intralaminar thalamic nuclei, the centrum medianum, etc., which give rise to the diffuse thalamic projection system, can inhibit or increase cortical activity according to the conditions of stimulation. Probably this system "may be involved in the 'higher level' integration of cerebral activity related to mechanisms of attention, consciousness and general alertness" (Hunter and Jasper). To sum up, sleep consists in the reversible depression of the activity of the whole cortex—activity which is controlled by impulses arising or integrated in the mesencephalon and diencephalon.
